for turbulent flow in smooth tubes of constant circular-cross section is found from the *Prandtl formula* (Ref. 2 Art. 17):

$$\frac{1}{\sqrt{C_{\Delta p_1}}} = 2 \log_{10} \left(\text{R.N.} \sqrt{C_{\Delta p_1}}\right) - 0.80 \qquad (38)$$

$$\text{R.N.} = \frac{\rho \bar{u} D}{\mu} = \frac{\bar{u} D}{\nu}$$

This formula appears to be the most reliable for large values of R.N. and replaces the older formulas of Blasius and Lees.

The additional pressure loss Δp_2 arising from changes in kinetic energy due to changes in velocity distribution is $\Delta p_2 = 1.09\left(\frac{\rho \bar{u}^2}{2}\right)$ if the pipe entrance is rounded. If the pipe entrance is sharp edged there is a further pressure drop due to the formation of a " vena contracta " downstream from the pipe entrance, and $\Delta p_2 = 1.40\left(\frac{\rho \bar{u}^2}{2}\right)$ (Ref. 3 Art. 17).

The total pressure drop Δp for a length, L, of tube is:

$$\Delta p = C_{\Delta p_1}\left(\frac{L}{D}\right)\left(\frac{\rho \bar{u}^2}{2}\right) + 1.40\left(\frac{\rho \bar{u}^2}{2}\right) \quad \text{Sharp-edged tube entrance} \qquad (39)$$

$$\Delta p = C_{\Delta p_1}\left(\frac{L}{D}\right)\left(\frac{\rho \bar{u}^2}{2}\right) + 1.09\left(\frac{\rho \bar{u}^2}{2}\right) \quad \text{Rounded tube entrance} \qquad (40)$$

Since the formula for $C_{\Delta p_1}$ is not directly solvable for $C_{\Delta p_1}$, an approximation method must be used. For rapid work the curve shown in Fig. 29 may be used.

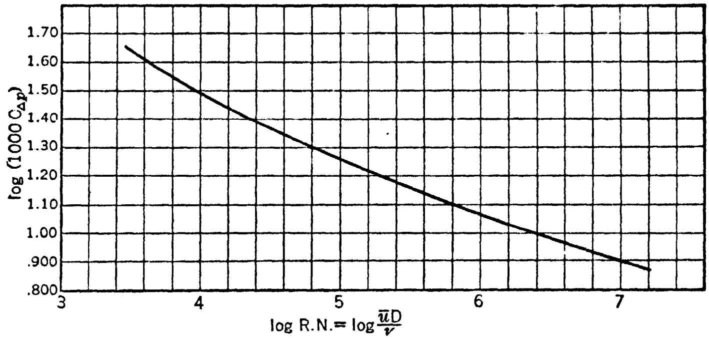

FIG. 29. Prandtl-Karman Law for Pressure Drop in Smooth Tubes. Turbulent Flow

Example: Air at 15° C is passing through a smooth circular pipe at 100 ft per sec. If $\rho = 2.40 \times 10^{-3}$ slug per cu ft and $\rho/\mu = 6000$ sec per ft², find the pressure drop in a length of 50 ft. Also for lengths of 100 ft and 1000 ft. Assume a diameter of 1/2 ft.

Solution: $\text{R. N.} = \frac{\rho \bar{u} D}{\mu} = 6000 \times 100 \times 1/2 = 3.00 \times 10^5$. Log R.N. = 5.4771.

Therefore the flow is turbulent.

From Fig. 29, log (1000 $C_{\Delta p}$) = 1.160; $C_{\Delta p_1} = 0.0144$.

$$\frac{\rho \bar{u}^2}{2} = 12 \text{ lb per ft}^2$$

Table III

For sharp-edged entrance:

$$\Delta p = 12\ (.0288\ L + 1.40) \text{ lbs per ft}^2$$

Length (ft)	Δp (lb per ft²)	Δp (lb per in.²)
50	34.1	0.236
100	51.3	0.356
1000	362.0	2.51

Pipes Which May Be Considered Smooth. Kemler (Ref. 4 Art. 17) has recently compiled practically all the experimental data on pipes and reduced them to the coefficient, $C_{\Delta p}$, method. The following kinds of pipes yield experimental results which follow the theoretical curves so closely that the theoretical formulas should be used:

(*a*) **Drawn brass pipes.**
(*b*) **Glass tubes.**
(*c*) **Drawn tin pipes.**
(*d*) **Drawn lead pipes.**

Any noticeable roughness of the interior surface of the pipe will cause increases in the coefficient $C_{\Delta p}$. Variations in pipe diameter also cause expansion and contraction effects if the interior surface of the pipe is smooth. For a pipe of circular cross-section

$$C_{\Delta p_1} = \frac{\pi^2 D^5 \Delta p}{8Q^2 \rho L} \tag{41}$$

where Q = volume of flow in unit time. Any small variation in D therefore results in a comparatively large effect on $C_{\Delta p_1}$, the viscous coefficient.

Pipes of Non-circular Cross-section. Schiller (Ref. 5 Art. 17) has found that for smooth pipes of non-circular cross-section the criterion

$$r_m = \frac{\text{Cross-section area of pipe}}{\text{Wetted perimeter}} \tag{42}$$

usually called the mean hydraulic radius may be used instead of the Reynolds' number for finding pressure loss in the turbulent region but not in the laminar-flow region.

Pipes of Non-uniform Cross-section. No extensive experimental data exist on flow in pipes of non-uniform cross-section.

In a uniformly converging tube the critical velocity is higher than in a tube of constant cross-section area. Gibson (Ref. 6 Art. 17) shows that, for the flow of water through circular pipes having sides converging uniformly at an angle θ, temperature 14° C, critical velocities are as follows:

Table IV. Critical velocity, ft per sec

θ	5°	7.5°	10°	15°
Large section (3-in. diameter)	1.50	1.94	2.44	3.25
Mean section (2 1/4-in. diameter)	2.70	3.45	4.34	5.73
Small section (1 1/2-in. diameter)	6.00	7.76	9.77	12.90

The lower critical velocity in a 1 1/2-in. pipe of uniform cross-section at this temperature is 0.20 ft per sec.

The velocity distribution in a converging tube is materially different from that in a tube of constant cross-section. The velocity is more uniformly distributed in the converging tube.

In a diverging tube the opposite is true as regards critical velocity; i.e., turbulent flow appears at much smaller values of Reynolds' number.

Flow in Rough Tubes. Experiments have shown that the viscous coefficient, $C_{\Delta p_1}$, for rough tubes is dependent upon other criteria than Reynolds' number alone. For circular tubes, $C_{\Delta p_1}$ depends on a " roughness number," $\frac{k}{D}$, where k is an average height of the protuberances on the interior surface compared with the diameter D. Concrete walls, rusted steel, and cast iron represent roughness of this character. Sometimes a " waviness number," $\frac{a}{b}$, modifies $C_{\Delta p_1}$. That is, the inner surface may be smooth but waves of amplitude a and wavelength b occur. Flumes made of wood and conduits made of thin metal sheet represent wavy types of roughness.

No reliable roughness criterion which represents materials commonly occurring in practice exists.

Pigott (Ref. 7 Art. 17) has recently summarized practically all the existing pipe-flow data. He assumes that

$$C_{\Delta p_1} = c\left(\frac{\nu}{uD}\right)^n \tag{43}$$

where c is a constant and n is a roughness index varying from about 0.25 to nearly zero. Table V and the curves in Fig. 30 are used together to select the friction coefficient, $C_{\Delta p_1}$.

It is stated by Pigott that the formula $\frac{\Delta p}{L} = C_{\Delta p_1} \frac{\rho}{g} \frac{\overline{V}^2}{8\, r_m}$ may be used with Table V given above and the curves for tubes or channels of non-circular section. r_m = mean hydraulic radius.

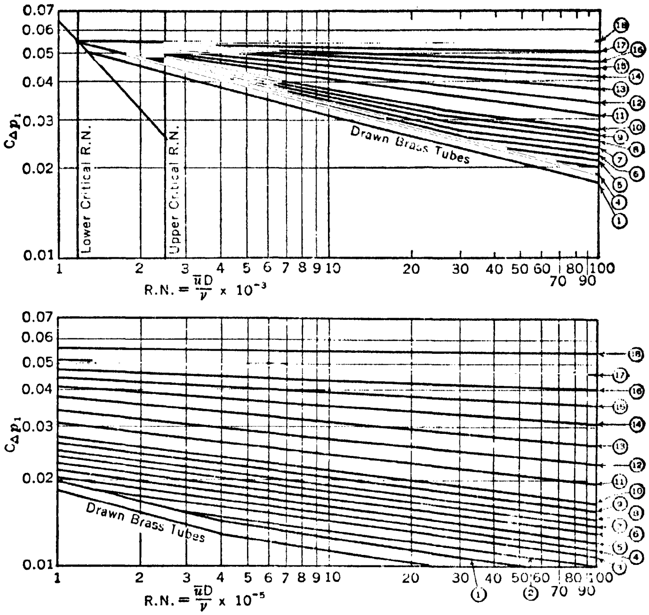

FIG. 30. Friction Coefficient for Tubes. (*Mechanical Engineering*, Aug. 1933, p. 501.)

Table V

Curve	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18
A	0.35 up	....	..	...	....	....	.....	.....	....	....	....	....	...	0.125	....	....	...	0.0625
B	72	48 to 66	14 to 42	6 to 12	4 to 5	2 to 3	1 1/2	1 to 1 1/4	3/4	1/2	3/8	1/4	1/8	...	...	.....	.....	.....
C	.....	...	30	10 to 24	6 to 8	3 to 5	2 1/2	1 1/2 to 2	1 1/4	1	3/4	1/2	.....	3/8	.....	1/4	....	1/8
D	.....	...	48 to 96	20 to 48	12 to 16	5 to 10	3 to 4	2 to 2 1/2	1 1/2	1 1/4	1	....	....	....	....	.....	....	......

The numbers in the table designate the diameter in inches.

A = drawn tubing, brass, tin, lead, glass. *B* = Clean steel, wrought iron. *C* = Clean, galvanized. *D* = Best cast iron, cement, light riveted sheet ducts. *E* = Average cast iron, rough formed concrete. *F* = First-class brick, heavy riveted, spiral riveted. In drawn tubing, actual inside diameter is given. In pipe, nominal size of standard weight is given.

18. FLOW OF VISCOUS INCOMPRESSIBLE FLUIDS THROUGH ORIFICES, NOZZLES, AND VENTURI TUBES

Orifices are really short tubes whose lengths are fractions of the diameters. End effects are so large for very short tubes that separate equations, distinct from the pipe equations, are developed.

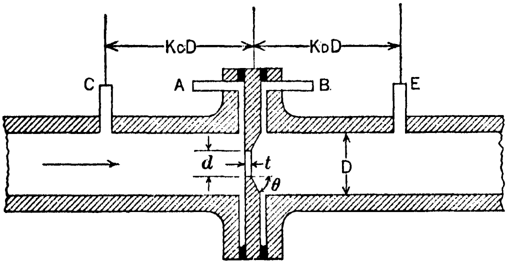

FIG. 31. Sharp Edge Orifice.

A Type of Orifice Frequently Used for measuring flow in a pipe line is shown in the sketch (Fig. 31). As the cross-section changes from a diameter D to a smaller diameter d the velocities and pressures change. On account of dissimilar flow patterns upstream and downstream, pressure taps at A and B or C and E record different pressures, the upstream taps recording the greater pressure.

The flow through such an orifice is usually expressed in the form

$$Q = C_Q \frac{\pi d^2}{4}\left[\frac{\dfrac{2\Delta p g}{w}}{1-\left(\dfrac{d}{D}\right)^4}\right]^{1/2} = C_Q \frac{\pi d^2}{4}\left[\frac{\dfrac{2w_0 h g}{w}}{1-\left(\dfrac{d}{D}\right)^4}\right]^{1/2} \tag{44a}$$

$$= C_Q \frac{\pi d^2}{4}\frac{\bar{u}}{\left[1-\left(\dfrac{d}{D}\right)^4\right]^{1/2}} \tag{44b}$$

where Q = volume of flow in unit time.
C_Q = coefficient of volume.
Δp = pressure difference across orifice.
w = weight density of fluid flowing through the orifice.
h = head on a manometer measuring Δp.
w_0 = weight density of manometer fluid.
$\bar{u}$ = average flow velocity through the orifice.

The Magnitude and Variation of C_Q depend upon the location and construction of the pressure taps, the ratios $\frac{d}{D}$ and $\frac{d}{t}$, the bevel angle θ, the workmanship of construction of the orifice and pipe surface, the location of the orifice with regard to bends, valves, etc., in the pipe line, and upon the Reynolds' number $\frac{\bar{u}D}{\nu}$, where ν is the kinematic viscosity of the fluid.

If two orifices in two pipes are geometrically similar and similarly located the flow coefficient depends only on Reynolds' number. A curve C_Q versus R.N. = $\frac{\bar{u}D}{\nu}$ obtained with a specified orifice installation will furnish information for the flow of any viscous incompressible fluid even if the calibration curve has been obtained with one certain liquid or a limited number of liquids.

A Typical Set of Curves taken from Hodgson (Ref. 1 Art. 18) obtained with an orifice of the type shown is given below (Fig. 32). The orifice had dimensions: d = 0.8032 cm, t = 0.0914 cm, θ = 45°. It was mounted concentrically in pipes 0.952, 1.27, and 1.904 cm in diameter. Pressure taps were located at A and B (Fig. 31).

These curves do not show enough detail for very small values of $\sqrt{\frac{\bar{u}D}{\nu}}$. Hodgson states (*loc. cit.*) that for values

$$\sqrt{\frac{\bar{u}D}{\nu}} \leq 5.00 \text{ (approx.) } C_Q = k\sqrt{\frac{\bar{u}D}{\nu}} \tag{45}$$

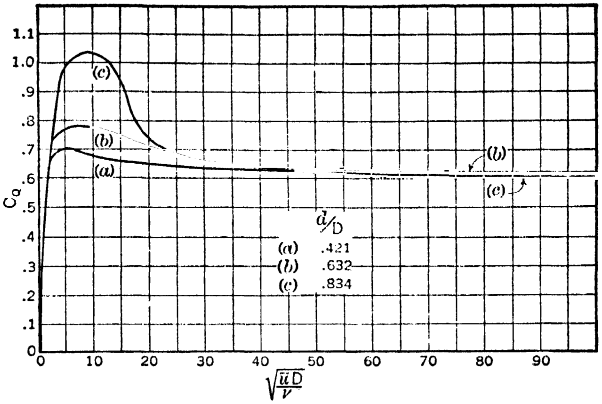

FIG. 32. C_Q vs. $\sqrt{\frac{uD}{\nu}}$ for Three Orifices

Table VI

k	0.136	0.118	0.106
$\frac{d}{D}$	0.421	0.632	0.834

Example: Fluid whose kinematic viscosity = 0.00618 ft² per sec is pumped through a pipe line having an orifice of the type shown. The head h = 50 in. is read on a manometer containing a fluid of specific gravity 0.905. If the specific gravity of the fluid in the pipe is 0.900, find Q for a pipe of internal diameter 2 in. and an orifice for which $\frac{d}{D} = 0.421$.

Solution:

$$\overline{u^2} = \frac{2\,w_0gh}{w} = 2 \times \frac{0.905}{0.900} \times 32.2 \times \frac{50}{12} = 270.$$

$$\bar{u} = 16.41 \text{ ft per sec.}$$

$$\frac{\bar{u}D}{\nu} = \frac{16.41 \times 0.421 \times \frac{2}{12}}{0.00618} = 186.$$

$$\sqrt{\frac{D}{\nu}} = 13.7.$$

From the curves $C_Q \propto$ R.N. $C_Q = 0.660$.

$$Q = \frac{0.660 \times \frac{\pi}{4} \times (.421)^2\left(\frac{1}{6}\right)^2 \times 16.41}{(1 - (.421)^4)^{1/2}} = 0.0432 \text{ cfs}$$

$$= 19.4 \text{ gal per min.}$$

For more detailed information see the references at the end of this article.

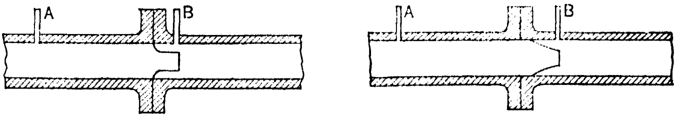

FIG. 33. Nozzles

Nozzles differ from orifices only in so far that the approach is noticeably well rounded (Fig. 33). They seem to be favored in Europe, especially in Germany, where they are called "Düsen." The coefficient defined by equation 44 is also used for nozzles. The coefficient, C_Q, is considerably higher than for orifices.

If the pressure tap *A* is one to two diameters ahead of the entrance plane of the nozzle and the pressure tap *B* is in or just below the plane of the end of the nozzle the value C_Q is somewhat higher. Tuve and Shoop (Ref. 2 Art. 18) state that $C_Q = 0.985$ is accurate within 1.5 per cent for flow nozzles having a diameter ratio of 20 to 70 per cent in pipes 2 to 12 in. in diameter. Suitable precautions (Ref. 2 Art. 18) must be taken to insure reliable results.

Venturi Tubes are frequently used as metering devices. The form commonly used is shown below (Fig. 34).

At a station where the original pipe diameter has not been changed, pressure holes communicating with a piezometer ring are drilled through the tube. The cross-section is then reduced gradually in the entrance cone of about 21° total angle. This is faired into a short cylindrical throat section whose diameter, *d*, is usually $^1/_2$ to $^1/_3$ of the pipe diameter, *D*. This throat section is also provided with holes connected to a piezometer ring and a pressure tap. The end of the throat section is gradually faired into the exit cone, which has a total angle of 5° to 7°.

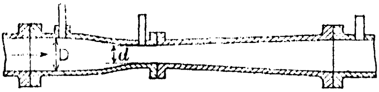

Fig. 34. Section of a Venturi Tube

The equation

$$Q = C_Q \bar{u} \frac{\pi d^2/4}{\left[1 - \left(\frac{d}{D}\right)^4\right]^{1/2}} \tag{46}$$

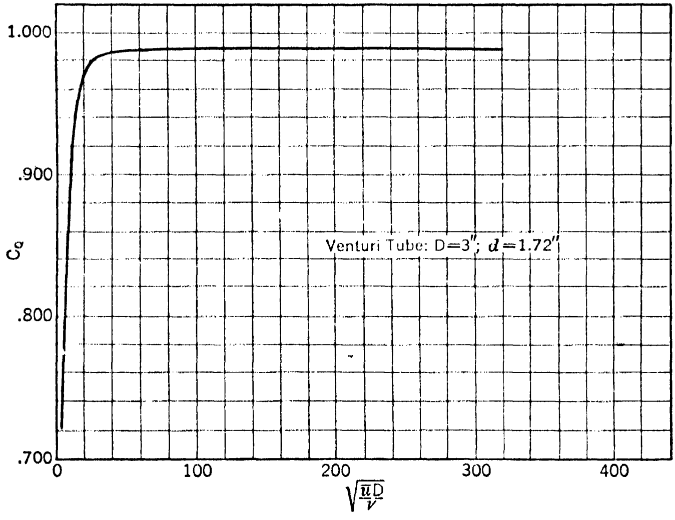

Fig. 35. Coefficient of a Venturi Tube

is also used to determine the characteristics of venturis. No extensive data are available on the variation of C_Q versus $\frac{\bar{u}D}{\nu}$ for venturis. A typical variation of C_Q versus $\sqrt{\frac{\bar{u}D}{\nu}}$ is shown in Fig. 35.

The addition of the exit cone or diffuser to the venturi permits a greater recovery of pressure than is possible for orifices and nozzles. In normal practice this is usually from 10 to 20 per cent of the differential from entrance to throat.

19. FLOW OF VISCOUS INCOMPRESSIBLE FLUIDS AROUND BODIES ENTIRELY SURROUNDED BY THE FLUID

Introductory. A dimensional analysis shows that the force exerted by a moving fluid on a body is of the form

$$F = C_F \frac{\rho A V^2}{2} \tag{47}$$

where F = force.
C_F = a dimensionless force coefficient.
ρ = mass density of the fluid.
V = velocity of motion of the body through the fluid.
A = area.

The coefficient, C_F, is dependent in the general case on many dimensionless criteria. The principal criteria are: Reynolds' number, $\frac{VL}{\nu}$; Mach's number, $\frac{V}{V_c}$; Froude's number, $\frac{V^2}{Lg}$; body attitude with reference to the relative wind; body shape; relative roughness of the surface of the body, and the degree of turbulence of the moving fluid.

Sometimes the surface tension forces become appreciable and must be considered.

Frequently the emphasis is placed on the component of force F along the relative velocity vector, $\overline{V}$. This component is usually called drag or resistance. For most practical cases the drag is divided into two parts: (i) friction forces tangential to the surface of the body—the resultant of these is called the *skin friction drag*; (ii) for an ideal fluid flow the normal forces on the body resolved in the direction of the relative velocity vector, $\overline{V}$, have a zero sum or resultant. Viscosity of the fluid causes a change in the flow pattern so that the pressure symmetry for the ideal fluid no longer exists. The resultant of the normal forces in the $\overline{V}$ direction is now different from zero. This additional drag is called *pressure* or *form drag*. The pressure drag is also explained by saying that it is determined by the kinetic energy of the eddies in the wake of the body.

Drag of a flat plate parallel to the relative velocity is practically all skin friction drag. If the flat plate is at right angles to the relative wind the drag is practically all pressure drag.

Tietjens (Ref. 1 Art. 19) uses the term "deformation drag" to characterize drag at very small values of Reynolds' number. The body in motion through the fluid sets up stresses which deform the fluid particles. This deformation extends to great distances from the body. For larger values of the Reynolds' number this deformation is appreciable only in the boundary layer.

Pressure drag may be measured by integration and resolution of normal forces obtained by static openings on the surface of the body. Total drag = skin friction drag + pressure drag is usually measured by means of balances.

Flow along Smooth Flat Plates. If the flat plate is in a uniform stream of fluid and the flow is parallel to the plate the drag coefficient is dependent mainly on the Reynolds' number, where R.N. = $\frac{uL}{\nu}$.

u = velocity of fluid far from the plate or it is the velocity of the plate in the quiescent fluid.
L = length of the plate in the direction of flow.
ν = kinematic viscosity of the fluid.

For a smooth plate the variation of C_F versus R.N. resembles the variation of $C_{\Delta p}$ for a pipe.

For $1 \leq$ R.N. $\leq 5 \times 10^5$,

$$C_F = \frac{1.327}{\sqrt{\text{R.N.}}} \quad \text{(Blasius)}. \tag{48}$$

For $5 \times 10^5 \leq$ R.N. $\leq 5 \times 10^6$, which is usually called the transition range, C_F changes from the Blasius law to a second type of law.

Prandtl (Ref. 2 Art. 19) has given as the law for C_F in the transition range,

$$C_F = \frac{0.074}{\sqrt[5]{\text{R.N.}}} - \frac{1700}{\text{R.N.}} \tag{49}$$

This law will not be followed closely in a given case. The transition depends on the shape of the leading edge of the plate and on the degree of turbulence of the fluid coming up to the plate.

$$\text{For R.N.} > 5 \times 10^6 \quad C_F = \frac{0.455}{[\log_{10}(\text{R.N.})]^{2.58}} \text{ (Schlichting)} \tag{50}$$

The value of C_F in the formulas cited is based on the entire area, A, exposed to the fluid.

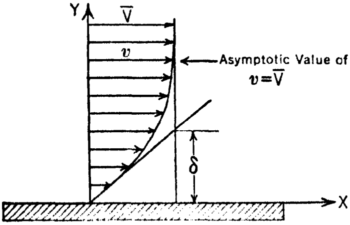

Fig. 36. Velocity Distribution Near a Flat Plate

The gradual transition from one law to another is usually attributed to a change from laminar flow in the boundary layer to turbulent flow in the boundary layer. The velocity distribution near a flat plate is represented in Fig. 36. The velocity, V, changes approximately in a linear way with distance, Y, from the plate at very small distances from the plate. Then it gradually becomes constant, $\bar{V}$. Blasius found that if the thickness of the boundary layer, δ, is defined as the distance from the plate to the intersection of the asymptotic line $\bar{V}$ and the tangent to the velocity diagram at the origin,

$$\delta = \frac{3.40\,L}{\sqrt{\dfrac{VL}{\nu}}} \tag{51}$$

where L = distance from a sharp leading edge of the plate.

The flow outside this very thin layer is practically identical with an ideal fluid flow.

For turbulent flow in the boundary layer an expression for δ was given by Prandtl as

$$\delta = \frac{0.37\,L}{\sqrt[5]{\dfrac{VL}{\nu}}} \tag{52}$$

If the flat plate is inclined to the relative velocity vector by an angle α, then the force F is usually resolved into a component L called the lift and a component D called drag. The corresponding coefficients C_L and C_D are defined by

$$L = C_L \frac{\rho}{2} SV^2 \quad \text{and} \quad D = C_D \frac{\rho}{2} SV^2 \tag{53}$$

where S is the plan area of the plate. Variation of C_L and C_D are like those of thin symmetrical airfoils. See Art. 20 for a discussion.

If $\alpha = 90°$ the plate has practically no lift and its drag is very nearly all pressure drag on account of the wide turbulent or eddying wake on the downstream side of the plate. The drag coefficient C_D varies with Reynolds' number and the shape of the plate. The variation with R.N. for shapes that are not unusual is not great.

Table VII

Flat plate (α = 90°)	C_D	Reynolds' number
Square	1.04–1.263	68,000– 680,000 (Eiffel)
Circular disk	1.08–1.14	210,000–4,440,000 (Shoemaker)

The values of C_D for a large square flat plate at large values of R.N. is usually given as 1.28.

No systematic data except for specially prepared rough surface exist on the drag of rough plates.

Flow around Cylinders. The drag of cylinders is usually written

$$D = C_D\,A(\tfrac{1}{2}\rho V^2) \tag{54}$$

A = the area of the orthogonal projection of the cylinder on a plane at right angles to the relative velocity vector.

ρ and V are as previously defined.

The drag coefficient C_D for steady flow of an incompressible fluid varies chiefly with Reynolds' number $\dfrac{\rho V d}{\mu} = \dfrac{Vd}{\nu}$, where d is a typical length characterizing the size of the cross-section of the cylinder.

Lamb (Ref. 3 Art. 19) has developed a theoretical expression for C_D of the form

$$C_D = \frac{a}{\text{R.N.}\,(b - c \log_{10}\text{R.N.})} \tag{55}$$

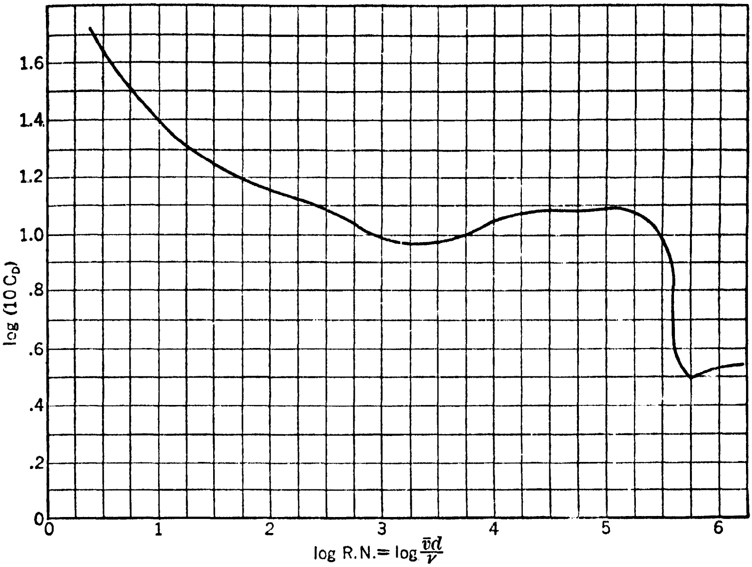

FIG. 37. Drag of a Cylinder, d = diameter (Two Dimensional Flow)

This holds for two-dimensional flow around circular cylinders, a, b, and c being constants. Since this theoretical formula holds only for R.N. $\lesssim 1$ it is rarely used. For larger values of R.N. the variation of C_D versus R.N. is shown in Fig. 37.

This curve given by Prandtl (Ref. 4 Art. 19) shows a typical variation of C_D for flow around a circular cylinder whose length is infinite compared to its diameter. The sudden drop of C_D between R.N. = 10^5 and 10^6 may vary if the cylinder is tested in a different fluid stream. For relatively greater turbulence the drop occurs for a smaller value of R.N.

As the cross-sectional area becomes more nearly "stream line" in shape the drop in C_D occurs at smaller values of R.N. Fig. 38 shows the variation of C_D with $VD \propto$ R.N. for a cylinder whose cross-section is that of a good airplane strut. Cylinders shaped in cross-section like airfoils will be discussed in Art. 20.

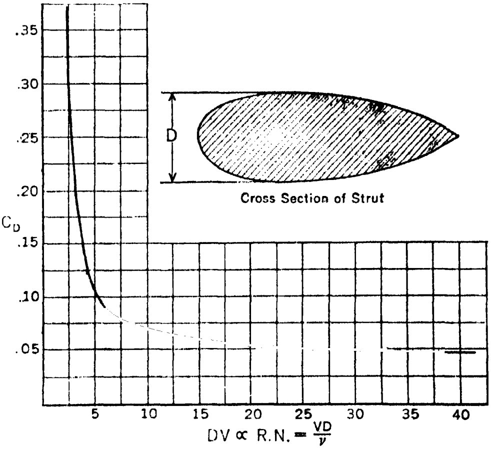

FIG. 38. Drag of Streamline Strut (Diehl; Engineering Aerodynamics)

Flow around Spheres and Ellipsoids. Spheres have relatively bad shapes and on account of a wide turbulent wake the drag of a sphere is largely pressure drag. Stokes has derived the theoretical law

$$C_D = \frac{D}{\frac{\rho}{2}\left(\frac{\pi d^2}{4}\right)V^2} = \frac{a}{\text{R.N.}} \tag{56}$$

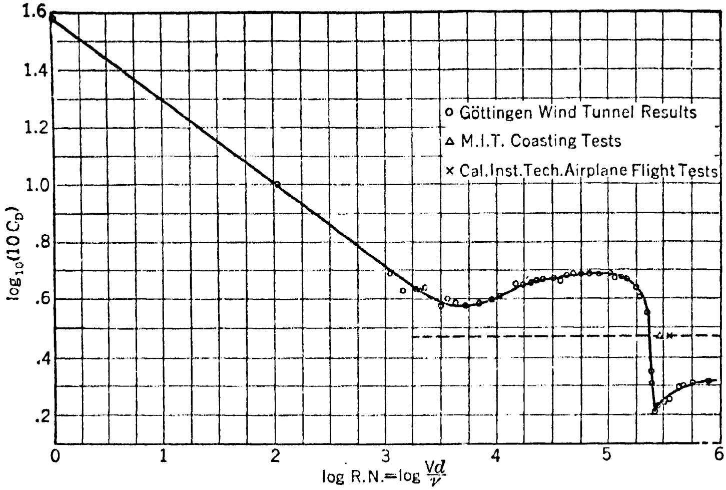

Fig. 39. Drag Coefficient of a Sphere (Göttingen Wind Tunnel)

where D = drag, d = sphere diameter, a = a constant. This law holds for R.N. $= \frac{Vd}{\nu} \leq 1/2$. For greater values of R.N. the variation obtained in a typical experiment is shown in Fig. 39. The sharp drop just beyond R.N. $= 10^5$ shifts as does the drop in C_D for a circular cylinders depending on the turbulence in the fluid stream.

The value of R.N. corresponding to $C_D = 0.3$ is frequently employed in aeronautics to determine the turbulence scale of an air stream. Millikan and Klein (Ref. 5 Art. 19) found that, for a sphere pushed through the air by an airplane, R.N. ≈ 365,000 corresponds to $C_D = 0.3$. Sauerwein. (Ref. 6 Art. 19) found from coasting tests in still air that R.N. = 290,000 at $C_D = 0.3$. For air streams in wind tunnels R.N. is usually less than 300,000 for $C_D = 0.3$. This indicates a greater degree of turbulence in the air stream.

Fig. 40 shows drags of ellipsoids compared with the drag of a sphere. As the ellipsoid becomes elongated in the direction of the relative velocity vector the drop in the value of C_D occurs for small values of R.N.

20. AERODYNAMICS OF VISCOUS INCOMPRESSIBLE FLUIDS

Recent Full-scale Tests on Airplane Propellers show that compressibility effects are practically non-existent at tip speeds of 600 mph. Theory indicates that the speed of sound must be attained in order that compressibility shall play an important part in determining the aerodynamic forces on bodies. Practically all our knowledge of this branch of fluid mechanics is based on the theory of a viscous incompressible fluid.

Wing Sections. Aerodynamics begins with the study of properties of wing sections, for without efficient wing sections there would be no lift. The term airfoil is in common use and refers in general to bodies whose shape makes them useful as lifting, propelling, and controlling elements of aircraft.

Efficient wing and airfoil shapes have been discovered in a relatively short time by a happy combination of theory and experiment. The cross-section of airfoils is represented by Fig. 41.

The leading edge at A is rounded so that the flow at various attitudes remains reasonably good. The thickness gradually increases to a maximum value, t, and then decreases quite gradually to almost nothing at the trailing edge B. The median or mean line is generally a flat curve like a circular or parabolic arc, although in some cases it crosses the X axis and approaches B from below the X axis. The maximum ordinate of the mean line is called the camber, m, and is located at a distance L from the leading edge. The length $AB = c$ is called the chord. The parameters m, L, and t are the important parameters which determine the airfoil section properties.

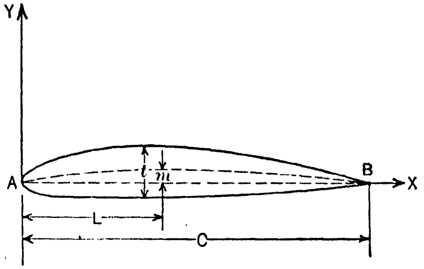

FIG. 41. Typical Airfoil Section and Section Parameters

Table VIII. Variation of Parameters m, L, and t (average)

	m/c	L/c	t/c
Wing sections	0.02 to 0.06	0.20 to 0.50	0.05 to 0.18
Propeller blade sections	0.02 to 0.06	0.20 to 0.50	0.06 to 0.20
Strut sections	0	....	0.33 average
Tail surfaces	0	....	Less than 0.08

Plan Forms of Airfoils vary considerably. The most common plan form now in use generally tapers from a constant value of chord over the central portion of the span to a smaller value near the wing tips which are ordinarily rounded. The thickness of the airfoil is usually tapered towards the tips to assist the plan form taper in the matter of weight saving. There are also aerodynamic advantages for taper in plan form as well as thickness. Theory and experiment agree in showing that the ratio of span to average chord, called the aspect ratio, should be large. Structural and weight considerations indicate that a small aspect ratio should be used. Values of the aspect ratio in common use vary from 6 to 8 for wings, although soaring gliders have aspect ratios in excess of 20.

Airfoil Characteristics are usually written:

$$L = \frac{C_L}{2}\rho SV^2; \quad D = \frac{C_D}{2}\rho SV^2; \quad M = \frac{C_M}{2}\rho c SV^2 \tag{57}$$

where L = component of air force at right angles to the relative wind.
D = component of air force along the relative wind direction.
M = moment of air force (usually measured about the leading edge).
C_L, C_D and C_M are dimensionless coefficients of lift, drag, and moment respectively.
ρ = mass density of air.
S = plan area of airfoil, also called wing area.
V = relative velocity of air.

The Aerodynamic Coefficients C_L, C_D, and C_M for an airfoil of given shape vary chiefly with: angle of attack, α (usually measured as the angle between the chord and the relative wind direction); Reynolds' number, $\frac{Vc}{\nu}$; surface texture of airfoil and the degree of turbulence of the air stream.

The Aerodynamic Characteristics of Airfoils are usually measured in wind tunnels. Fig. 42 shows diagrammatic sketches of a modern wind tunnel. Space and power requirements usually make the initial and operating costs of large wind tunnels capable of good speed very high. In order to measure results which can safely be used to estimate the performance of modern airplanes, Reynolds' numbers of the order of 2,000,000 $\left(\text{R.N.} = \frac{Vc}{\nu}\right)$ should be used in testing. For air at ordinary working conditions Vc must then be $\approx$ 330 ft per sec. An airfoil of 6 sq ft area and aspect ratio 6 should then be tested at about 200 mph wind speed. The variable density or compressed air tunnel uses air compressed to 20 atmospheres at moderate speeds and small model sizes. Since in this way ν may be reduced to approximately $^1/_{20}$ of its normal value, the value of Vc may be correspondingly reduced without reducing $\frac{Vc}{\nu}$.

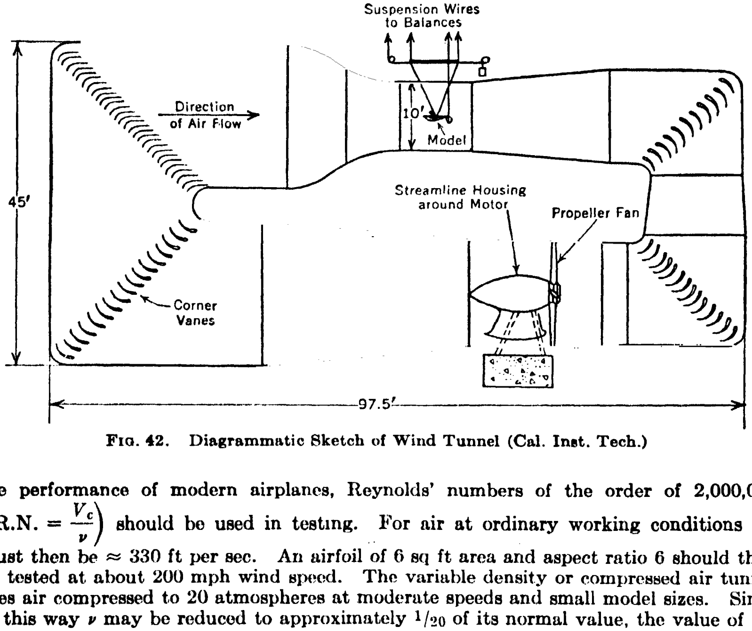

FIG. 42. Diagrammatic Sketch of Wind Tunnel (Cal. Inst. Tech.)

Typical airfoil characteristics measured in a wind tunnel are shown in Fig. 43 (N.A.C.A.T.R. 502).

Many experiments on airfoils verify that the variation of C_L with α predicted by theory (see Art. 13) for thin airfoils is true for the range of values of α generally used in flight. The slope, $\frac{dC_L}{d\alpha}$, of the C_L curve has been found to depend principally on the thickness parameter. Theory does not give any information regarding the maximum value of C_L which may be attained with a given airfoil shape. The value of C_L max. depends very much on the degree of turbulence of the airstream. Excessive values of turbulence result in optimistic predictions of C_L max.

The Drag Coefficient is usually written,

$$C_D = C_{Dp} + C_{Di} \tag{58}$$

where C_{Dp} is called the profile drag coefficient and C_{Di} the induced drag coefficient (see Art. 15). The profile drag coefficient must be found by experiment. It depends on t and m and also on surface smoothness. The theoretical formula derived in Art. 15 for conversion of airfoil data from one aspect ratio and plan form to another gives good results in practice. A standard aspect ratio and plan form may thus be chosen in order to investigate the properties of a particular airfoil section.

The curve C_M versus C_L in Fig. 43 shows that the linear relation between C_M and C_L

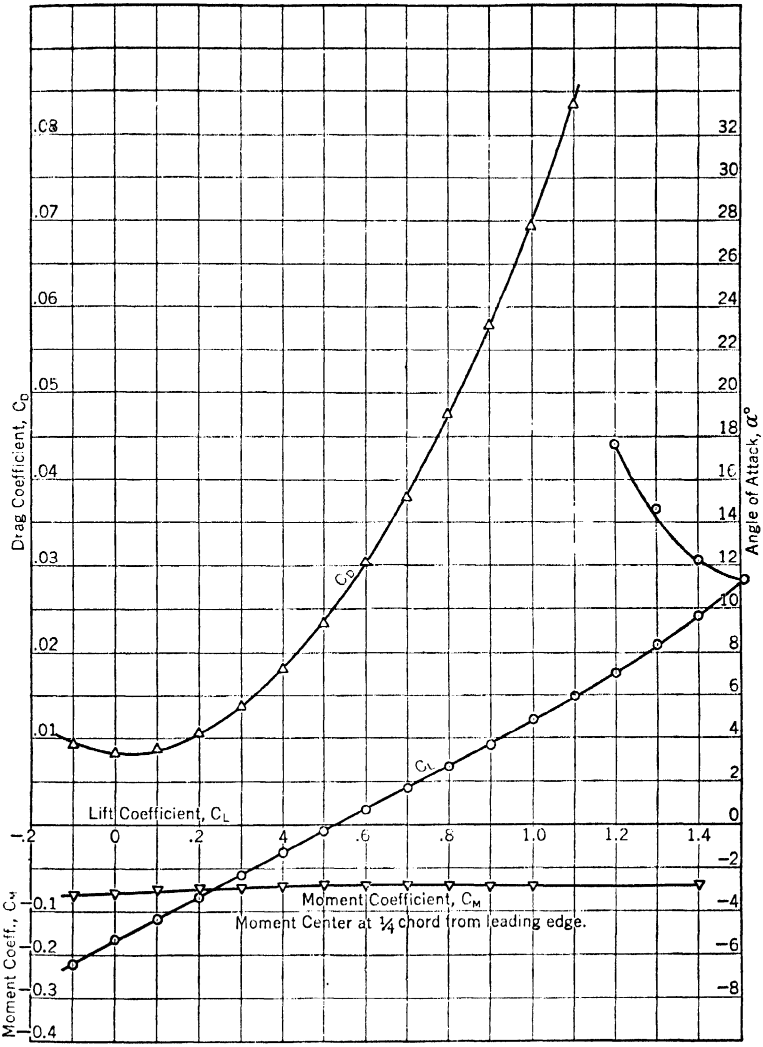

FIG. 43. Characteristics of Airfoil; Clark-Y.
Airfoil: 8′ × 48′; R.N. = 6,000,000; c = chord

is realized in actual tests. C_{M_0} depends on m, L, and t. The center of pressure coefficient is

$$\frac{x_{cp}}{c} = n - \frac{C_{M_0}}{C_L} \tag{59}$$

where x_{cp} is the distance from leading edge to the center of pressure measured along the chord. Theory indicates that $n = 0.25$ for thin airfoils. Tests on airfoils indicate that n varies with thickness principally.

Critical or Stalling Angle. The most unsatisfactory part of airfoil behavior consists in the flow around the airfoil at angles near that of maximum lift. This angle is usually called the *stalling angle* by pilots. The term indicates that the airfoil refuses to generate more lift beyond the stalling angle and that the wing shows bad stability characteristics in roll; i.e., if either wing tip is deflected when the wing is near the stalling angle, forces arise which increase this deflection. This tendency is so strong that the airplane is momentarily out of control, and this is fraught with considerable danger when the craft has insufficient altitude.

Recently considerable progress has been made in improving the flow over airfoils at the critical or stalling angle. The phenomenon of the stall is intimately connected with the flow in the boundary layer. The air flowing over the top surface of the airfoil is practically flowing through a venturi-like region. Near the surface the fluid must flow against an increased pressure just as in the diverging part of a venturi. In addition in this region the fluid friction causes an adverse pressure gradient so that particles near the surface are brought to rest long before they reach the trailing edge. These particles of fluid leave the surface in an unstable manner and there is consequently much turbulence with an adverse effect on the flow and lift. By removing this turbulent boundary layer near the surface, improved performance results. Suction and pressure are both beneficial. Marked improvement with small expenditure of power has been found in laboratory tests.

21. APPLICATIONS OF AERODYNAMIC THEORY OF VISCOUS INCOMPRESSIBLE FLUIDS

Propellers and Fans. Dimensional analysis shows that

$$T = \rho N^2 d^4 f_1\left(\frac{\rho V d}{\mu}, \frac{V}{Nd}\right) = C_T \rho N^2 d^4 \tag{60}$$

$$Q = \rho N^2 d^5 f_2\left(\frac{\rho V d}{\mu}, \frac{V}{Nd}\right) = C_Q \rho N^2 d^5 \tag{61}$$

where T = propeller thrust, C_T = thrust coefficient.
Q = propeller torque, C_Q = torque coefficient.
N = angular velocity of propeller.
d = propeller diameter.
V = velocity of advance of the propeller.
ρ = mass density of the air.
μ = coefficient of viscosity.

Since most propellers are now tested at full scale or very nearly at full scale and the effects of R.N. $= \frac{Vd}{\nu}$ may be neglected it is usually assumed that C_T and C_Q vary only with $\frac{V}{Nd}$.

Propeller theory has advanced to a fairly satisfactory solution of the performance of a propeller at cruising or maximum speed. Calculations for climbing speeds and altitudes and for zero advance of the propeller may be in serious error.

Measurements of Propellers are usually made with a full-scale propeller and engine in large wind tunnels. Flight conditions may be accurately duplicated, and such factors as body interference and deflections of the propeller may also be investigated.

The most convenient method to calculate the propeller characteristics is to use Weick's coefficient

$$C_S = V\sqrt[5]{\frac{\rho}{PN^2}} = \frac{0.638 \times \text{mph}}{(\text{bhp})^{1/5} \times (\text{rpm})^{2/5}} \tag{62}$$

A typical variation of C_S versus $\frac{V}{Nd}$ is shown in Fig. 44. For a desired speed and a given engine the propeller characteristics may be determined very quickly and accurately from such charts.

The Propeller Efficiency is given by

$$\eta = \frac{\text{thp}}{\text{bhp}}, \tag{63}$$

thp = thrust horsepower and bhp = brake horsepower. The curve (line of max. η for C_S) shown in Fig. 44 is usually termed the best performance propeller since it performs best at high speed and very well at climbing speed. Since a propeller of fixed blade angle setting for best performance does not give good performance at take-off and climb, where a smaller blade angle setting is necessary, it has become necessary to resort to variable

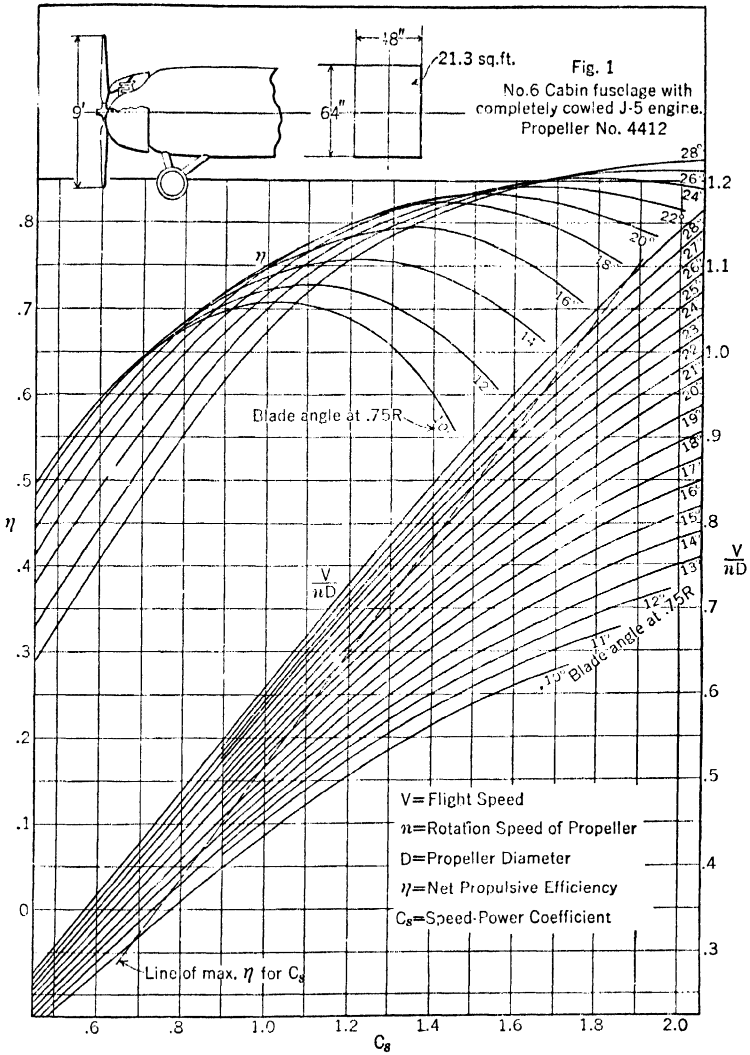

Fig. 44. Propeller Characteristics

pitch propellers. The difference in performance of an airplane with fixed and variable pitch propellers is shown by the following table.

Table IX. Performance of an Airplane with Fixed Pitch and Variable Pitch Propellers

Taken from N.A.C.A. Tech. Note 484

Propeller	High Speed (mph)	Maximum Rate of Climb (ft per min)	Take-off Run (ft)
Best fixed pitch...........	211	1415	1445
Best variable pitch........	209	1825	669

Propeller-type Fans. The conditions of operation of a propeller-type fan are quite different from those of a propeller for use on air or water craft. In the former case axial speeds on each side of the fan disk are alike while the pressure on the downstream side is greater than the pressure on the upstream side. For the latter case the reverse is true. The axial velocity of the fluid on the downstream side of the propeller fan disk exceeds that on the upstream side; the pressure, except at points very near the disk, is everywhere the same. The pressure rise which the propeller fan furnishes is concerned with the rotational velocity increase since there is no axial velocity change. This pressure rise is usually written $p_t = p_d + p_s$, where $p_d = {}^1/_2\,\rho V^2$ = velocity or dynamic pressure and p_s = static pressure. The diagram in Fig. 45 shows a typical variation of pressure for a fan installation. The working conditions of the fan depend on the ratio p_d/p_t.

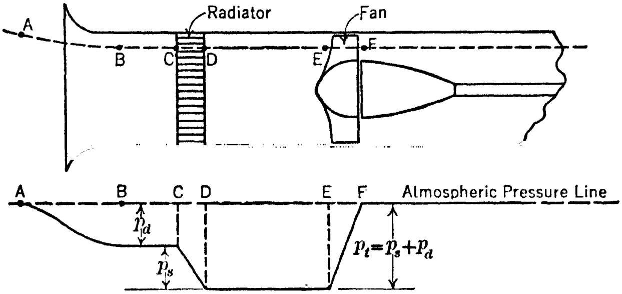

FIG. 45. Variation of Pressure in a Fan Installation

The efficiency
$$\eta = \frac{Q \times p_t}{\text{Power input}} \tag{64}$$

Q = volume flowing per unit of time through the fan area, A. Sometimes the static efficiency $\eta_s = \dfrac{Q \times p_s}{\text{Power input}}$ is essential.

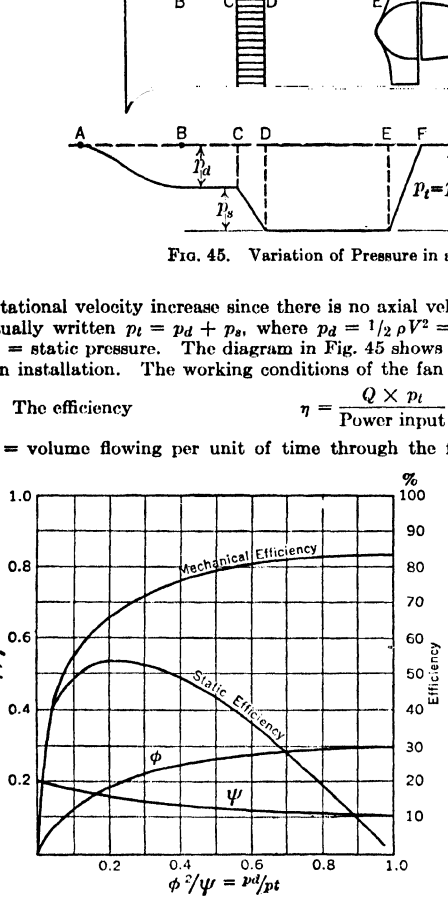

FIG. 46. Typical Performance of a Propeller Fan (Tietjens)

The Characteristics of a Fan are sometimes written in terms of two dimensionless numbers ϕ and ψ, where

$$\phi = \frac{Q}{A\,v_t}\,; \quad \psi = \frac{p_t}{\frac{\rho}{2}v_t^2} \tag{65}$$

v_t = peripheral speed of fan, $= r\omega$, where r = fan radius and ω = angular speed of fan.

The ratio $\dfrac{p_d}{p_t} = \dfrac{\phi^2}{\psi}$ is then the criterion defining the working condition of the fan.

Fig. 46 shows a typical performance of a propeller fan.

Propeller fans are designed by means of the airfoil theory. Tietjens (Ref. 1 Art. 21) states that a simple method for an approximate design is given by

$$T = \frac{Qp_t}{V} = Ap_t = 3.2\,n\left(\frac{\text{rpm}}{1000}\right)^2 b_2r_2\,(r_2^2 - r_1^2) \tag{66}$$

where T = thrust, V = axial velocity through the fan, n = number of blades, b_2 = blade width at tip, r_1 = hub radius, r_2 = tip radius. This formula depends upon a relation, C_LVb = constant, where C_L = lift coefficient of an airfoil having approximately 50 per cent larger ratio of length to width than for the fan blade. This method becomes inaccurate when the ratio $\frac{p_d}{p_t} \leqq 0.3$. In such cases doubt exists about the relative efficiency of a propeller type fan as compared with other types.

Airplane Performance. The fundamental equation to determine airplane performance is

$$\frac{dh}{dt} = \left(\frac{\text{thp}_a - \text{thp}_r}{W}\right) 550 \text{ (Ref. 2 Art. 21)} \tag{67}$$

where h = altitude in feet.
t = time in seconds.
W = gross weight in pounds.
thp_a = thrust horsepower available.
thp_r = trust horsepower required.

This may be written $\frac{dh}{dt} = w_h - w_s$ = rising speed − sinking speed.

$$w_s = \frac{\sigma V^3}{L_p} + \frac{1}{\sigma}\frac{L_s}{V} \tag{68}$$

where σ = relative air density, $L_p = \frac{W}{f}$, f = equivalent parasite area to represent the parasite drag,

$$L_s = \frac{W}{b_e^2} \tag{69}$$

where b_e is the effective span and V = flight speed.

$$w_h = \frac{1}{L_t} T_a T_v \tag{70}$$

where $L_t = \frac{W}{\text{thp}_m}$, thp_m = thrust horsepower available at maximum speed $V = V_m$,

$$T_a = \frac{\text{thp}_a \text{ at altitude}}{\text{thp at sea level}} \tag{70a}$$

$$T_v = \frac{\text{thp}_a \text{ at speed } V}{\text{thp}_a \text{ at speed } V_m} \tag{70b}$$

A graphical solution of this equation shows that most of the important performance characteristics may be determined from a parameter

$$\Lambda = \frac{L_s L_t^{4/3}}{L_p^{1/3}} \tag{71}$$

Charts have been prepared in the reference from which it is a very simple matter to calculate landing speed, maximum velocity at any altitude, maximum rate of climb and speed at any altitude, absolute and service ceiling, and the time to climb to any altitude.

Loads on an Airplane in Flight. The load on an airplane in flight is usually expressed as $m = \frac{L}{W}$, where L is the momentary load and W the normal load which equals the gross weight. Measurements made on airplanes in flight show the following representative values of m in typical maneuvers.

Table X. Values of *m* for an Airplane at Two Speeds

Maneuver	80 mph	175 mph
Sudden pull-up from a dive	3.5	9.3
Loop	3.7	5.0
Roll	4.2	5.2
Spin	3.1	2.3
Steeply banked turn	1.4	3.0

The load multiple is usually multiplied by a safety factor of 1.5 to 2 and this is then taken as a design load factor.

The sudden pull-up from a dive subjects an airplane to the most severe loads, but there are other loading conditions not quite so severe which materially change the position of the center of pressure. In others the load may be a twisting couple, for example, at high speed and in a steep dive.

Turbulence and gusts in thunder storms and over mountainous terrain cause upward or downward currents into which an airplane may run with abruptness. The load multiple for such a condition is

$$m = \frac{\frac{\rho}{2}\frac{dC_L}{d\alpha}UV}{\frac{W}{S}} \qquad (72)$$

where ρ = mass density of the air, $\frac{dC_L}{d\alpha}$ = slope of the wing lift curve, U = upward or downward gust velocity, V = airplane flight speed, and $\frac{W}{S} = \frac{\text{gross weight}}{\text{wing area}}$ = wing loading. The following table shows measured values of U and the corresponding values for an airplane of wing loading $\frac{W}{S} = 15$ and flight speed $V = 190$ mph. Then $m = 0.215\,U$.

Table XI. Load Multiples Due to Gusts (Ref. 3 Art. 21)

	Thunder storms	Mountainous terrain	Convection currents
Vertical velocity (ft per sec)....	44–110	10–27	7–24
m..........................	9.5–23.7	2.15–5.81	1.5–5.2

22. FLOW OF VISCOUS INCOMPRESSIBLE FLUIDS NEAR BOUNDARIES—GENERAL THEORY

The boundaries may be solid walls or surfaces of separation between two fluids. A dimensional analysis shows that the force experienced by a body in such cases is given by

$$R = \rho V^2 L^2 \phi\left(\frac{VL}{\nu}, \frac{gL}{V^2}, \frac{\gamma}{\rho g L^2}\right) \qquad (73)$$
$$= C_R \rho V^2 L^2$$

where R = force exerted on the body, C_R = force coefficient.
ρ = mass density of the fluid.
V = relative speed of body and fluid.
μ = coefficient of viscosity.
g = acceleration of gravity.
L = a typical length of the body defining its size.
γ = surface tension of the fluid in contact with the solid boundary.

It is in general impossible in model testing to make all three numbers on which C_R depends alike. Sometimes one or two of these criteria of the motion may be disregarded. Several examples of interest will be considered.

23. RESISTANCE OF SURFACE VESSELS

Surface Ships may be broadly divided into two general types.

(*a*) Those which are practically supported by buoyant or hydrostatic forces.

(*b*) Those which are practically supported by dynamic forces.

Type (*a*) has been in use for a long time, and methods for predicting the characteristics for such vessels are very reliable. Froude's method is generally used. According to this method the resistance, R, is written: R = skin friction resistance + wave or eddy resistance. The former depends chiefly on Reynolds' number, $\frac{VL}{\nu}$, and the latter on Froude's number, $\frac{gL}{V^2}$. The number $\frac{\gamma}{\rho g L^2}$, called Weber's number, does not enter the problem unless very small models are tested.

If the subscript m designates the model, then the wave or eddy resistance, R_w, is given by

$$\frac{R_w}{R_{wm}} = \frac{\rho D}{\rho_m D_m} \qquad (74)$$

where D designates displacement. This is dependent upon the fact that $\frac{gL}{V^2} = \frac{gL_m}{V_m{}^2}$ which defines corresponding speeds for model and full scale.

This leads to Froude's formula:

$$R = \left(R_m - C_{Rm}A_m \frac{\rho}{2} V_m^2\right)\lambda^3 + C_R A \frac{\rho}{2} V^2 \tag{75}$$

where R = resistance of full-sized ship.
R_m = resistance of model (measured by towing the model).
C_{Rm} = skin friction coefficient of model = f(R.N.).
A_m = wetted surface of model.
λ = scale ratio (full size to model).
C_R = skin friction coefficient of full scale = f'(R.N.).
A = wetted surface of full-sized ship.

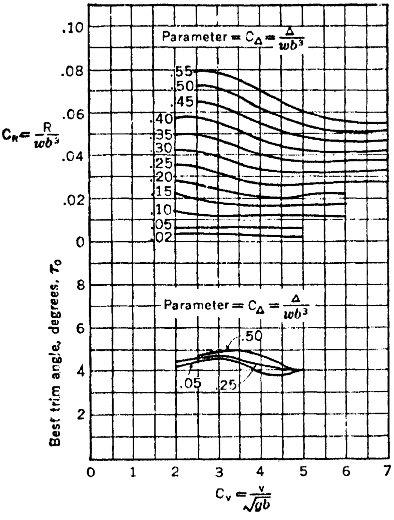

FIG. 47. Variation of C_R at Best Trim Angle and τ_0 with C_v (N.A.C.A. Tests)

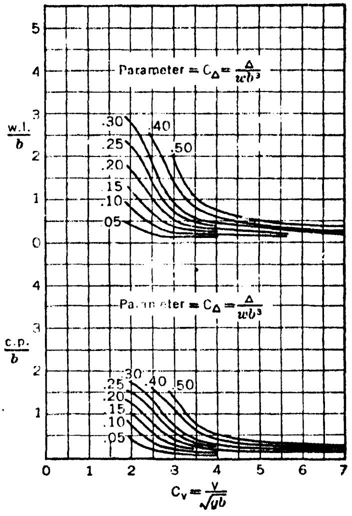

FIG. 48. Variation of w.l./b and c.p./b at Best Trim Angle with C_v

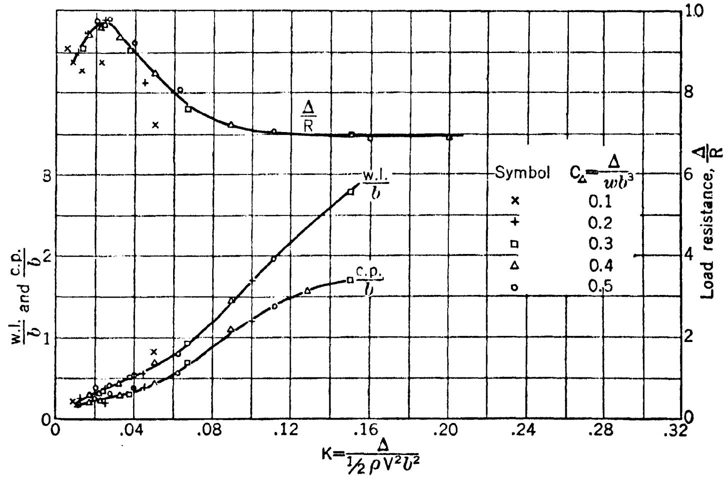

FIG. 49. Variation of Δ/R, w.l./b, and c.p./b at Best Trim Angle with Planing Coefficient, K (N.A.C.A. Tests)

Careful analyses of trial runs show that model experiments predict power within ± 2 per cent and engine revolutions within ± 1 per cent.

Type (b) Vessels in Which Dynamic Forces Predominate are usually called planing vessels or craft. Examples are fast motor boats and seaplanes. The action of the seaplanes is somewhat different in so far as the dynamic lift of the wings predominates in the later stages of the motion just preceding take-off. The Froude method cannot be employed for a planing craft for several reasons (Ref. 1, Art. 23):

(i) The wetted surface changes with the speed and with the angle of trim.

(ii) The mean speed of the water on a planing surface differs substantially from the towing speed.

(iii) At smaller scales, the friction coefficients at equal Reynolds' numbers may assume different values, depending upon whether the boundary layer is laminar or turbulent, or turbulent after laminar approach.

No method based on rational formula or complete experiments exists to predict planing characteristics.

Figs. 47 to 49 show results recently measured (Ref. 3, Art. 23) on a flat planing surface 60 in. long and 16 in. wide. Trim angles from 2° to 8°, loads from 5 lb to 80 lb, and speeds from 12 fps to 46 fps were used.

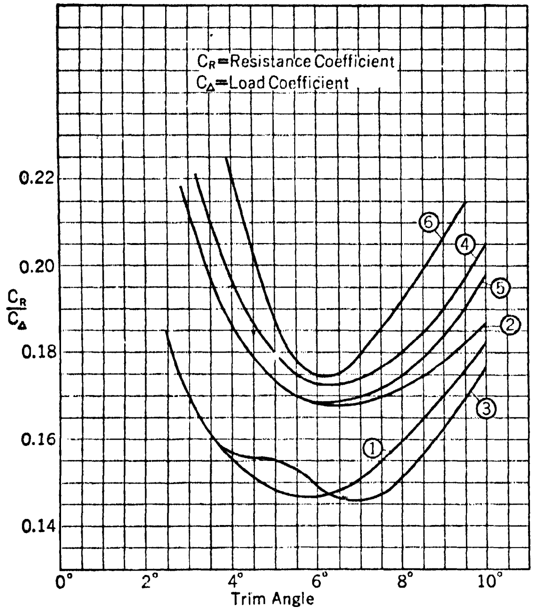

Fig. 50. Resistances of Various Planing Surfaces (Sottorf)

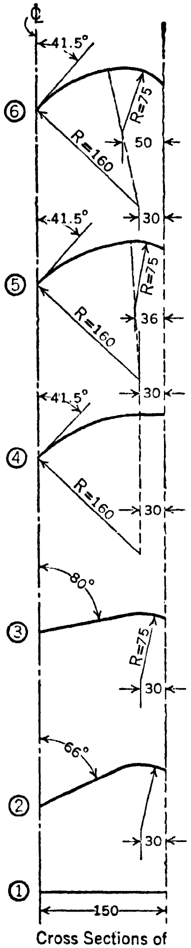

Cross Sections of Planing Surfaces

Results are shown by means of dimensionless parameters as follows:

$$K = \frac{\Delta}{{}^1/_2 \rho\, V^2 b^2}\,; \quad \Delta = C_\Delta \rho\, b^3 \tag{76}$$

$$V = C_v \sqrt{gb}; \quad C_R = \frac{R}{\rho\, g b^3} \tag{76a}$$

where K = planing coefficient (dimensionless).
Δ = load in pounds.
R = resistance in pounds.
ρ = mass density of water in slugs per cubic foot.
V = planing speed in feet per second.
b = width of planing surface in feet.

g = acceleration of gravity in feet per second per second.
C_Δ = load coefficient (dimensionless).
C_v = speed coefficient (dimensionless).
C_R = resistance coefficient (dimensionless).

Example: An aquaplane to be towed behind a motor boat weighs with the rider 200 lb. The boat makes 30 mph. How wide should the aquaplane be, at what trim should it ride, and how much pull would it exert on the tow rope?

From Fig. 49 we see that $K = 0.027$ corresponds to the best ratio of load to resistance, $\frac{\Delta}{R}$. For salt water $^1/_2\,\rho \approx 1$; 30 mph = 44 ft per sec. Hence $K = 0.027 = \frac{200}{(44)^2 b^2}$; $b = 1.96$ ft, required width. $C_v = \frac{V}{\sqrt{gb}} = \frac{44}{\sqrt{32.2 \times 1.96}} = 5.51$. From Fig. 47 we see that the best trim angle is 4°. $\frac{\Delta}{R} = 9.75$ and hence the resistance on the tow line is 20.5 lb.

Some experiments have been made with planing surfaces which are not flat in a transverse plane. Sottorf (Ref. 1, Art. 23) found results as shown in Fig. 50.

Results found by Sottorf also indicate that curvature in the longitudinal plane may have favorable effects.

If the bottom of the planing surface of a planing craft ends abruptly in a step and the surface then continues for some distance aft of the step the wake behind the step will add additional resistance. Model experiments must be resorted to in such cases to obtain the resistance.

24. FLOW IN OPEN CHANNELS

Pressure Drop Coefficient. A dimensional analysis shows that the pressure drop coefficient $C_{\Delta p} = \frac{\Delta p}{L} \cdot \frac{2\,D'}{\rho\,\bar{u}^2}$ (see Art. 17) for open channels depends upon Reynolds' number $\frac{\bar{u}\,D'}{\nu}$; Froude's number, $\frac{\bar{u}}{\sqrt{gD'}}$; and Weber's number, $\frac{\gamma}{\rho\,gD'^2}$. D' is a length which for open channels is usually taken as $\frac{A}{w.p.}$, where A = cross-sectional area of the fluid stream and $w.p.$ = wetted perimeter. It is called the mean hydraulic radius.

The Influence of Weber's Number or the surface-tension effect is usually negligible except where very small models are used. Sometimes gravity forces predominate as compared with friction forces. In such a case Froude's method may be used to determine the effect of gravity and then the friction effect may be obtained by approximate calculation or experiment. If both gravity and friction forces are important, systematic model testing must be undertaken.

Von Mises' Formula. Many formulas for obtaining the friction loss have been used in hydraulics. A recent formula by Von Mises is:

$$C_{\Delta p_1} = 0.0029 + \sqrt{\frac{k}{D'}} + \frac{3}{\sqrt{\text{R.N.}}} \tag{77}$$

where k = a roughness number, R.N. $= \frac{\bar{u}D'}{\nu'}$.

Values of k are given in the following table (Ref. 1, Art. 24).

Table XII

Material	$k \times 10^4$ in feet	Material	$k \times 10^4$ in feet
Glass	0.33–1.33	New cast iron	165–330
Drawn brass, lead, copper	0.33–1.65	Old cast iron	400–500
Smooth cement	12–25	Masonry (brick)	330–1000
Rough cement	33–66	Masonry (rough stone)	3300–6600
Asphalted zinc	50–100	Earth walls	16,500–33,000

Chezy's Formula. The lowest value of R.N. for which Von Mises' formula holds is R.N. ≈ 500. Other formulas are in constant use by hydraulic engineers. In the United States, Chezy's formula or modifications of it are favored. This formula is

$$Q = C_Q A \sqrt{D'} \sqrt{S} \tag{78}$$

the quantities Q, A, D' have been defined, and S = hydraulic slope = (head lost due to friction)/D'.

Values of C_Q are found in all hydraulics tables.

25. FLOW OVER NOTCHES AND WEIRS

A Common Form of Notch is a Vee-cut in the top of an end wall of a tank with the point of the Vee down. If the difference of level between the liquid surface and the point of the Vee is h, we may establish by dimensional analysis that

$$Q = g^{1/2} h^{5/2} f\left(\theta, \frac{h^{3/2} \rho g^{1/2}}{\mu}\right) = C_Q g^{1/2} h^{5/2} \tag{79}$$

In many cases viscosity effects are negligible and $C_Q = f(\theta)$. By experiment, $f(\theta) = 0.477 \tan \frac{\theta}{2}$. Exceptions occur if the jet runs down the vertical wall, if obstructions are placed near the notch, or the notch is too near a side wall of the channel.

Rectangular Notches or Weirs are also in common use. If the notch has a breadth b, then we find, neglecting viscosity and surface tension,

$$Q = g^{1/2} b h^{3/2} f\left(\frac{h}{b}\right) = C_Q g^{1/2} b h^{3/2} \tag{80}$$

Hydraulics tables list values of the coefficient C_Q.

26. WIND TUNNEL BOUNDARY EFFECTS

In Testing Models of Airplanes in wind tunnels the effect of the boundaries is appreciable. By means of the vortex theory it is possible to correct for this influence of the boundary. A very simple instance is a tunnel of a circular cross-section.

Prandtl found that an approximation consists in assuming constant span loading over the airfoil. The principal effect of the boundaries is due to the tip vortices at A and B. If two image vortices at A' and B' opposite in sense to A and B are added at a distance $\frac{2R^2}{b}$ from the center at O, where b = airfoil span, then the system of four vortices produces a velocity field which has a zero normal velocity component at all points of a circle of radius R, center at O. It may then be demonstrated that the principal effects are given by:

$$\left.\begin{aligned} \alpha^\circ &= \alpha_T{}^\circ + \frac{\delta S C_L}{S_S} \times 57.3^\circ \\ C_D &= C_{DT} + \frac{\delta S C_L}{S_S} \end{aligned}\right\} \begin{array}{l} \text{Airfoil span} \leq \\ {}^3/_4 \times \text{tunnel width} \end{array} \tag{81}$$

where $\alpha_T{}^\circ$ = an angle of attack used in the wind tunnel.
α = corrected angle of attack used in the wind tunnel.
C_{DT} = drag coefficient of the airfoil measured in the wind tunnel at $\alpha_T{}^\circ$.
C_D = corrected drag coefficient.
S = plan area or wing area.
S_S = cross-sectional area of the wind stream.
C_L = lift coefficient of airfoil measured at $\alpha_T{}^0$.
δ = a constant varying with the shape of the cross-section.

For the Circular Tunnel $\delta = +0.125$ when the boundary is solid. If the working section is open but circular in cross-section, $\delta = -0.125$. Values of δ have been determined for various types of tunnels. By leaving the working section partly open and partly closed the boundary effect may become negligible.

27. GROUND EFFECT ON AUTOMOBILES AND TRAINS

This effect has become of importance in testing the effects of shape changes on the air resistance of automobiles, trains, fast water craft, etc. Some tests have been made in wind tunnels and one under actual trial runs of an automobile. There is no conclusive experimental evidence concerning the effect of the boundary layer on the drag of a surface vehicle. If an automobile is moving in a dead calm there is no boundary layer near the surface of the ground. If a natural wind is blowing there is a boundary layer near the ground or water surface. Since the effects are more pronounced when there is a natural wind opposing the motion this condition is of interest especially in the case of a steamship steaming into a gale and also for any land craft.

Tests recently made at Case School of Applied Science using a flat plate to measure the ground effect show the following values of the air drag coefficient

$$C_D = \frac{D}{{}^1/_2\, \rho\, A\, V^2} \tag{82}$$

where D = drag (pounds), ρ = mass density of air (slugs per cubic foot), A = projected area of model at right angles to wind stream (square feet), V = relative wind speed (feet per second). Results corrected to 15° C and 760 mm.

Table XIII

Type of model	C_D (at 0° yaw)	Reynolds' number	Length used in calculating Reynolds' number
Locomotive (Hudson J-1)	0.632	3.57×10^6	Overall length (4 ft)
Locomotive (partially stream-lined)	0.402	3.86×10^6	" " (4.25 ft)
Locomotive (Stream-lined)	0.0565	3.86×10^6	" " (4.25 ft)
Automobile (1932 model sedan)	0.463	0.873×10^6	" " (19 in.)
Automobile (Stream-lined)	0.239	0.661×10^6	" " (15 in.)
Automobile (1932 sedan, run backwards)	0.428	0.867×10^6	" " (19 in.)
Steamship (*Pres. Hoover*)	0.392	3.0×10^6	" " (35 in.)
Steamship (Partially stream-lined)	0.239	3.0×10^6	" " (35 in.)
Steamship (Well stream-lined)	0.142	3.0×10^6	" " (35 in.)

Stalker (Ref. 1, Art. 27) states that if a model is tested near a flat plate from which the boundary layer has been partially removed the following results are obtained for a 0° yaw altitude:

Table XIV

Test method	Air drag
Flat plate, boundary layer partially removed	1.00
Flat plate, no boundary layer removed	0.87
Free model, no plate	1.11
Two identical models, one upside down, half of total drag	1.17

ENGINEERING THERMODYNAMICS

PRINCIPLES OF THERMODYNAMICS

The science of engineering thermodynamics develops means for determining the nature and amounts of the energy transformations occurring in engineering processes. Articles 1 to 7 present those principles which are common to all processes, regardless of the particular kind of working fluid used and the particular form of the machine or device in which the process is carried out.

1. ENERGY FORMS

The energies encountered in engineering thermodynamics are of several well-defined forms, named and described as follows:

(a) **Mechanical Potential Energy** is the form in which energy is stored by virtue of the relative vertical distance of a body above a horizontal reference plane.

(b) **Mechanical Kinetic Energy** is the form in which energy is stored by virtue of the relative motions existing between parts of a system.

(c) **Internal Energy** is the form in which energy is stored within a body, such as a quantity of gas, liquid, or solid, by virtue of the relative motions of, and the forces between, the molecules or atoms composing the body. It is evidenced by some properties of the body, usually temperature, but also by pressure and specific volume, and by physical phase, i.e., whether solid, liquid, or gaseous. Energy stored in substances and released in chemical reactions also comes under this classification of internal energy. In this case, the energy is ascribed to the arrangement of the atoms within the molecules. Considerable needless confusion has been introduced in many works by referring to internal energy in an ad lib. fashion as " heat." See discussion of the proper use of the term *heat* below.

The energy forms (*a*), (*b*), and (*c*) just described have the common characteristic that they are forms in which energy may be stored away for possible future use. The two forms (*d*) and (*e*) about to be described have quite different characteristics in that they represent the forms or means by which energy may be transferred or transformed.

(d) **Work** is a transient form of mechanical energy by means of which certain transformations of other forms of energy are brought about through the agency of a force acting through a distance. Several examples of energy transformation by means of work may be given. Work done by lifting a body stores mechanical potential energy in the system consisting of the body and the earth. Work done on a body to set it in motion stores mechanical kinetic energy in the system of which the body is one part. When a gas is compressed, work is transformed into internal energy which then exists as energy stored in the gas.

(e) **Heat,** like work, is a transient form of energy. Heat is defined as the energy in transition or transfer from one body to another by virtue of a temperature difference existing between the bodies. Conduction and radiation are the two methods through which heat transfer occurs.

Conduction is energy transfer from one body to another body at a lower temperature by tangible contact. It may be thought of as the transfer of some of the internal molecular kinetic energy of the hotter body to the more slowly moving molecules of the colder body.

Radiation is energy transmission through space from a hotter body to a colder body. In most processes involving heat flow it is impossible to distinguish the exact amounts transmitted by radiation and by conduction, but this distinction need seldom be made in practice as the category heat includes all transfer of energy due to temperature differences existing between two systems.

In identifying the various forms of energy, care must be exercised to preserve two distinctions. First there must be recognized the distinction between the group consisting of the *three stored forms of energy,* mechanical potential, mechanical kinetic, and internal energy; and the group comprising the *two transient forms*, work and heat. A second important distinction is that which exists *between internal energy and heat.* Energy stored in any molecular or atomic system such as energy in air, steam, or fuel comes under the category of internal energy. The name heat is used only to identify energy actually in transition or flow between systems at two different temperatures.

Convection is not a form of energy or energy transformation. When a body with its associated energy is moved from one position to another without state changes or energy transformations, the process is designated by the term *convection.* A typical example of convection is the movement of heated air from one part of a room to another. The internal energy has moved from one location to another, but no energy transformation has occurred. Another example of convection is the movement through a pipe of the kinetic energy or the potential energy associated with the fluid flowing in the pipe, without any energy transformations taking place.

2. UNITS OF ENERGY

Units of Energy. Any form of energy may be expressed quantitatively in any unit of energy. Fundamental units of energy are the *erg* in the metric system and the *foot-pound* in the English system. These units are derived from the standards of mass, length, and time. From the erg or foot-pound are derived numerous other energy units such as the joule, meter-kilogram, kilowatthour, horsepower-hour, etc.

From the earliest days of the science of thermodynamics there has existed an independent set of energy units, the *caloric* and the *British thermal unit* (Btu), related in no way to the standards of force or distance, but independently defined in terms of the thermal properties of water. For example, a widespread definition of the Btu is $^1/_{180}$ of the quantity of energy required (heat required) to change 1 lb of water from the ice-point to the steam-point at standard atmospheric pressure. With respect to these units there have evolved no accepted standards of definition of the units, methods of experimental procedure, or numerical results.

In order to recognize a common basis for all energy units and at the same time retain the calorie and Btu, the International Steam Table Conference, meeting in London in 1929, recommended that the international calorie be defined as $^1/_{860}$ of an International watthour. By arithmetic, using the defined relations between the English and metric systems, the Btu can be thus established, by definition, as 778.26 ft-lb.*

In honor of Dr. Joule who, in his classical experiment of raising the temperature of water by stirring it, demonstrated the conversion of mechanical potential energy into internal energy by the agency of work, the factor 778.26 is called *Joule's equivalent* and is represented by the symbol J. For all engineering purposes J may be taken as equal to 778. From the viewpoint of this treatment, J is not the "mechanical equivalent of heat," but merely a conversion factor between two energy units.

Since *power* is the time rate of expenditure of energy, we have a series of units of power which correspond to the energy units. Here, also, any power unit may be used to measure the expenditure or transition of energy by any method; either by work, or heat, or electrical energy. The watt (1 joule per sec) and the horsepower (550 ft-lb per sec) are the commonest forms of power units.

Factors for the ready conversion of the various energy and power units are found in Section 1, Tables 42 and 43. Below are given some of the definitions and conversion factors for the energy and power units most frequently encountered in engineering practice.

Conversion Factors for Energy Units.

1 Btu = 778 ft-lb (by definition) = 1055 joules = 252 calories.
1 erg = 1 dyne-cm (by definition).
1 joule = 10^7 ergs (by definition) = 0.73756 ft-lb.
1 horsepower-hour = 2545 Btu = 0.7457 kwhr.
1 kilowatthour = 860 international calories (by definition of calorie) = 1.341 hp-hr.

Conversion Factors for Power Units.

1 horsepower = 550 ft-lb per sec (by definition) = 33,000 ft-lb per min = 2545 Btu per hr = 0.7457 kw.
1 watt = 1 joule per sec (by definition).
1 kilowatt = 1000 watts (by definition) = 1.341 hp = 3413 Btu per hr.

3. ENERGY TRANSFORMATIONS

Processes. In a broad sense, a *process* is any event in nature in which a redistribution or transformation of energy occurs. Engineering thermodynamics considers chiefly those processes in which energy transformation occurs by means of changes in physical state of fluids.

The processes of engineering thermodynamics may be conveniently classified into well-defined groups in several ways. One classification is into the groups of reversible and irreversible processes. Another classification which is of much value is into the divisions called flow and non-flow processes.

Reversible Processes are those which meet two criteria as follows:

(*a*) The process, after completion, may be caused to occur in an exactly reverse order whereby the immediate system and any other systems associated with it may be returned from their last to their initial state.

(*b*) All the energy which was transformed during the process may be returned from its final to its original form, location, and amount.

Irreversible Processes are those which do not meet the above criteria. Among the conditions which contribute to the irreversibility of a process are the following:

(*a*) Heat flow from a higher to a lower temperature, (*b*) mixing of fluids at different temperatures, (*c*) fluid turbulence, (*d*) fluid or solid friction, (*e*) inelastic deformation.

Some examples of reversible processes are:

(*a*) A frictionless pendulum swinging in a vacuum, (*b*) a gas expanding slowly without friction or turbulence in a heat-insulated system.

Non-flow Processes are those occurring in a container or a space in such a way that the fluid does not flow in or out of the container or space during the process. An example is the expansion of steam in a cylinder during the period when the valves are closed.

Steady-flow Processes are those in which the fluid passes continuously through a region under conditions of steady flow. The conditions for the ideal steady-flow process are:

(*a*) At entrance to the region or apparatus considered, all properties which fix the state of the fluid maintain fixed values, that is, they do not vary with respect to time. Velocity of the fluid at entrance does not vary.

(*b*) Likewise, at exit from the region, fluid properties and velocity do not vary. But note that the exit properties may be and usually are quite different from the entrance properties.

(*c*) The mass flow at exit must equal the mass flow at entrance.

(*d*) At points between entrance and exit, not only may properties change in value, but they may be quite variable and unsteady. It is only at entrance and exit that conditions must be steady.

The steady-flow process or a process which closely approximates steady flow exists in most of the devices and machines employed in engineering practice. Examples are the steam engine, turbine, condenser, pump, boiler, nozzle, valve, and most heat-exchange appliances.

Other common types of processes are defined as follows:

Constant-pressure Process, in which the pressure of the fluid is constant throughout the process.

Constant-volume Process, in which the volume of the fluid is constant throughout the process.

Isothermal Process, in which the temperature of the fluid is constant throughout the process.

Adiabatic Process, in which no heat is added to or removed from the fluid during the process. (Caution: Refer to definition of heat in the previous section.)

Isentropic or Constant-entropy Process, in which the entropy is constant throughout the process.

Each of the five preceding processes may, in general, be either flow or non-flow, reversible or irreversible.

4. ENERGY EQUATIONS

Principal Symbols of Arts. 4, 5 and 6

E = internal energy, Btu per pound.
H = enthalpy, Btu per pound = $E + PV/J$.
J = Joule's equivalent, 778 ft-lb per Btu.
M = mass, pounds (numerically, the same as weight).
P = absolute pressure, pounds per square foot.

PV = flow work (displacement energy), foot-pounds per pound.
Q = energy supplied to or departing from a system or region as heat, Btu per pound.
$d'Q$ = a small quantity of heat (the inexact differential of Q).
Q_R = the unavailable energy of a process, Btu per pound.
S = entropy per pound.
T = absolute temperature, degrees fahrenheit.
T_R = absolute temperature of a receiver into which the unavailable energy of a process is rejected.
t = ordinary temperature, degrees fahrenheit.
U = velocity, feet per second.
$\frac{U^2}{64.34}$ = mechanical kinetic energy of a fluid stream or jet, foot-pounds per pound ($64.34 = 2 \times 32.17$).
V = specific volume, cubic feet per pound.
W = a general symbol for work, including all the mechanical energies or effects, namely: flow work, shaft work, and mechanical kinetic and potential energies.
W_s = work supplied to or departing from a system by means of a shaft, or its equivalent, foot-pounds per pound of fluid.
Z = elevation, ft.
$(\oint)$ = symbol for the integral of a function or quantity which completes a cycle.

Subscript 1 designates entrance to a system, or start of a process.
Subscript 2 designates exit from a system, or end of a process.

The First Law of Thermodynamics is the *Principle of the Conservation of Energy.* A statement of this principle most useful in this work is: In any process the net amount of energy added to a system equals the net change in energy within the system. This principle is expressed in a general energy equation as follows:

$$W + JQ = J(E_2 - E_1) \tag{1}$$

in which W stands for work and all other forms of mechanical energy; Q stands for heat, and $(E_2 - E_1)$ represents the change in internal energy within the system.

Equation 1 as written is for work and heat both entering the system. If work or heat leaves the system during the process, use minus signs for W or Q, or transpose W or Q to the right-hand side of the equation.

For mechanically reversible processes

$$W = -\int P dV \tag{2}$$

The minus sign is required because W is taken as positive when work is added to the system, and for this condition dV is negative.

For all reversible processes,

$$Q = E_2 - E_1 + \int P dV/J \tag{3}$$

and in the differential form

$$d'Q = dE + P dV/J \tag{4}$$

Note that equations 2, 3, and 4 apply for reversible processes only, but 1 applies for irreversible processes also.

Application of the Conservation of Energy Principle to the Steady-flow Process is made by reference to a diagrammatical sketch (Fig. 1) representing any device through which *steady flow* exists.

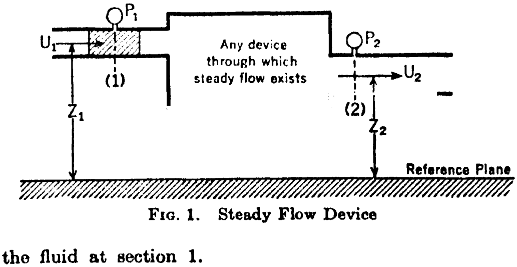

FIG. 1. Steady Flow Device

Energy may enter the system in the following forms and places.

(*a*) Mechanical potential energy (Z_1) entering with the fluid at section 1.

(*b*) Mechanical kinetic energy $\frac{U_1^2}{64.34}$ entering with the fluid at section 1.

(*c*) Internal energy (E_1) entering with the fluid at section 1.

(*d*) Work required to cause flow into the system against the pressure existing at the entrance section 1 in amount equal to the product of pressure and specific volume, viz., P_1V_1 foot-pounds per pound. This energy is termed flow work or displacement energy.

(*e*) Heat (Q) may be supplied to the system at any point between the entrance section 1 and the exit section 2, for example, as to the water in a boiler.

(*f*) Shaft work (W_s) may be added to the system at any point between the entrance and exit by means of a shaft, for example, as in a compressor.

Energy may leave the system in six forms analogous to those entering: potential energy, kinetic energy, internal energy, and flow work, at the point at which the fluid leaves the system, and heat or work delivered from the system at some point between the entrance and exit. The total amount of energy within the system remains constant.

The steady flow energy equation then becomes:

$$Z_1 + \frac{U_1^2}{64.34} + JE_1 + P_1V_1 + W_{\text{in}} + JQ_{\text{in}} = Z_2 + \frac{U_2^2}{64.34} + JE_2 + P_2V_2 + W_{\text{out}} + JQ_{\text{out}}$$

Enthalpy. The combination $JE + PV$ occurs here and in other places with such frequency that there has been established a universal custom of combining them into a single term. Since E, P, and V are each properties of the fluid, the sum $E + PV/J$ is a property which is designated by the symbol H, so that, by definition, $H = E + PV/J$. Modern usage gives to this property or function the name *enthalpy* (pronounced ĕn-thăl'py, with accent on the second syllable). Other names in wide usage are heat content and total heat.

The mechanical potential energy term Z is of importance in hydraulic applications, but is usually of negligible value in thermodynamics.

The simplified energy equation for the steady-flow process is:

$$\frac{U_1^2}{64.34} + JH_1 + W_s + JQ = \frac{U_2^2}{64.34} + JH_2 \tag{5}$$

where W_s and JQ are *net* values.

In *non-flow processes* energy may enter or leave the system as shaft work, W_s, or heat Q, and changes of energy within the system are limited to changes in internal energy, E. The non-flow energy equation is therefore similar to equation 1.

$$W_s + JQ = J(E_2 - E_1) \tag{6}$$

For reversible non-flow processes this becomes

$$JQ = J(E_2 - E_1) + \int PdV \tag{7}$$

5. ENTROPY AND THE AVAILABILITY OF ENERGY

The energy equations, though perfectly true, do not contain in themselves the means for evaluating them for all processes. For example, in a certain ideal (reversible) adiabatic process, the energy equation merely states that the work obtained from the process is equal to the change in the internal energy of the fluid, but no information whatever is given as to the amount of work which will be obtained or the magnitude of the change in the internal energy. The first law of thermodynamics is embodied in the energy equations. The second law of thermodynamics, as expressed in the entropy function, is required to make possible the computation of the maximum possible amount of work which may be obtained in certain ideal processes, particularly the reversible adiabatic process, and the reversible cycles upon which ideal heat engines operate.

In order to trace briefly how the entropy concept is developed from the second law of thermodynamics and the Carnot principle, a number of concepts and definitions must be stated.

A Cycle is a series of processes which may be repeated in a given order, the working fluid passing through various state changes and returning periodically to its initial state.

A Reversible Cycle is one made up of a number of reversible processes.

A Heat Power Cycle is a fluid cycle the object of which is to obtain work from heat. Regardless of the number of processes comprising the heat power cycle, three essential elements are always present, namely, (*a*) the reception of energy as heat from a high-temperature source, (*b*) the delivery of some of this energy as work, and (*c*) the rejection of the remainder of the energy as heat to a low-temperature receiver. The reception of energy may consist alternatively of a combustion process occurring with the working fluid, as in the internal-combustion engine.

The Cycle Efficiency is the ratio of the work delivered to the heat supplied.

Let Q = heat supplied from the source.
Q_R = heat rejected to the receiver.
W/J = work delivered by the cycle. Then for all cycles, reversible or irreversible,

$$Q = Q_R + W/J$$

(since in a cycle $\Delta E = 0$)

$$\text{Efficiency} = \frac{W/J}{Q} = \frac{Q - Q_R}{Q} = 1 - \frac{Q_R}{Q} \tag{8}$$

The Carnot Principle. In 1824 Sadi Carnot, in one of the most important contributions ever made to science, established the factors which affect the efficiency of cycles, and stated the necessary conditions for maximum efficiency. The full import of *the Carnot principle* may be given by stating it in the form of the three propositions which follow. These propositions are the embodiment of the *second law of thermodynamics.*

Proposition I. No cycle which continuously delivers work by the reception or conversion of energy at a high temperature (with rejection of any residue of energy at a lower temperature) can be more efficient than a reversible cycle operating between a source and receiver at these temperatures.

Proposition II. The efficiency of all reversible cycles working between the same temperatures is the same, irrespective of the differences in the character of the cycle or of the working fluid.

Proposition III. The efficiency of a reversible cycle depends only on the temperatures of the source and of the receiver.

Working with the third proposition of the Carnot principle, Kelvin established a thermodynamic temperature scale which made temperature a function of the amount of heat rejected and the amount of heat received in a reversible cycle. The Carnot principle states that Q_R/Q is a function of the temperature of the receiver and of the source. Kelvin made this temperature function as simple as possible by establishing the ratio of any two temperatures as being equal to the ratio of the amount of heat rejected and the amount of heat received by a reversible cycle operating between these temperatures.* By computing the efficiency of a particular reversible cycle (the Carnot cycle) which used a perfect gas as the working substance, and then using the perfect gas as a thermometer, numerical values of the thermodynamic temperature scale were obtained.

The Kelvin Temperature Scale is summarized in the following relation, which may be appropriately called the *Carnot–Kelvin relation*

$$\frac{T_R}{T} = \frac{Q_R}{Q}$$

where T_R = absolute temperature of a receiver.
T = absolute temperature of a source.
Q_R = heat rejected from the reversible cycle to a receiver at a constant temperature T_R.
Q = heat added to a reversible cycle from a source at a constant temperature T.

Since the efficiency of a cycle is $1 - \frac{Q_R}{Q}$, the efficiency of any *reversible* cycle operating between the constant temperatures of T and T_R is

$$1 - \frac{T_R}{T} \quad \text{or} \quad \frac{T - T_R}{T} \tag{9}$$

The Carnot Cycle. Carnot further described a particular reversible cycle of much theoretical interest. Contrary to impressions sometimes received, the Carnot cycle need not be operated with a perfect gas as a working fluid. Any fluid may be used, since the Carnot principle states that the efficiency of the reversible cycle depends only on the temperatures of the source and the receiver and not on the nature of the working fluid or on any other consideration. The *Carnot cycle* is described essentially and completely by describing four processes of which it is composed, as follows:

1. A reversible isothermal expansion in which heat in the amount Q is received from a source at a constant temperature T.
2. A reversible adiabatic expansion in which the fluid passes from the source temperature T to the receiver temperature T_R.
3. A reversible isothermal compression in which heat in amount Q_R is rejected to a receiver at a constant temperature T_R.
4. A reversible adiabatic compression in which the fluid is returned from the receiver temperature T_R to the source temperature T, and its original state.

During processes 1 and 2, work is delivered to an external system. During processes 3 and 4, work must be supplied from an external system.

For this cycle, as for all cycles, the net work output = $Q - Q_R$ and the efficiency is $\frac{Q - Q_R}{Q}$ or $1 - \frac{Q_R}{Q}$. Since, from the Kelvin temperature scale, $\frac{Q_R}{Q} = \frac{T_R}{T}$, the efficiency of the Carnot cycle becomes $1 - T_R/T$. This is also the efficiency of all reversible cycles operating between temperatures of source and receiver of T and T_R respectively.

Availability of Energy. The idea of availability of energy, like the idea of reversibility, is of essential importance in thermodynamics. The availability of energy refers to the maximum amount of energy of a given process that may be transformed into work. Energy which is in the mechanical stored forms, kinetic or potential mechanical energy, may, by a reversible process, be converted wholly into mechanical work. A part of the internal energy of a gas under pressure may be converted into work. By the process of combustion, the internal chemical energy of a fuel may be first converted into heat and then a portion of this heat converted into work by means of the heat power cycle. Any quantity of energy which is already in the form of mechanical energy or which may be converted into mechanical energy or work is called available energy. In all reversible processes there is no change in the availability of the energy evolved in the process. An irreversible process always decreases the available portion of energy involved and thus increases the unavailable portion. When available energy becomes unavailable through the agency of an irreversible process, the energy is said to be degraded.

The availability of the energy for a reversible process is determined by the efficiency of a reversible cycle (any reversible cycle, the Carnot cycle, for convenience) or more simply by the mere statement of the Kelvin temperature scale. If, in a process, a quantity of heat Q is supplied to a system at a temperature T, the amount of energy Q_R which cannot under any circumstances be converted into work, and which must therefore become unavailable, depends upon the realizable receiver temperature T_R and the temperature T at which Q is added. This statement is in accordance with the fundamental relation which has been referred to as the Carnot-Kelvin relation.

$$\frac{Q_R}{Q} = \frac{T_R}{T}; \quad \text{or} \quad \frac{Q_R}{T_R} = \frac{Q}{T}; \quad \text{or} \quad Q_R = T_R\frac{Q}{T}$$

If the temperature T of the source varies from T_1 to T_2 during the addition of the heat Q the expressions above must be given in the integral form

$$\frac{Q_R}{T_R} = \int_1^2 \frac{d'Q}{T} \quad \text{or} \quad Q_R = T_R\int_1^2 \frac{d'Q}{T} \tag{10}$$

It is only for reversible processes that the above expressions are true.

Recalling that the reversible process gives the maximum amount of available energy and therefore the minimum amount of unavailable energy, it follows that for an irreversible process the amount of unavailable energy which must be discarded will be greater than the amount of unavailable energy of the reversible cycle. The important conclusion follows that, for the *irreversible* process,

$$Q_R > T_R\int \frac{d'Q}{T} \quad \text{and} \quad \frac{Q_R}{T_R} > \int \frac{d'Q}{T} \tag{10a}$$

Entropy. The above expression is known as the *inequality of Clausius*. Because of its essential utility in evaluating the availability of energy of a *reversible process* as given in equation 10, the function $\int \frac{d'Q}{T}$ was given by Clausius the name *entropy*, applicable, however, only to reversible processes.

For $d'Q$ in the above entropy expression we may substitute its value from the general energy equation for reversible process, $d'Q = dE + PdV/J$, and obtain

$$S = \int \frac{dE + PdV/J}{T}$$

This function, S, may be shown to have a very important property, namely, that its value for any given process in which a fluid passes from state 1 to state 2 is also its value for every process by which the fluid may pass from state 1 to state 2. This property is described by saying that *entropy is a point function*, meaning that the change in its value for processes depends only on the end points of the process and not at all upon the particular path taken by the process between the end points. For various reversible processes between states 1 and 2, Q may have various values, but $\int_1^2 \frac{d'Q}{T}$ and $\int_1^2 \frac{dE + PdV/J}{T}$ may have but one value. Also, it may be shown that the ratio Q_R/T_R for all processes between two states will have a single value regardless of the nature of the process and whether reversible or irreversible. For this reason entropy is sometimes defined as Q_R/T_R. An alternate definition of entropy change, true, however, only for reversible processes, is:

$$S_2 - S_1 = \int_1^2 \frac{dE + PdV/J}{T} \tag{11}$$

If the process is reversible and the path is known, the entropy change may be computed directly from equation 11. If the process is irreversible the fluid is not in a state of equilibrium at any point. The path may not be stated functionally and may not be depicted graphically. We may, however, substitute for any irreversible process any reversible process or series of reversible processes passing between the same end points. The computed entropy change for the reversible processes thus substituted is the entropy change for the original irreversible process. But *note carefully* that for the irreversible process

$$S_2 - S_1 \neq \int_1^2 \frac{d'Q}{T} \tag{12}$$

The entropy change $(S_2 - S_1)$ for any process being known, the amount of available energy Q_a for the process may be determined thus:

$$\left.\begin{aligned} Q_R &= T_R\,(S_2 - S_1) \\ Q_a &= Q - Q_R \end{aligned}\right. \tag{13}$$

In a reversible adiabatic process, Q = zero, $S_2 - S_1 = \int_1^2 \frac{d'Q}{T} = 0$, Q_R = zero, and there is no change in availability. The principal use of entropy in engineering computations is to determine the final state in the reversible adiabatic for which $S_2 = S_1$.

Entropy as a Coordinate. Since entropy is a property or state function of a fluid it may be employed as a coordinate, in connection with various of the other properties, in the graphical representation of state changes. The more common diagrams in which entropy is so employed are: (*a*) the temperature-entropy (T, S) diagram in which absolute temperature is the ordinate and entropy per pound of fluid is the abscissa, and (*b*) the "Mollier" diagram (named after its inventor) in which enthalpy is the ordinate and entropy again the abscissa. The latter is of more particular convenience in connection with the portrayal of processes in which steady flow occurs.

The temperature-entropy diagram acquires a particular utility from the relationships between the properties T and S as they enter into the definition of the change of entropy of a fluid as follows:

For any process, reversible or irreversible,

$$Q_R/T_R = \Delta S, \quad \text{or} \quad Q_R = T_R\Delta S \tag{14}$$

For reversible processes,

$$\left.\begin{aligned} Q_R/T_R &= Q/T = \Delta S \\ Q &= T\Delta S \\ Q &= \int_a^b T dS \end{aligned}\right\} \tag{15}$$

To illustrate the use of these expressions in connection with the T, S diagram let the line ab in Fig. 2 be a graphic record of the simultaneous values of the absolute temperature and the entropy of a fluid during any assumed process and state change, and let the horizontal line mn be a contour line of constant temperature at absolute temperature T_R. From equation 14 the change in the unavailable energy chargeable to the fluid as a result of the process is represented by the cross-hatched area below the line mn (the area $mnb'a'm$) since that area is the product of T_R and ΔS. Furthermore, from equation 15, if the process were one without fluid friction or other internal irreversibility and were accomplished solely by the reception of energy by the fluid (as heat), then the area between the line ab and the S axis (the area $abb'a'a$) would represent the amount of heat received by the fluid during the process, since that area represents the summation of all infinitesimal products of T and dS between the limits of a and b, or equals $\int_a^b TdS$.

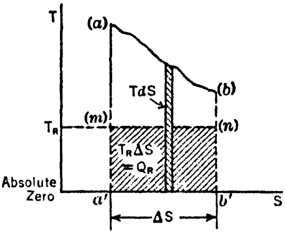

Fig. 2. T–S Relation in Process

A constant temperature (isothermal) state change is represented by a straight line parallel to the S axis. Also a reversible adiabatic, being a constant entropy or isentropic process, is a straight line parallel to the T axis. For a fluid undergoing the sequence of reversible processes of the Carnot cycle the state changes are represented by the sequence of lines forming the rectangular figure $abnma$ of Fig. 3. In that figure the area $a'abb'a'$ again represents and is a measure of the "heat" energy received by the fluid during the isothermal expansion at T, the area $a'mnb'a'$ measures the unavailable energy rejected during the isothermal compression at T_R and also, since the work output of the cycle is the difference between the energy supplied and that rejected, the area *mabnm* measures the available portion of the energy supplied. The thermal efficiency of the cycle is thus the ratio $\frac{mabnm}{a'abb'a'}$, which equals the ratio $\frac{T - T_R}{T}$. The advantageous effect of increased T and of decreased T_R is thus portrayed graphically.

For the irreversible adiabatic, due to the increase of unavailable energy (Q_R) which is inherent in any such process, the essential and invariable characteristic is an increase in the entropy of the fluid as a result of the process, this irrespective of whether the temperature may tend to decrease (as in an expansion) or to increase (as in a compression). Thus an irreversible adiabatic expansion from T to T_R starts at point *b* and ends at some point such as *o*, with increase of entropy, and a like irreversible adiabatic compression may start at *o* and end at some point *p* with an increase of entropy. The exact paths for irreversible processes cannot be shown graphically. For the expansion the increase of unavailable energy with respect to a receiver at T_R would be represented by the area *b'noo'b'*.

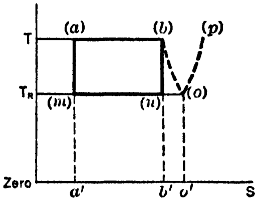

FIG. 3. Reversible and Irreversible Cycles

6. SUMMARY OF ENERGY EQUATIONS AND ENTROPY EXPRESSIONS

Table I. Distinctions to be Made between Reversible and Irreversible Processes

For All Reversible Processes		For All Irreversible Processes *	
$W + JQ = J(E_2 - E_1)$	(1)	Same as for reversible	
$W = -\int PdV$	(2)	$W < \int PdV$ *	
$Q = (E_2 - E_1) + \int PdV/J$	(3)	$Q < (E_2 - E_1) + \int PdV/J$	
$d'Q = dE + PdV/J$	(4)	$d'Q < dE + PdV/J$ *	
$dS = \frac{dE + PdV/J}{T}$	(11)	For an irreversible process, substitute any reversible process between the same end points, and compute entropy change from (11)	
$dS = \frac{d'Q}{T}$		$dS > \frac{d'Q}{T}$	
$S_2 - S_1 = \int_1^2 \frac{d'Q}{T}$	(12)	$S_2 - S_1 > \int_1^2 \frac{d'Q}{T}$	
$\frac{Q_R}{T_R} = \int \frac{d'Q}{T}$	(10)	$\frac{Q_R}{T_R} > \int \frac{d'Q}{T}$	(10*a*)
$S_2 - S_1 = Q_R/T_R$	(13)	Same as for reversible	
$Q_R = T_R (S_2 - S_1)$		Same as for reversible	
For Reversible Adiabatic		**For Irreversible Adiabatic**	
$Q = 0$		Same as for reversible	
$\int \frac{d'Q}{T} = 0$		Same as for reversible	
$S_2 - S_1 = 0$		$S_2 > S_1$	
$Q_R = 0$		$Q_R > 0$	
$\frac{Q_R}{T_R} = 0 = S_2 - S_1$		$\frac{Q_R}{T_R} = (S_2 - S_1) > 0$	
$dE = -PdV/J$		$dE \neq PdV/J$ *	
$W = J\int dE = -\int PdV$		$\int dE = W/J \neq \int PdV/J$ *	

---

* For irreversible processes, the path cannot be definitely stated. Such expressions as $\int PdV$ must be considered as pertaining to a substitute reversible path between the same end points.

Table I—*Continued*

For All Reversible Cycles		For All Irreversible Cycles
$(\int)\, dS = 0$		Same as for reversible
$(\Sigma)Q = (\Sigma)W/J$		Same as for reversible
$(\int)\, dE = 0$		Same as for reversible
$(\Sigma)\frac{Q_R}{T_R} = (\int)\frac{d'Q}{T} = 0$		$(\Sigma)\frac{Q_R}{T_R} > (\int)\frac{d'Q}{T}$
Efficiency $= \frac{Q - Q_R}{Q} = \frac{W}{JQ}$	(8)	Same as for reversible
Efficiency $1 - T_R/T$ (with constant source temperature)	(9)	Eff. $< (1 - T_R/T)$

Steady-flow Energy Equation for Reversible and Irreversible Processes

$$\frac{U_1^2}{64.34} + JH_1 + W_s + JQ = \frac{U_2^2}{64.34} + JH_2 \tag{5}$$

Adiabatic Flow through Orifices, Nozzles, etc.

Reversible	Irreversible
$\frac{U_2^2 - U_1^2}{64.34} = J(H_1 - H_2)_{S=C}$	$\frac{U_2^2 - U_1^2}{64.34} = J(H_1 - H_2)_{S_2>S_1}$
$= \int_1^2 VdP$	and $(H_1 - H_2) < (H_1 - H_2)_{S=C}$

Adiabatic Engines, Turbines, etc. (W_s = shaft work)

Reversible	Irreversible
$W_s = J(H_1 - H_2)_{S=C}$	$W_s = J(H_1 - H_2)_{S_2>S_1}$
$= \int_1^2 VdP$	and $(H_1 - H_2) \neq (H_1 - H_2)_{S=C}$

For All Adiabatic Flow Processes

Reversible	Irreversible
$J(H_1 - H_2)_{S=C} = \int_1^2 VdP$	$J(H_1 - H_2) \neq \int_1^2 VdP$

Throttling Flow (Irreversible)

$W_s = 0$; $Q = 0$; $\Delta \frac{V^2}{64.43} = 0$ $\quad$ $P_2 < P_1$

$H_1 = H_2$ and $S_2 > S_1$

Summary of Energy Equations for Non-Flow Processes

For all non-flow processes,

$$W_s + JQ = J(E_2 - E_1) \tag{6}$$

in which W_s = shaft work, or equivalent.

For all reversible non-flow processes,

$$JQ = J(E_2 - E_1) + \int PdV \tag{7}$$

For all reversible processes, $W_s = -\int PdV$

For irreversible processes, $W_s \neq \int PdV$.

For constant volume processes, $W_s = 0$ $\quad Q = E_2 - E_1$.

For constant pressure reversible processes, $W_s = P(V_1 - V_2)$, $\quad Q = (H_2 - H_1)$

For adiabatic reversible processes, $Q = 0$, $S_2 = S_1$;

$$W_s = J(E_2 - E_1)_{S=C} = -\int PdV.$$

7. GENERAL THERMODYNAMIC RELATIONS

Equations expressing general relations which exist between and among the various thermodynamic properties of any substance are called general thermodynamic relations. These equations are of value in calculating various properties of fluids from experimentally determined values of other properties. They are also of use in the development and application of the general theory of thermodynamics in the fields of physics and chemistry. The general thermodynamic relations are derived by the application of certain mathematical methods to the general energy equations presented in Art. 4 and 5.

The following symbols are used in this article. No units are attached to the quantity, and the Joule's equivalent J is not used, since it is desired to leave the equations in a general form, applicable in any consistent system of units.

c_P = specific heat at constant pressure.
c_V = specific heat at constant volume.
d = "differential of."
∂ = "partial differential of."
E = internal energy per unit mass.
$H = E + PV$, or enthalpy per unit mass.
l_P = latent heat of pressure change.
l_V = latent heat of expansion.
P = pressure, force per unit area.
$\Psi = E - TS$, or "psi" function, per unit mass.
Q = energy in transition by conduction or radiation, per unit mass.
R = the gas constant (1545/mol wt, in ft-lb-°F system, and 82.9×10^6/mol wt, in cm-gram-°C system).
S = entropy per unit mass.
T = absolute temperature.
V = volume per unit mass.
W = mechanical effects, per unit mass of fluid.
$Z = E + PV - TS$, or "zeta" function, per unit mass.

Inserting in the general energy equation,

$$W + Q = E_2 - E_1 \tag{1}$$

the expression

$$W = -\int P dV \tag{2}$$

and the entropy expression,

$$Q = \int T dS \tag{15}$$

there is obtained an equation which contains only property functions, and which is the basis for the derivation of the general thermodynamic relations. This basic equation is, for reversible processes,

$$-\int P dV + \int T dS = E_2 - E_1$$

or in differential form:

$$T dS - P dV = dE \tag{16}$$

In addition to the five properties or functions T, S, P, V, and E of the foregoing equations, there are defined three additional property functions as follows:

$H = E + PV$,	enthalpy
$\Psi = E - TS$,	psi function (after Gibbs)
$Z = E + PV - TS$,	zeta function (after Gibbs)

A very great number of relations may be written connecting these eight state functions.* In this work only a few are presented that have been found to be particularly useful in connection with the engineering aspects of thermodynamics. These formulas provide significant relations between the property functions of a fluid and are relations that must be true for any fluid whatever. Relations between partial derivatives of the state functions are:

---

* Bridgman in his Condensed Collection of Thermodynamic Formulas (Harvard University Press) presents an ingenious collection of tables by which any of the general thermodynamic relations may be readily obtained. He notes that, including relations involving W and Q, 11×10^6 relations between first derivatives are possible and 9.5×10^{21} between second derivatives.

$$\left(\frac{\partial T}{\partial V}\right)_S = -\left(\frac{\partial P}{\partial S}\right)_V \tag{17}$$

$$\left(\frac{\partial T}{\partial P}\right)_S = \left(\frac{\partial V}{\partial S}\right)_P \tag{18}$$

$$\left(\frac{\partial S}{\partial V}\right)_T = \left(\frac{\partial P}{\partial T}\right)_V \tag{19}$$

$$\left(\frac{\partial S}{\partial P}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_P \tag{20}$$

$$\left(\frac{\partial E}{\partial V}\right)_S = \left(\frac{\partial \Psi}{\partial V}\right)_T = -P \tag{21}$$

$$\left(\frac{\partial E}{\partial S}\right)_V = \left(\frac{\partial H}{\partial S}\right)_P = T \tag{22}$$

$$\left(\frac{\partial H}{\partial P}\right)_S = \left(\frac{\partial Z}{\partial P}\right)_T = V \tag{23}$$

$$\left(\frac{\partial \Psi}{\partial T}\right)_V = \left(\frac{\partial Z}{\partial T}\right)_P = -S \tag{24}$$

A very useful characteristic of a fluid is one which shows the energy required as heat to effect a unit change in the magnitude of the pressure, the temperature, or the specific volume of a unit mass of the fluid when one of these properties is maintained constant. Such a characteristic of the fluid is known as a *thermal capacity*. The familiar specific heat at constant pressure c_P is thus one of the several thermal capacities, being the amount of heat energy required to change the temperature of unit mass of the substance one degree while the pressure is maintained constant. Four thermal capacities are of particular practical utility. These, together with their names and conventional symbols, are:

$$\left(\frac{\partial' Q}{\partial T}\right)_P = c_P; \quad \text{specific heat at constant pressure} \tag{25}$$

$$\left(\frac{\partial' Q}{\partial T}\right)_V = c_V; \quad \text{specific heat at constant volume} \tag{26}$$

$$\left(\frac{\partial' Q}{\partial P}\right)_T = l_P; \quad \text{latent heat of pressure change} \tag{27}$$

$$\left(\frac{\partial' Q}{\partial V}\right)_T = l_V; \quad \text{latent heat of expansion} \tag{28}$$

The notation $d'Q$ and $\partial' Q$ which appears in these relations is a reminder of the important consideration that Q is not a point function. Relations among these coefficients and the other properties are as follows:

$$dS = \frac{c_P}{T}\,dT + \frac{l_P}{T}\,dP \tag{29}$$

$$dS = \frac{c_V}{T}\,dT + \frac{l_V}{T}\,dV \tag{30}$$

$$l_P = T\left(\frac{\partial S}{\partial P}\right)_T = -T\left(\frac{\partial V}{\partial T}\right)_P \tag{31}$$

$$l_V = T\left(\frac{\partial S}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V \tag{32}$$

$$c_P = -l_P\left(\frac{\partial P}{\partial T}\right)_S = T\left(\frac{\partial V}{\partial T}\right)_P\left(\frac{\partial P}{\partial T}\right)_S \tag{33}$$

$$c_V = -l_V\left(\frac{\partial V}{\partial T}\right)_S = -T\left(\frac{\partial P}{\partial T}\right)_V\left(\frac{\partial V}{\partial T}\right)_S \tag{34}$$

$$\begin{aligned} c_P - c_V &= l_V\frac{dV}{dT} - l_P\frac{dP}{dT} \\ &= l_V\left(\frac{\partial V}{\partial T}\right)_P \left[\text{or } = -l_P\left(\frac{\partial P}{\partial T}\right)_V\right] \\ &= T\left(\frac{\partial P}{\partial T}\right)_V\left(\frac{\partial V}{\partial T}\right)_P \qquad (35a) \end{aligned}$$

or

$$= -T\left(\frac{\partial P}{\partial T}\right)_V^2\left(\frac{\partial V}{\partial P}\right)_T \tag{35b}$$

or

$$= -T\left(\frac{\partial V}{\partial T}\right)_P^2\left(\frac{\partial P}{\partial V}\right)_T \tag{35c}$$

$$c_P/c_V = k = -\frac{\left(\frac{\partial V}{\partial T}\right)_P \left(\frac{\partial P}{\partial T}\right)_S}{\left(\frac{\partial P}{\partial T}\right)_V \left(\frac{\partial V}{\partial T}\right)_S} = -\left(\frac{\partial V}{\partial T}\right)_P \left(\frac{\partial T}{\partial P}\right)_V \left(\frac{\partial P}{\partial V}\right)_S$$

$$= \left(\frac{\partial V}{\partial P}\right)_T \left(\frac{\partial P}{\partial V}\right)_S \tag{36}$$

$$\left(\frac{\partial c_P}{\partial P}\right)_T = -T\left(\frac{\partial^2 V}{\partial T^2}\right)_P \tag{37}$$

$$\left(\frac{\partial c_V}{\partial V}\right)_T = T\left(\frac{\partial^2 P}{\partial T^2}\right)_V \tag{38}$$

The utility of equations 31 to 38, correlating as they do the thermal capacities and the property functions P, V, T, and S, is quite varied. They afford an opportunity for cross-checking the consistency of the more difficultly and generally less accurately measurable calorimetric data on thermal capacities by use of the more accurately determinable relations among the property functions of a fluid.

Equation 32, which is in effect the historical Clapeyron's equation, has the particular utility that it enables the computation of the latent heat of vaporization of a fluid solely from data on the change of volume during vaporization and the relation between the pressure and temperature of saturated vapor. Thus, interpreting the latent heat of expansion in terms of the heat supplied during vaporization at constant temperature,

$$l_V = \frac{Q_{\text{vaporization}}}{\Delta V_{\text{vaporization}}} = \frac{H_{fg}}{V_{fg}}$$

(see Art. 16), whence, from equation 32,

$$H_{fg} = V_{fg}\,T\left(\frac{dP}{dT}\right)$$

In this expression, since the ratio dP/dT for a saturated vapor is the same for any process whether at constant volume or otherwise, it is written as the total derivative instead of the partial derivative. Physically it is the rate of change of the saturation pressure with temperature (the slope of the P–V curve) at the temperature T.

Several useful expressions which correlate the internal energy and enthalpy with the thermal capacities and the property functions follow.

$$dE = c_V\,dT + \left[T\left(\frac{\partial P}{\partial T}\right)_V - P\right]dV \tag{39}$$

$$\left(\frac{\partial E}{\partial V}\right)_T = T\left(\frac{\partial P}{\partial T}\right)_V - P \tag{40}$$

$$\left(\frac{\partial E}{\partial T}\right)_V = c_V \tag{41}$$

$$dH = c_P\,dT + \left[-T\left(\frac{\partial V}{\partial T}\right)_P + V\right]dP \tag{42}$$

$$\left(\frac{\partial H}{\partial P}\right)_T = V - T\left(\frac{\partial V}{\partial T}\right)_P \tag{43}$$

$$\left(\frac{\partial H}{\partial T}\right)_P = c_P \tag{44}$$

The Joule–Thomson Experiment. A type of physical experiment which is of much value in assisting to ascertain and check the characteristics of a fluid is the *Joule–Thomson* experiment. In this experiment the fluid is caused to flow to, throttle through, and pass from a porous plug, without energy reception or departure as heat and without appreciable velocity or velocity change in any phase of the process. The pressures and temperatures are measured on each side of the plug.

The energy equation for this pure throttling and wholly irreversible process is $H_1 = H_2$. Alternatively, its characteristic is that $dH = 0$. Introducing this consideration in equation 42, the relation for the process becomes

$$c_P\,(\partial T)_H = \left[T\left(\frac{\partial V}{\partial T}\right)_P - V\right](\partial P)_H$$

or

$$\left(\frac{\partial T}{\partial P}\right)_H = \frac{1}{c_P}\left[T\left(\frac{\partial V}{\partial T}\right)_P - V\right] \tag{45}$$

The coefficient $(\partial T/\partial P)_H$ in this expression is called the *Joule–Thomson coefficient* (μ).

It is evidently to be interpreted as the change of temperature of the fluid per unit fall of pressure under the above irreversible adiabatic throttling conditions. It may be shown that for a perfect gas, which has the state equation $PV = RT$, there would be no temperature change. With most gases, excepting hydrogen, there is a temperature drop or *cooling effect* at normal temperature levels, but a temperature *rise* at temperature levels above the so-called *inversion temperature*. For most gases the inversion temperature is high but for hydrogen it is at about −80 deg cent.

This experiment is further useful for reducing the readings of a gas thermometer to the energy or thermodynamic scale of temperature and for determining the location of the absolute thermodynamic zero of temperature.

The cooling effect which is characteristic of the actual gases is used regeneratively for the liquefaction of gases by the *Linde* process.

GASES

Symbols and Notations

A = area, square feet.
a = a coefficient in specific heat formulations.
b = a coefficient in specific heat formulations.
c_p = specific heat at constant pressure, Btu per pound.
c_v = specific heat at constant volume, Btu per pound.
E = molecular (internal) energy, Btu per pound.
f = a coefficient in specific heat formulations; also "a function of."
H = enthalpy $(E + PV/J)$, Btu per pound.
J = Joule's equivalent (=778 ft-lb per Btu).
k = ratio of c_p/c_v (a variable, but approaching constancy).
M' = mass rate of flow, pounds per second.
m = molecular weight.
n = an exponential constant (as in the property relation PV^n = a constant).
P = absolute pressure, pounds per square foot.
Q = energy transferred by heat (radiation or conduction), Btu per pound.
R = the gas constant for any given gas.
S = entropy, per pound.
T = absolute temperature, degrees Rankine (=degrees fahrenheit + 460).
U = velocity, feet per second.
V = specific volume, cubic feet per pound.
W = shaft-work, foot-pounds per pound.

8. GAS LAWS

P-V-T Relation for the Perfect Gas. The relation between the pressure, specific volume, and temperature of a perfect gas in any given condition or state is given by the *characteristic equation for gases*, which is:

$$PV = RT \tag{1}$$

in which R is a constant for any gas, and is called the *gas constant*.

The above relation embodies Boyle's and Charles' laws.

Boyle's Law states that, when the temperature of a given mass of gas is held constant, the volume and pressure vary inversely, or PV = a constant.

Charles' Law states that, when the volume of a given mass of gas is held constant, the change in the pressure of the gas is proportional to the change in temperature, or $\frac{\Delta P}{\Delta T}$ = a constant.

Gas Constant. Actual gases at moderate pressure and also very low-pressure vapors approach this perfect gas criterion that R is a constant. However, for many practical purposes it may be sufficiently accurate to neglect this variation, and it is therefore customary to assign to the various gases values of R which correspond to some standard state. In Table I are presented, for the gases of more usual interest, the values of the gas constant as determined by physical measurement of the specific volume (V_0) at the standard atmospheric pressure (14.7 lb per sq in. abs) and 32 deg fahr. There are also tabulated the molecular weights of the fluids (m, referred to oxygen as 32), the product of the molecular weight and the gas constant (= mR), and the product mV_0. For a more complete table of the properties of gases see Section 1.

Table I. Characteristic Properties of Gases

Gas	V_0, at 14.7 lb and 32° F	R	m	mR	mV_0
Sulfur dioxide (SO_2)	5.47	23.6	64.0	1512	350
Carbon dioxide (CO_2)	8.10	34.9	44.0	1536	356
Oxygen (O_2)	11.2	48.3	32.0	1546	358
Atmospheric air	12.4	53.3	(29.0)	(1545)	(358)
Nitrogen (N_2) (atmos.)*	12.74	54.9	(28.1)	(1545)	(358)
Nitrogen (N_2) (chem.)	12.8	55.1	28.0	1543	358
Carbon monoxide (CO)	12.8	55.1	28.0	1545	358
Ammonia (NH_3)	20.8	89.5	17.0	1516	354
Helium (He)	89.7	386	4.0	1544	359
Hydrogen (H_2)	178	767	2.0	1546	358.5

Representative value of $mR = 1545$; of $mV_0 = 358$.

* By "atmospheric nitrogen" is meant the residue of atmospheric air after abstraction of the oxygen but retaining the argon, carbon dioxide, etc., which exist in traces in the atmosphere.

It is significant that in this table the values of mR and of mV_0 are found to show relative uniformity, particularly for the permanent gases of less than three atoms per molecule. For convenience it is customary to select as representative the values of 1545 and 358 for these respective quantities, designating them as the "universal gas constant" (mR) and the "standard mol volume" (mV_0).* It follows from this approximate constancy of the product mV_0 that the specific volumes of the permanent gases at a given temperature and pressure are inversely proportional to their molecular weights, or that the densities are directly proportional.†

9. SPECIFIC HEAT OF GASES

Specific Heat. When energy is delivered to or withdrawn from a substance *as heat* (by conduction or radiation) and during the process the temperature of the substance changes, the ratio of the quantity of heat interchange per unit mass of the substance to the change in temperature is called the *specific heat*, c, of the substance for the particular process. Symbolically,

$$c = \frac{Q}{\Delta t} \tag{2}$$

where c = specific heat of the substance for the process in question.

Q = energy interchange as heat during the process, per unit mass of substance, regarded as positive if incoming and negative if outgoing.

Δt = change of temperature of the substance, regarded as positive if increasing and negative if decreasing.

In the case of solids and liquids there is only one characteristic process which is of usual concern, namely, the heat interchange while the substance is at constant pressure. Therefore when the specific heat of such a substance is quoted it may be taken implicitly to be the specific heat *at constant pressure*. With gases, however, there is in practice an infinite variety of processes or state changes of the gas during which energy may be transferred as heat, frequently under circumstances where energy transition as work occurs simultaneously and affects correspondingly the temperature change. Thus the specific heat of a given gas may have an infinite range of values. For definiteness, however, there is commonly quoted for any particular gas its specific heat for a *constant volume* state change and that for a *constant pressure* state change, the two being designated respectively as the *specific heat at constant volume* (c_v) and the *specific heat at constant pressure* (c_p).

Not only is the specific heat of a substance dependent upon the type of process but also, for a given process, it may vary with other conditions, such as the instantaneous temperature at which the process is operating. In that case, to determine the specific heat *at* a particular temperature we must pass to differential changes of temperature, dt, in place of Δt and write

$$c = \frac{d'Q}{dt}\ddagger \tag{2a}$$

---

* Since a mass of m pounds of a fluid is commonly known as a "mol" the volume of m pounds is known as the "mol volume."

† This relationship is one of the bases for Avogadro's "law," which states that for all gases at a given pressure and temperature the number of molecules per unit volume is the same. If that were strictly true the densities of various gases would necessarily be proportional to their molecular weights and their specific volumes would be inversely proportional. The above relative uniformity of mV_0 is an approximate verification of the hypothesis.

‡ See p. 7-05 for meaning of symbol $d'Q$.

Transposing, $d'Q = cdt$, **and for a finite rise from temperature** t_1, **to temperature** t_2,

$$Q = \int_{t_1}^{t_2} cdt \tag{3}$$

This expression shows the use to which information concerning the specific heat is frequently put, namely, that of computing the amount of energy transferred *as heat* during the performance of a specified process. If the specific heat varies with the temperature (as it usually does) a functional relation between c and t must be known before the expression may be integrated. A functional relation which is frequently found to be suitable is of the form,

$$c = a + bt + ft^2$$

where a, b, and f are coefficients which are determined by experiment.

Specific Heat of Actual Gases. For the perfect gas, c_v and c_p must either be constants or functions only of the temperature. Whether they are constants or variables their difference must be constant ($c_p - c_v = R/J$).

In all the real gases these specific heats are found actually to vary rather materially with the temperature and to a slight degree with the pressure,* and also there is evidence that their difference is not exactly constant nor does it exactly equal R/J, where R is the gas constant as ascertained from specific volume data (Table II). However, a degree of accuracy which is sufficient for most practical purposes as well as a great gain in convenience is attained if these specific heats are regarded as effectively constant when the temperature range is moderate and as a function only of the temperature for greater ranges, and also if their differences may be regarded as virtually constant.

In Table II are presented, for certain gases of more usual engineering interest, expressions for the relations between the specific heat at constant volume (c_v) and the absolute temperature (T) and also corresponding values of the mean ($c_p - c_v$) ($=R/J$), and finally of the mean values of c_p and c_v and of the mean value of the ratio c_p/c_v ($=k$) for the temperature range between 32 and 400 deg fahr. Unless materially greater temperature ranges are involved, these mean values may be employed as generally representative figures. In the table two values are presented for certain of the gases, those designated by the bracketed a being ones proposed by Partington and Shilling† as the result of exhaustive analyses of all available data and those designated by the bracketed b being

Table II. Specific Heats of Gases

(At Standard Atmospheric Pressure)

According to (a) Partington and Shilling, (b) Goodenough and Felbeck.

Expressions for c_v at the Absolute Temperature T (deg R)	Mean Values, 32° to 400° F			
	$c_p - c_v$ ($=R/J$)	c_v	c_p	k
Carbon dioxide (CO_2)				
(a) $0.1260 + 0.0_457\ T - 0.0_872\ T^2$	.0457	0.162	0.208	1.28
(b) $0.1037 + 0.0_3115\ T - 0.0_7284\ T^2 + 0.0_{11}247\ T^3$	.0451	0.171	0.216	1.26
Oxygen (O_2)				
(a) $0.1539 + 0.0_530\ T + 0.0_830\ T^2$	.0622	0.156	0.218	1.40
(b) $0.1545 + 0.0_8375\ T^2$	.0621	0.156	0.218	1.40
Air				
(a) $0.1699 + 0.0_533\ T + 0.0_833\ T^2$	.0687	0.173	0.241	1.40
Nitrogen, atmospheric				
(a) $0.1751 + 0.0_545\ T + 0.0_834\ T^2$	.0708	0.177	0.248	1.40
Nitrogen (chem.) and carbon monoxide				
(a) $0.1760 + 0.0_534\ T + 0.0_834\ T^2$	.0711	0.178	0.249	1.40
(b) $0.1766 + 0.0_8428\ T^2$	.0710	0.179	0.250	1.40
Hydrogen (H_2)				
(a) $2.314 + 0.0_3193\ T$	.985	2.44	3.43	1.40
(b) $1.990 + 0.0_3331\ T$	.986	2.21	3.20	1.44

(Note that, for example, $0.0_53\ T$ is the symbol for $0.000003\ T$ or $0.3\ T \times 10^{-5}$.)

---

* For air at 140 deg fahr the specific heat has been shown to vary with the pressure according to the relation $c_p = 0.2414 - 0.0_42014\ P - 0.0_92478\ P^2 - 0.0_{12}3795\ P^3$. For ranges less than 1500 lb per sq in. the relation $c_p = 0.2414 - 0.0_42\ p$ is quite adequately accurate. See Ford, Compressor Theory and Practice.

† Partington and Shilling, The Specific Heat of Gases, Benn Ltd., London, 1924.

ones proposed by Goodenough and Felbeck * as the result of like analyses. The two are observed to check closely except for H_2 and CO_2. The differences in these at least reflect the difficulties in the way of accurate experimental determinations.

All of the relations are observed to be of the form

$$c = a + bT + fT^2 + \dots$$

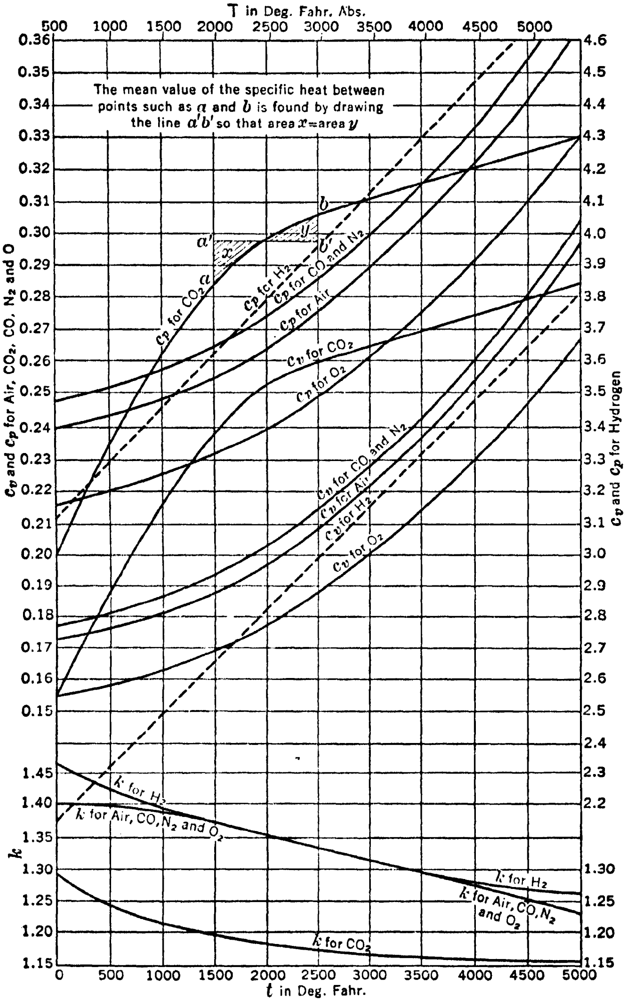

FIG. 1. Chart of c_p, c_v, and k for Several Gases†

where a, b, and f are numerical coefficients which are established from the experimental evidence.

Fig. 1 shows the values graphically of the specific heat at constant pressure (c_p), specific heat at constant volume (c_v), and their ratio ($k = c_p/c_v$) for air, CO_2, N_2, O_2, CO, and H_2 in the temperature range 0 deg fahr to 5000 deg fahr.

10. PROPERTY RELATIONS OF GASES

For vapors, such as steam, ammonia, etc., the relations which exist between the properties which must be known for the solution of engineering problems are given in tables of properties of the substances in question. For gases that adequately approach perfect gas characteristics, the relations between properties are given by means of quite simple mathematical equations. The properties and characteristic constants of gases which are of interest are P, V, T, E, H, S, c_v, c_p, k, and R. In addition to the relations between specific heats and temperatures given on p. 7–17 the following table gives the more useful relations which exist between and among the various properties of gases.

Table III. General Property Relations: Perfect Gas

$$\frac{PV}{T} = R, \text{ a constant for any given gas.} \tag{4}$$

$$\Delta E = \int_1^2 c_v\, dT, \text{ if } c_v \text{ is a function of } T, \text{ or}$$

$$= c_v\,(T_2 - T_1), \text{ if } c_v \text{ is effectively constant, or} \tag{5}$$

$$= \frac{1}{J\,(k-1)}\,(P_2\,V_2 - P_1\,V_1). \tag{5a}$$

$$\Delta H = \int_1^2 c_p\, dT, \text{ if } c_p \text{ is a function of } T, \text{ or}$$

$$= c_p\,(T_2 - T_1), \text{ if } c_p \text{ is effectively constant, or} \tag{6}$$

$$= \frac{k}{J\,(k-1)}\,(P_2\,V_2 - P_1\,V_1). \tag{6a}$$

$$\frac{c_p}{c_v} = k;\quad c_p - c_v = \frac{R}{J};\quad c_p = \frac{Rk}{J\,(k-1)} \tag{7}$$

$$\Delta S = \int_1^2 c_v \frac{dT}{T} + \frac{R}{J} \log_e \frac{V_2}{V_1}, \text{ if } c_v \text{ is a function of } T, \tag{8}$$

$$= c_v \log_e \frac{T_2}{T_1} + \frac{R}{J} \log_e \frac{V_2}{V_1}, \text{ if } c_v \text{ is constant;} \tag{8a}$$

$$= \int_1^2 c_p \frac{dT}{T} - \frac{R}{J} \log_e \frac{P_2}{P_1}, \text{ if } c_p \text{ is a function of } T, \tag{8b}$$

$$= c_p \log_e \frac{T_2}{T_1} - \frac{R}{J} \log_e \frac{P_2}{P_1}, \text{ if } c_p \text{ is constant;} \tag{8c}$$

$$= c_p \log_e \frac{V_2}{V_1} + c_v \log_e \frac{P_2}{P_1}, \text{ if } c_p \text{ and } c_v \text{ are constant.} \tag{8d}$$

11. ENERGY EQUATIONS FOR GASES

All the energy equations of Art. 4 apply to processes with all fluids, therefore to processes with perfect gases. The general method of solving processes with gases is to set up the energy equation in a form in which the energy transformation for the process is equated to a property change, such as the following.

For a non-flow reversible constant pressure process $Q = H_2 - H_1$. The property H must then be expressed in terms of some directly measurable properties such as P, V, and T, and a characteristic constant such as R or specific heat. In the above example,

$$H_2 - H_1 = \Delta H = c_p\,(T_2 - T_1) \quad \text{or} \quad = \frac{k}{J\,(k-1)}\,(V_2 - V_1)P$$

if c_p is taken as constant.

Table IV below gives a summary of the special property and energy relations required for the usual processes encountered with gases. Note that the term *mechanical effects* includes shaft work, flow work, and changes in mechanical kinetic or potential energy. Mechanical effects $= W_s + (P_1V_1 - P_2V_2) + \dfrac{U_1^2 - U_2^2}{64.34} + (Z_1 - Z_2)$. For non-flow s, mechanical effects consist only of shaft work.

Table IV. Special Property and Energy Relations for State Changes of Perfect Gas

Constant (specific) volume:

$$\frac{P}{T} = \frac{R}{V} = \text{a constant during the state change} \tag{9}$$

$$\Delta E = \int_1^2 c_v\,dT = \frac{1}{J(k-1)}(P_2 - P_1)V$$

$$\Delta H = \int_1^2 c_p\,dT = \frac{k}{J(k-1)}(P_2 - P_1)V$$

$$\Delta S = \int_1^2 c_v \frac{dT}{T}, \quad \text{or} \quad = c_v \log_e \frac{P_2}{P_1} \text{ if } c_v \text{ is constant}$$

Mechanical effects, if reversible = zero; $Q = \Delta E$.

Constant pressure:

$$\frac{V}{T} = \frac{R}{P} = \text{a constant during the state change} \tag{10}$$

$$\Delta E = \int_1^2 c_v\,dT = \frac{1}{J(k-1)}(V_2 - V_1)P$$

$$\Delta H = \int_1^2 c_p\,dT = \frac{k}{J(k-1)}(V_2 - V_1)P$$

$$\Delta S = \int_1^2 c_p \frac{dT}{T}, \quad \text{or} \quad = c_p \log_e \frac{V_2}{V_1} \text{ if } c_p \text{ is constant}$$

Mechanical effects, if reversible = $P(V_1 - V_2)$; $Q = \Delta H$.

Isothermal (constant temperature):

$$PV = RT = \text{a constant during the state change} \tag{11}$$

$$\Delta E = \text{zero}; \quad \Delta H = \text{zero}; \quad \Delta S = \frac{R}{J}\log_e \frac{P_1}{P_2} \quad \text{or} \quad = \frac{R}{J}\log_e \frac{V_2}{V_1}$$

Mechanical effects, if reversible $= -RT \log_e (P_1/P_2)$ or

$$-RT \log_e (V_2/V_1) \tag{12}$$

$$Q = \frac{RT}{J}\log_e \frac{P_1}{P_2} \quad \text{or} \quad \frac{RT}{J}\log_e \frac{V_2}{V_1} \tag{13}$$

Reversible adiabatic (isentropic):

PV^k = a constant during the change; TV^{k-1} = a constant;

$$\frac{T}{P^{(k-1)/k}} = \text{a constant} \tag{14, 15, 16}$$

$$\Delta E = \int_1^2 c_v\,dT \quad \text{or} \quad = \frac{R}{J(k-1)}T_1\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \text{ if } k \text{ is constant} \tag{17}$$

$$\Delta H = \int_1^2 c_p\,dT \quad \text{or} \quad = \frac{kR}{J(k-1)}T_1\left[\left(\frac{P_2}{P_1}\right)^{(k-1)/k} - 1\right] \text{ if } k \text{ is constant} \tag{18}$$

ΔS = zero; Q = zero; mechanical effects = $J\Delta E$.

Irreversible adiabatics may frequently be characterized approximately by the property relations:

$$PV^n = \text{a constant}; \quad TV^{n-1} = \text{a constant}; \quad \frac{T}{P^{(n-1)/n}} = \text{a constant} \tag{19, 20, 21}$$

$$\Delta E = \int_1^2 c_v\,dT \quad \text{or} \quad = \frac{R}{J(k-1)}T_1\left[\left(\frac{P_2}{P_1}\right)^{(n-1)/n} - 1\right] \tag{22}$$

$$\Delta H = \int_1^2 c_p\,dT \quad \text{or} \quad = \frac{kR}{J(k-1)}T_1\left[\left(\frac{P_2}{P_1}\right)^{(n-1)/n} - 1\right] \tag{23}$$

$$\Delta S = c_v \frac{n-k}{n}\log_e \frac{P_2}{P_1}, \quad \text{where} \begin{cases} n > k \text{ in a compression.} \\ n < k \text{ in an expansion.} \end{cases}$$

Mechanical effects = $J\Delta E$ but $\neq -\int_1^2 P\,dV$; Q = zero.

Table IV—*Continued*

Throttling process is primarily characterized by the relation:

$$H_2 = H_1 \qquad (24)$$

Polytropics, which virtually are internally reversible but are not adiabatic, may frequently be characterized by the property relations:

$$PV^n = \text{a constant}; \quad TV^{n-1} = \text{a constant}; \quad \frac{T}{P^{(n-1)/n}} = \text{a constant} \qquad (19, 20, 21)$$

$$\Delta E = \int_1^2 c_v\, dT = \frac{R}{J(k-1)} T_1 \left[\left(\frac{P_2}{P_1} \right)^{(n-1)/n} - 1 \right] \qquad (22)$$

$$\Delta H = \int_1^2 c_p\, dT = \frac{kR}{J(k-1)} T_1 \left[\left(\frac{P_2}{P_1} \right)^{(n-1)/n} - 1 \right] \qquad (23)$$

$$S = c_v \frac{n-k}{n} \log_e \frac{P_2}{P_1}, \quad \text{where} \quad \begin{cases} n < k \text{ in a compression with heat emission.} \\ n > k \text{ in an expansion with heat emission.} \end{cases}$$

$$\text{Mechanical effects} = \frac{R}{n-1} T_1 \left[\left(\frac{P_2}{P_1} \right)^{(n-1)/n} - 1 \right] \qquad (25)$$

$$Q = \frac{R}{J} \frac{(n-k)}{(k-1)(n-1)} T_1 \left[\left(\frac{P_2}{P_1} \right)^{(n-1)/n} - 1 \right] \qquad (26)$$

---

12. GRAPHICAL REPRESENTATION OF GAS STATE CHANGES

The property relations and state changes of gases may with advantage be portrayed graphically by curves drawn to coordinate axes of selected properties. The properties which are so employed with most frequency are the absolute pressure P as ordinate and specific volume V as abscissa. To these coordinates may be drawn contour lines of constant volume, constant pressure, or constant entropy (reversible adiabatic) state changes as well as any other sort of state changes. The typical forms of curves representing the commonly occuring state changes, as they would appear on P-V coordinates, are shown in Fig. 2. One evident feature of the family of curves is their increasing "steepness" with increase in the magnitude of n.

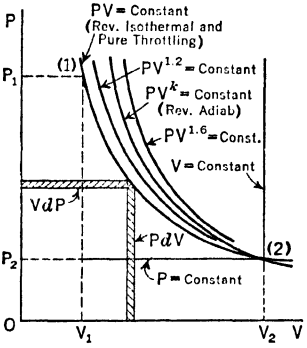

FIG. 2. P-V Curves for a Gas

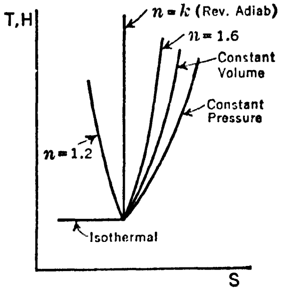

FIG. 3. T-S or H-S Curves for a Gas

Aside from the general utility of the P-V curves they offer the usual particular utility that $-\int_1^2 P\, dV$ is represented by the area below the state change curve and that this area is thus a graphic measure of the work in a mechanically reversible non-flow process, as well as the sum of all the *mechanical effects* in a mechanically reversible process, but *only* for a reversible one. In this connection note similarly that $\int_1^2 V\, dP$ is the area "back of" the state change curve and that, referring to the figure,

$$P_1 V_1 + \int_1^2 P\, dV - P_2 V_2 = -\int_1^2 V\, dP$$

However, for a reversible steady-flow process,

$$W + (U_1^2 - U_2^2)/64.34 + P_1V_1 - P_2V_2 = -\int_1^2 PdV$$

whence

$$W + (U_1^2 - U_2^2)/64.34 = -P_1V_1 - \int_1^2 PdV + P_2V_2 = \int_1^2 VdP$$

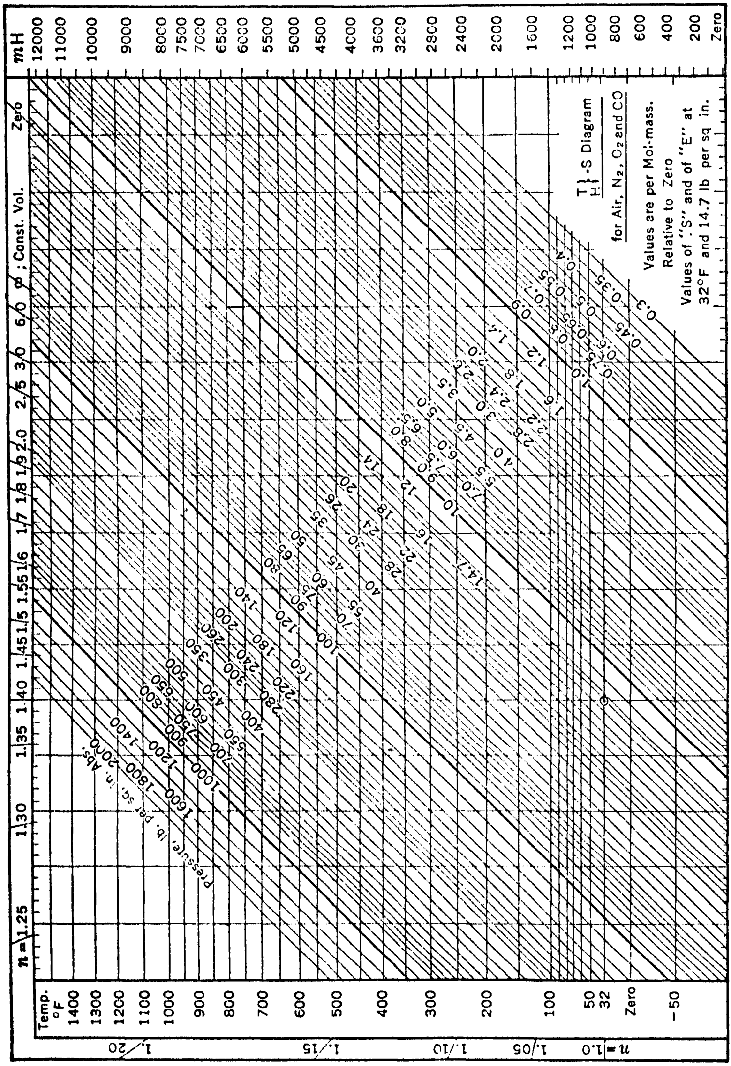

FIG. 4. *T–S* and *H–S* Diagrams for Diatomic Gases

This is to say that for a steady-flow reversible process the summation of the shaft work and the change of kinetic energy, or either individually if the other is negligible or not germane, is measured graphically by the area "back of" the state change curve.

Curves *T–S* and *H–S*, though not commonly provided for gases, may for some purposes be used to advantage, particularly with *T* and *H* plotted jointly against *S*, Fig. 3.

A T, H–S diagram for air, N_2, O_2, and CO appears in Fig. 4. For the plotting of the properties of these four diatomic gases, advantage is taken of the unique phenomenon that for all, the specific heat *per mol-mass* (per m pounds, where m is the molecular weight) is the same and therefore that their enthalpy and entropy per mol-mass are identical.* The relation for the specific heat per mol-mass, or the "molar" specific heat, of these gases, is

$$mc_v = 4.924 + 0.0_495\,T + 0.0_796\,T^2;\ m(c_p - c_v) = 1.99 \text{ (Partington and Shilling,)}$$

$$mc_v = 4.945 + 0.0_612\,T^2;\ m(c_p - c_v) = 1.98 \text{ (Goodenough and Felbeck,)}$$

The relation of Partington and Shilling has been used for the plotting of the curves, Fig. 4.

The values of mH and mS used in the figure are ones relative to a standard reference state at 32 deg fahr (492 deg R) and 14.7 lb per sq in. abs, at which state the entropy and the internal energy are regarded as zero. The values of T and mH have been plotted to logarithmic scales in order to make the pressure contours virtually straight lines (departing from those only by reason of specific heat variation with temperature). On this figure any polytropic or adiabatic state change conforming to the relation "PV^n = constant" would be representable by a straight line of the proper slope. The slope corresponding to various values of n may be found by passing a line through the reference state point, at 32 deg and 14.7 lb, and the proper one of the various indices appearing in left and upper margins. For a state change passing through any other state, pass a line of proper slope through the desired state point.

13. FLOW OF GASES THROUGH PIPES, NOZZLES, AND ORIFICES

Flow of Gases through Pipes or Ducts

For flow through pipes or ducts, if the energy transitions as heat and velocity changes are negligible, the energy equation becomes $H_1 = H_2$ ($dH = 0$). A further condition is actual increase of entropy in the amount of $-\frac{1}{J}\int \frac{V}{T}\,dP$ (if $dH = 0$), or of $\frac{R}{J}\log_e \frac{P_1}{P_2}$ for a perfect gas. The pressure *drop* that actually occurs in passage from (1) to (2) is thus an indicator of the entropy increase and corresponding energy degradation.

The usual practical concern in such flow is this pressure drop, and its relation to the features that influence it. Those features are (1) the general geometrical form and relative interior roughness of the flow-channel and (2) its length if a channel of extensive character, (3) the diameter and area of a circular channel, the equivalent diameter ($=\sqrt{\text{Area}/0.7854}$) and area of an extensive non-circular channel, or any size dimension of a non-extensive channel such as a valve or elbow, (4) the mass-rate of flow of the gas through the channel, and (5) the temperature, pressure, gas constant, and absolute viscosity of the gas.

For conditions of relatively small pressure drop along an extensive channel, or of greater pressure drop if the gas temperature remains effectively constant, an expression suitably relating these factors is

$$\frac{\Delta P}{L} = \frac{f'}{64.34}\,\frac{RT}{P}\,\frac{(M'/A)^2}{D}, \quad \text{or} \quad = \frac{f'}{40}\,\frac{RT}{P}\,\frac{(M')^2}{(D)^5} \tag{27}$$

where A = cross-sectional area of channel, square feet.
D = diameter of circular channel, feet, or equivalent diameter of non-circular channel ($=\sqrt{\text{area}/0.7854}$).
f' = "friction factor" (see below).
L = length of channel, feet.
M' = mass-rate of flow, pounds per second.
P = *mean* pressure in line, pounds per square foot, or pressure at any point if pressure drop is relatively small.
ΔP = pressure drop in length L, pounds per square foot.
R = gas constant, foot-pounds/(pounds × degrees Rankine).
T = mean absolute temperature of gas, degrees Rankine (=deg fahr + 460).

The value of the friction factor, f', depends on the interior form and relative surface roughness of the channel through which the flow occurs. For a given character of channel it bears further a relatively definite relation to certain criteria that serve indirectly as indices of the general character of the flow (that is, as regards whether turbulent or stream line in character and, if turbulent, the order of turbulence). The basic one of such criteria is the ratio

---

* This may be verified by reference to the expressions of Table II, multiplying the various coefficients in the expressions for air, N_2, O_2, and CO by the respective molecular weights.

$$\frac{DU}{\mu V}, \quad \text{or} \quad \frac{DUP}{\mu RT} \text{ for a gas}$$

where U = velocity, feet per second.
V = specific volume, cubic feet per pound.
μ = absolute viscosity of the fluid, pounds per foot-second (= absolute viscosity in poises $\times$ 0.0672).

This criterion will be recognized as the Reynolds' index (section 6, Art. 13).

For purposes of practical computation it is advantageous to recognize that $M' = AU/V = (\pi/4)D^2\, U/V$, whereby the above index may be modified to a more convenient form, $\frac{M'}{\mu D}\left(= \frac{\pi}{4} \times \text{Reynolds' index}\right)$. Further convenient criteria are combinations of f' and the above, namely, $\frac{\Delta P}{L}\,\frac{P}{RT}\,\frac{(M')^3}{(\mu)^5}$ and $\frac{\Delta P}{L}\,\frac{P}{RT}\,\frac{(D)^3}{(\mu)^2}$. $\left(\text{These are respectively } \frac{f'\,(RI)^5}{133} \text{ and } \frac{f'(RI)^2}{64.34}\right)$.

Table V gives reasonable values of f' as found by experiment for the flow through *circular* ducts of various relative interior-surface roughnesses at the various characters of flow indicated by the quoted values of the above criteria. For other than circular ducts equation 27 still applies, but further specific information would be required as regards the proper values of f' and of its relation to the Reynolds' index.

Table V. Turbulent Flow through Circular Channels

(Stream-line Flow Would Rarely be Encountered with Gas)

Criteria				Friction Factor, f'
Reynolds' Index $\frac{DU}{\mu V}$	"A" $\frac{M'}{\mu D}$	"B" $\frac{\Delta P}{L}\,\frac{P}{RT}\,\frac{M'^3}{\mu^5}$	"C" $\frac{\Delta P}{L}\,\frac{P}{RT}\,\frac{D^3}{\mu^2}$	
Interior Surface, Relatively Fairly Rough				
3×10^3	2.36×10^3	9.4×10^{13}	7.2×10^3	0.052
10^4	7.85×10^3	3.3×10^{16}	6.8×10^4	0.044
3×10^4	2.36×10^4	2.0×10^{18}	5.3×10^5	0.038
10^5	7.85×10^4	2.6×10^{21}	5.4×10^6	0.035
3×10^5	2.36×10^5	6.0×10^{23}	4.6×10^7	0.033
10^6 and up	7.85×10^5 and up	2.4×10^{26} and up	5.0×10^8 and up	0.032
Interior Surface, Relatively Quite Smooth				
3×10^3	2.36×10^3	9.1×10^{13}	7.0×10^3	0.050
10^4	7.85×10^3	2.6×10^{16}	5.4×10^4	0.035
3×10^4	2.36×10^4	5.3×10^{18}	4.0×10^5	0.029
10^5	7.85×10^4	1.7×10^{21}	3.6×10^6	0.023
3×10^5	2.36×10^5	3.7×10^{23}	2.8×10^7	0.020
10^6	7.85×10^5	1.3×10^{26}	2.7×10^8	0.017
3×10^6	2.36×10^6	2.7×10^{28}	2.1×10^9	0.015
10^7	7.85×10^6	1.0×10^{31}	2.0×10^{10}	0.013

Units for the items of the several criteria are as above.

In using the table to ascertain f' in equation 27:

(*a*) If M', μ and D are specified, plus all except f' and one other term of equation 27, as for example ΔP, use column "A."

(*b*) If P, R, T, μ, M', ΔP, and L are specified and the required diameter (D) is to be estimated, use column "B."

(*c*) If P, R, T, μ, ΔP, D, and L are specified and the attainable M' is to be estimated, use column "C."

For conditions of relatively small pressure drop through non-extensive channels and obstructions, such as pipe fittings or valves, an expression suitably relating the pressure drop and the controlling variables is

$$\Delta P = \frac{r'}{40}\,\frac{RT}{P}\,\frac{(M')^2}{(D)^4} \tag{28}$$

where all symbols and units are as in equation 27, excepting that D = any representative linear dimension of the obstructing device, such as the interior diameter of a pipe fitting; and r' = a "resistance factor" the magnitude of which depends on the geometrical form of the flow channel through the device, and also depends in principle on $M'/\mu D$ (the modified form of the Reynolds' index, Table V) but in practice is nearly constant *for a particular character of flow channel*, irrespective of the value of the criterion. For example, the value of r' for a short-radius, 90-deg circular elbow is about 1.0.

Flow through Orifices, Nozzles, etc., with Large Velocity Changes

For such flow, which is almost invariably adiabatic ($Q = 0$), the energy equation becomes

$$\frac{U_2^2 - U_1^2}{64.34} = J(H_1 - H_2)$$

with an ideal constancy of the entropy if ideal flow, without fluid friction or turbulence, were securable. Because of friction, there is always some entropy increase. A necessary adjunct in the usual analysis of such flow is the continuity equation

$$M' = A_1\,U_1/V_1 = A_2\,U_2/V_2$$

The usual objective in the analyses of orifice or nozzle flow is an estimate either of the velocity U_2 at any section of area A_2, or of the mass-rate of flow M'. As it is convenient to evolve such estimates by considering ideal and thus isentropic flow, it is advantageous to combine the energy and continuity equations to give the relations

$$U_{2,\,\text{ideal}} = 8.02\sqrt{\frac{J(H_1 - H_2)_S}{1 - (A_2/A_1)^2\,(V_1/V_2)_S^2}}$$

and

$$\frac{M'}{A_2}\,(\text{ideal}) = \frac{U_{2,\,\text{ideal}}}{V_{2,\,S}} = \frac{8.02}{V_{2,\,S}}\sqrt{\frac{J(H_1 - H_2)_S}{1 - (A_2/A_1)^2\,(V_1/V_2)_S^2}},$$

where the subscript S indicates the constancy of the entropy for ideal expansion.

For the flow of gases (and of supersaturated vapors, p. 7–49), introduction of their isentropic relations (p. 7–20) enables the transpositions of the above equations to more useful ones involving the initial temperature T_1, the initial and terminal pressures, P_1 and P_2, and pertinent characteristics of the gas. The resultant equations are

$$U_{2,\,\text{ideal}} = \frac{8.02\begin{Bmatrix}\sqrt{RT_1}\text{, or}\\ \sqrt{P_1V_1}\end{Bmatrix}\sqrt{\dfrac{k}{k-1}\left[1 - \left(\dfrac{P_2}{P_1}\right)^{(k-1)/k}\right]}}{\sqrt{1 - \left(\dfrac{A_2}{A_1}\right)^2\left(\dfrac{P_2}{P_1}\right)^{2/k}}} \tag{29}$$

$$\frac{M'}{A_2}\,(\text{ideal}) = \frac{8.02\begin{Bmatrix}P_1/\sqrt{RT_1}\text{,}\\ \text{or }\sqrt{P_1/V_1}\end{Bmatrix}\sqrt{\dfrac{k}{k-1}\left[\left(\dfrac{P_2}{P_1}\right)^{2/k} - \left(\dfrac{P_2}{P_1}\right)^{(k+1)/k}\right]}}{\sqrt{1 - \left(\dfrac{A_2}{A_1}\right)^2\left(\dfrac{P_2}{P_1}\right)^{2/k}}} \tag{30}$$

or

$$= \frac{8.02\begin{Bmatrix}P_2/\sqrt{RT_1}\text{, or}\\ P_2/\sqrt{P_1\,V_1}\end{Bmatrix}\sqrt{\dfrac{k}{k-1}\left(\dfrac{P_1}{P_2}\right)^{(k-1)/k}\left[\left(\dfrac{P_1}{P_2}\right)^{(k-1)/k} - 1\right]}}{\sqrt{1 - \left(\dfrac{A_2}{A_1}\right)^2\left(\dfrac{P_2}{P_1}\right)^{2/k}}} \tag{31}$$

For air at moderate temperature, with $R = 53.3$ and $k = 1.4$, these become

$$U_{2,\,\text{ideal}} = \frac{109.7\sqrt{T_1}\,\sqrt{1 - (P_2/P_1)^{0.286}}}{\sqrt{1 - (A_2/A_1)^2\,(P_2/P_1)^{1.429}}}$$

$$\frac{M'}{A_2}\,(\text{ideal}) = \frac{2.055\,(P_1/\sqrt{T_1})\,\sqrt{(P_2/P_1)^{1.429} - (P_2/P_1)^{1.714}}}{\sqrt{1 - (A_2/A_1)^2\,(P_2/P_1)^{1.429}}}$$

or

$$= \frac{2.055\,(P_2/\sqrt{T_1})\,\sqrt{(P_1/P_2)^{0.286}\,[(P_1/P_2)^{0.286} - 1]}}{\sqrt{1 - (A_2/A_1)^2\,(P_2/P_1)^{1.429}}}$$

In these equations the denominator originated in effecting an elimination of the term U_1 from the original energy equation. Consequently its reciprocal is frequently regarded and designated as a "correction factor for the initial velocity." It may evidently be omitted when U_1 is of relatively negligible magnitude, or in general when (A_2/A_1) is less than 0.10.

Table VI. Pertinent Functions of P_2, P_1, and k

$\frac{P_2}{P_1}$	$\left(\frac{P_2}{P_1}\right)^{2/k}$			$\sqrt{\frac{k}{k-1}\left[1-\left(\frac{P_2}{P_1}\right)^{(k-1)/k}\right]}$			$\sqrt{\frac{k}{k-1}\left[\left(\frac{P_2}{P_1}\right)^{2/k}-\left(\frac{P_2}{P_1}\right)^{(k+1)/k}\right]}$			$\sqrt{\frac{k}{k-1}\left(\frac{P_1}{P_2}\right)^{(k-1)/k}\left[\left(\frac{P_1}{P_2}\right)^{(k-1)/k}-1\right]}$

It is evident from equations 30 or 31 that, if facilities are to be provided for ideal or isentropic flow at a particular rate and with a given initial state, a definite relation exists between the transverse areas A_2 at successive sections in a flow channel and the pressure P_2 at those sections. Solution of the equations for A_2 at successive values of P_2 would further disclose that, again if facilities for isentropic flow are to be provided: the fluid stream (*a*) must first be convergent (that is, with decreasing area), until the pressure attains a certain proportion of the initial pressure, and (*b*) must thereafter diverge.

Except under rather abnormal conditions as regards U_1, at the consequent point of minimum area or the *throat* of the stream,

$$\left(\frac{P_2}{P_1}\right)_{\text{throat, ideal flow}} = \left(\frac{2}{k+1}\right)^{k/(k-1)}.$$

This particular ratio is conventionally known as the *critical pressure ratio*. By introduction of the ratio into equation 30 it develops that

$$\frac{M'}{A_{\text{throat}}}\,(\text{ideal}) = 8.02 \begin{Bmatrix} P_1/\sqrt{RT_1} \\ \text{or } \sqrt{P_1/V_1} \end{Bmatrix} \sqrt{\frac{k}{k+1}\left(\frac{2}{k+1}\right)^{2/(k-1)}} \tag{32}$$

$$= 0.53\ P_1/\sqrt{T_1} \text{ for air at moderate temperature.}$$

Values of various of the functions of P_2, P_1, and k that appear in the above equations are tabulated for convenience in Table VI for values of P_2/P_1 from 0.9 to 0.1 and at values of k of 1.3, 1.4, and 1.67, these being fair average values of k at moderate temperature for, respectively, triatomic, diatomic, and monatomic gases.

For values of P_2/P_1 between 1.0 and 0.9 (that is, for values of $\Delta P/P_1$ from zero to 0.1), accurate evaluation of these functions is bothersome. Convenient equivalents that give results accurate within 0.5 per cent are tabulated herewith.

Table VII. Equivalents of Pertinent Function, for $\Delta P/P_1$ from 0.0 to 0.10

Function	Equivalent when $\Delta P/P_1$ is not greater than—	
	0.10	0.01
$(P_2/P_1)^{2/k}$	$1-\frac{2}{k}\left(\frac{\Delta P}{P_1}\right)$	$\frac{P_2}{P_1}$
$\sqrt{\frac{k}{k-1}\left[1-\left(\frac{P_2}{P_1}\right)^{(k-1)/k}\right]}$	$\sqrt{\frac{\Delta P}{P_1}\left[1+\frac{0.5}{k}\frac{\Delta P}{P_1}\right]}$	$\sqrt{\frac{\Delta P}{P_1}}$
$\sqrt{\frac{k}{k-1}\left[\left(\frac{P_2}{P_1}\right)^{2/k}-\left(\frac{P_2}{P_1}\right)^{(k+1)/k}\right]}$	$\sqrt{\frac{\Delta P}{P_1}\left[1-\frac{1.5}{k}\frac{\Delta P}{P_1}\right]}$	$\sqrt{\frac{\Delta P}{P_1}}$
$\sqrt{\frac{k}{k-1}\left(\frac{P_1}{P_2}\right)^{(k-1)/k}\left[\left(\frac{P_1}{P_2}\right)^{(k-1)/k}-1\right]}$	$\sqrt{\frac{\Delta P}{P_2}\left[1-\frac{(1.5-k)}{k}\frac{\Delta P}{P_2}\right]}$	$\sqrt{\frac{\Delta P}{P_2}}$

Nozzles. Regarding the term *nozzle* as inclusive of any simple flow channel that aims to provide ideally suitable facilities for an isentropic expansion and acceleration of a flowing gas, the foregoing relations provide all that is necessary for estimates of the velocity or the mass-rate of flow ideally securable with specified P_1 and T_1 and upon expansion to pressure P_2 at a section of area A_2. Recall that, from above thermodynamic considerations, a convergent channel is adequate for an expansion to a region that is at any pressure greater than or equal to the critical pressure ($=0.528\ P_1$ for air or other diatomic gases, see Table VI), whereas convergence to a throat and a subsequent carefully controlled divergence are required to enable an approach to isentropic expansion to a region having a pressure less than the critical.

Actual flow conditions are conventionally accounted by employing *coefficients* of *velocity* and *discharge*, also a *nozzle efficiency*, where

Coefficient of velocity (C_U) $= U_{2,\ \text{actual}}/U_{2,\ \text{ideal}}$

Coefficient of discharge (C_D) $= M'_{\text{actual}}/M'_{\text{ideal}}$

Nozzle efficiency $= \dfrac{(U_2^2 - U_1^2{}_{\text{actual}}}{(U_2^2 - U_1^2)_{\text{ideal}}}$

$= \dfrac{U_2^2\,(\text{actual})}{U_2^2\,(\text{ideal})}$ if U_1 is negligible

Thus $U_{2,\,\text{actual}} = C_U \times U_{2,\,\text{ideal}}$; $M'_{,\,\text{actual}} = C_D \times M'_{,\,\text{ideal}}$

$$\frac{U_2^2}{64.34}\,(\text{actual}) = \text{Eff.}_{\text{nozzle}} \times \frac{U_2^2}{64.34}\,(\text{ideal}) \quad (\text{if } U_1 \text{ is negligible})$$

The discharge coefficient for the flow of a gas through well-formed convergent nozzles or through the convergent portion of convergent-divergent nozzles attains a value of 0.98 and over at conventional rates of flow, but so decreases at very low rates (sensible decrease beginning at a Reynolds' number of about 2×10^5) as in general to require calibration when nozzles are employed at such rates. The efficiency of advantageously formed convergent nozzles or of the convergent section of convergent-divergent nozzles attains values of 0.96 and over.

The inertia of the rapidly flowing fluid entering the divergent section of convergent-divergent nozzles does not permit so efficient an expansion in that section, reducing the efficiencies of such nozzles to 0.92 or less. Improper design or unsuitable operation, in the feature of an $\frac{\text{Exit area, } A_2}{\text{Throat area, } A_{th}}$ ratio greater than that suitably corresponding to the actual $\frac{\text{Discharge region pressure, } P_2}{\text{Throat pressure, } P_{\text{crit.}}}$ ratio (that is, *over-expansion*), or the reverse condition (*under-expansion*), will act to further and materially decrease the efficiency.

Orifices. The control or the metering of gases is frequently effected (without concern as to efficient jet formation) by directing flow through circular apertures located in plates or diaphragms. These apertures, or orifices, may be simply straight-sided holes through a thin plate (or its equivalent), or a converging profile may be provided on the upstream side of an orifice in a thicker plate. The orifice plates may be located at the entrance end or the exit end of a duct or as a constrictive passage in the run of a duct or pipe, the location being in general one of convenience or expediency. Provisions are necessary for measurement of at least the supply pressure (P_1) and temperature (T_1) and the pressure differential (ΔP) across the orifice.

Several unique characteristics pertain to orifice flow. One pertains more directly to a smoothly convergent orifice, and relates to the circumstance that by reason of its convergence such an orifice provides for and effects a full and efficient expansion within its confines from the initial pressure down to any pressure that exceeds or equals the critical pressure. By the same token, however, it will do no more, with the consequences that:

(*a*) If the pressure in the discharge region *exceeds* (or equals) the critical pressure the gas will have expanded *to the discharge-region pressure* when it has reached the orifice throat, so that the ideal mass-rate of flow is directly computable by equations 30 or 31 (see also Table VI and/or VII), with P_2 regarded as the discharge-region pressure and A_2 as the throat-area of the orifice. Rounded orifices may advantageously be employed that provide facilities for direct measurement of P_2 *at the throat.*

(*b*) If the pressure in the discharge region *is less than* the critical pressure the gas will have expanded at the orifice throat *only to the critical pressure*, so that the ideal mass-rate of flow is to be computed either by equations 30 or 31 (see also Table VI), with A_2 regarded as the throat area and P_2 as the critical pressure, or preferably it is directly computed by equation 32. The persistence of the critical pressure at the orifice throat, irrespective of the amount by which the discharge-region pressure may be less than the critical, is well substantiated by experiment. Subsequent expansion from the critical to the discharge-region pressure occurs after passing the throat, quite as in a convergent-divergent nozzle, but now in a highly turbulent and irreversible manner because of the absence of a suitably divergent guide channel. Flow through orifices to regions at a pressure less than the critical is frequently known as *unaffected* flow, as the flow rate is not affected by the discharge-region pressure.

With a thin-plate orifice somewhat parallel conditions exist. They differ, however, in the features that:

(*c*) Even in the absence of a convergent channel, the fluid will itself establish and issue as a convergent stream and will consequently have expanded efficiently to any pressure exceeding or equal to the critical pressure when it has reached the stream-section of minimum area, or the *vena contracta*; but

(*d*) The location and area of this *vena contracta* may be quite variable. Its location may range from a distance that is downstream from the orifice by perhaps the diameter of the orifice when the pressure differential (ΔP) is small and the flow rate low, to a location virtually in the plane of the orifice at maximum flow rates, thus making uncertain the suitable location at which to measure P_2. Its area may correspondingly range from some 60 per cent of the orifice area when the flow rate is low to effectively 100 per cent of the orifice area when the flow rate is maximum and the *vena contracta* is in the orifice plane.

Actual flow rates through orifices are estimated by multiplying the ideal rate, computed in the manner and by the equations indicated above, by a suitable coefficient of discharge. This coefficient may be as high as 0.99 for rounded-entrance orifices and also for thin-plate orifices at maximum flow rates, but for the latter orifices at lower rates it may be as low as about 0.6 if in the use of the equations the actual orifice area is used as A_2, rather than the (usually not measurable) stream area at the *vena contracta*. At quite low rates of flow ($\Delta P/P_1$ not much greater than 0.01) some degree of coordination of coefficients may be secured for geometrically similar orifices, if installed in geometrically similar environs and with geometrically similar locations of the pressure taps, by correlating the coefficient with the Reynolds' index.

When metering orifices are employed in circumstances where the velocity of approach of the stream to the orifice is not inherently negligible and a correction for initial velocity is necessary, that correction may be made by routine inclusion of the denominator of equations 30 or 31, or it may alternatively be made by measuring P_1 by means of a suitably placed impact tube in the upstream, when the denominator may be taken as unity.

Diffuser and Ejector. When a fluid is supplied at a lower pressure but higher and sufficient velocity the corresponding mechanical kinetic energy of the stream may be caused to effect its delivery against a higher pressure. The process is a decelerative compression that is the reverse of the accelerative expansion occurring in a nozzle; its energy relation is identical with that of a nozzle excepting as regards a reverse significance of subscript 1 as pertaining to a supply region now of *lower pressure and higher velocity* and of subscript 2 as pertaining to a discharge region of *lower velocity and higher pressure*. The required channel form is effectively the reverse of that of a nozzle, or is alternatively that of a nozzle through which the direction of flow is reversed, with need simply for a divergent (vs. convergent) channel if the $\dfrac{\text{Lower (supply) pressure}}{\text{Higher (discharge) pressure}}$ ratio exceeds the critical ratio of the fluid, and a convergent-divergent channel otherwise. Given the pressure, temperature, and velocity of the entering stream, the relation expressing the discharge pressure against which it might be caused to deliver if deceleration were continued to a negligible velocity is:

$$\left.\begin{aligned} P_{2,\,\text{ideal}} &= P_1\left[\frac{k-1}{kRT_1}\,\frac{U_1^2}{64.34}+1\right]^{k/(k-1)} \\ \text{and}\qquad P_{2,\,\text{actual}} &= P_1\left[\frac{k-1}{kRT_1}\,\frac{U_1^2}{64.34}+1\right]^{n/(n-1)} \end{aligned}\right\} \tag{33}$$

where n = the effective P–V exponent of the more or less irreversible adiabatic compression process, the value of which exponent will exceed the k of the gas in a degree that corresponds to the degree of turbulence and irreversibility associated with the flow.

The principle of diffuser action is employed in the after-section of the Venturi meter, in the impact and Pitot tube (see below), in the delivery sections of centrifugal blowers, and in ejectors. In this last a lower-pressure and high-velocity jet acts to entrain mechanically a second fluid, thereby to withdraw it from some region of like pressure and then to deliver the mixture by diffuser action to a region of higher pressure, with, however, the encountering of high turbulence and rather low efficiency.

Impact and Pitot Tube. These devices employ primarily a small tube the open end of which is squarely across the path of a flowing stream and the other end of which is extended to a point outside of the stream and is closed by some suitable pressure-measuring device. The action at the stream-end of the tube is a decelerating compression of the thread of fluid as it approaches among the (extended) axis of the open tube, essentially equivalent to that action as it occurs in a diffuser. The velocity of that stream thread is directly computable by equation 29 without denominator or its equivalent (Table VII), P_1 being the *impact* pressure measured as indicated above and P_2 the *static* pressure of the region in which the fluid is flowing as measured wholly without impact effect. The Pitot tube provides facilities for both measurements by a single instrument consisting of two concentric tubes, with impact pressure imposed on the open end of the center one and the static pressure transmitted to the interior of the outer tube by small flush openings in its walls. The value of T_1 is that taken with a thermometer which likewise is exposed to impact effect.

The impact or Pitot tube determines only a point velocity, whereas the mass or volumetric rate of flow in a stream depends on an average velocity. For ascertaining an average a conventional procedure is to take an arithmetical mean of a series of velocity determinations made at a number of points so located that the velocity at each individual one is reasonably representative of the mean velocity in one of the same number of equal subdivisions of the aggregate cross-sectional area of the stream. For a circular stream or duct a schedule that reasonably accomplishes this specifies locations taken at points along one or more diameters, and along each at radial distances on each side of the center line of the stream as follows:

$$r_1 = R\sqrt{1/n}, \quad r_2 = R\sqrt{3/n}, \quad r_3 = R\sqrt{5/n}, \quad r_{n/2} = R\sqrt{(n-1)/n}$$

where R = radius of stream, and n = total number of locations to be employed in traversing a diameter, with $n/2$ locations on each side of the center line. An alternative procedure permits tube locations at any desired points along a diameter and ascertains the mean velocity by finding the mean ordinate of a curve plotted with individual velocities as ordinates and with the square of the corresponding radial distances of the tube from the center line as abscissas, the curve extending to the square of the stream or duct radius.

14. COMPRESSION OF GASES IN COMPRESSORS

A compressor is actually or in effect a steady-flow device. From the steady-flow energy equation,

$$W_{\text{in}}\text{, ft-lb per lb of fluid} = \frac{U_2^2 - U_1^2}{64.34} + Jc_p\,(T_2 - T_1) + JQ_{\text{out}}$$

or

$$= \frac{U_2^2 - U_1^2}{64.34} + \frac{k}{k-1}\,(P_2 V_2 - P_1 V_1) + JQ_{\text{out}}$$

where the subscripts 1 and 2 refer to conditions respectively at the intake and the discharge regions of the compressor. Under most conditions of compressor operation any energy transition by conduction or radiation (as heat) is an outward one; therefore the term Q_{out} is introduced in these relations. Work energy is always put into the cycle, so the term W_{in} is also introduced.

Isothermal Compression. Using the characteristic equation of state of a gas, $PV = RT$, and considering the process as reversible isothermal,

$$W_{\text{in}}\text{, reversible isothermal compression, ft-lb per lb} = \frac{U_2^2 - U_1^2}{64.34} + RT_1 \log_e \frac{P_2}{P_1}$$

or

$$= \frac{U_2^2 - U_1^2}{64.34} + P_1 V_1 \log_e \frac{P_2}{P_1},$$

For cases where the kinetic energy term can be omitted the equations become,

$$W_{\text{in}}\text{, reversible isothermal compression, ft-lb per lb} = P_1 V_1 \log_e \frac{P_2}{P_1}$$

$$= RT_1 \log_e \frac{P_2}{P_1}$$

If $\dfrac{P_2 - P_1}{P_1}$ does not exceed 0.01,

$$W_{\text{in}}\text{ (ideal)} = \frac{U_2^2 - U_1^2}{64.34} + (P_2 - P_1)V_1$$

which is the usual equation for low-pressure fan performance.

The power requirement for isothermal compression is

$$\text{Hp input, reversible isothermal compression} = \frac{M'P_1 V_1 \log_e P_2/P_1}{550} = \frac{P_1 V'_1 \log_e P_2/P_1}{550}$$

or

$$= \frac{M'RT_1 \log_e P_2/P_1}{550}$$

When $\dfrac{P_2 - P_1}{P_1}$ does not exceed 0.01,

$$\text{Hp input} = \frac{M'[(P_2 - P_1)\,V_1 + (U_2^2 - U_1^2)/64.34]}{550}$$

In these relations,

M' = pounds of gas delivered per second.

$M'\,V_1 = V'_1$ = volume of gas, in cubic feet per second, at the state under which it exists in the region from which the compressor suction is taken.

Adiabatic Compression, Single Stage. The work required for single-stage adiabatic compression,

$$W_{\text{in}}\text{, reversible adiabatic compression, ft-lb per lb} = Jc_p\,T_1\,[(P_2/P_1)^{(k-1)/k} - 1]$$

or

$$= \frac{k}{k-1} P_1 V_1\,[(P_2/P_1)^{(k-1)/k} - 1]$$

The power required

$$\text{Hp input, reversible adiabatic compression} = \frac{M'Jc_p\, T_1[(P_2/P_1)^{(k-1)/k} - 1]}{550}$$

or

$$= \frac{\frac{k}{k-1} P_1 V'_1 [(P_2/P_1)^{(k-1)/k} - 1]}{550}$$

When $\frac{P_2 - P_1}{P_1}$ does not exceed 0.10,

$$W_{\text{in}}\text{, reversible adiabatic compression, ft-lb per lb} = RT_1 \frac{P_2 - P_1}{P_1}\left(1 - \frac{1}{2k}\frac{P_2 - P_1}{P_1}\right)$$

or

$$= V_1(P_2 - P_1)\left(1 - \frac{1}{2k}\frac{P_2 - P_1}{P_1}\right)$$

Also,

$$\text{Hp input, reversible adiabatic compression} = \frac{M'RT_1 \frac{P_2 - P_1}{P_1}\left(1 - \frac{1}{2k}\frac{P_2 - P_1}{P_1}\right)}{550}$$

or

$$= \frac{V'_1(P_2 - P_1)\left(1 - \frac{1}{2k}\frac{P_2 - P_1}{P_1}\right)}{550}$$

When $\frac{P_2 - P_1}{P_1}$ does not exceed 0.01, the last term in the expression $\left(1 - \frac{1}{2k}\frac{P_2 - P_1}{P_1}\right)$ becomes negligible.

Adiabatic Compression, Multistage with Complete Recooling between Stages.

$$W_{\text{in}}\text{, ideal two-stage isentropic compression} = 2\,Jc_p\, T_1\,[(P_2/P_1)^{(k-1)/2k} - 1]$$

or

$$= \frac{2k}{k-1} P_1\, V_1\,[(P_2/P_1)^{(k-1)/2k} - 1]$$

Where, with N stages of compression, the intermediate pressures follow the schedule:

$$P' = [(P_1)^{(N-1)}(P_2)]^{1/N}; \qquad P'' = [(P_1)^{(N-2)}(P_2)^2]^{1/N};$$

$$P''' = [(P_1)^{(N-3)}(P_2)^3]^{1/N};\ \ldots\ ;\ P^{N-1} = [(P_1)(P_2)^{(N-1)}]^{1/N}$$

the corresponding minimum work requirement for the entire compressor is

$$W_{\text{in}} = NJc_p\, T_1[(P_2/P_1)^{(k-1)/Nk} - 1]$$

or

$$= \frac{Nk}{k-1} P_1\, V_1\,[(P_2/P_1)^{(k-1)/Nk} - 1]$$

LIQUIDS AND VAPORS

Symbols

f = a subscript attached to any property of a saturated liquid.
g = a subscript attached to any property of a (dry) saturated vapor.
fg = a subscript employed to designate the change of any property between the saturated liquid and saturated vapor states, at constant pressure.
E = molecular (internal) energy, Btu per pound.
H = enthalpy $(E + PV/J)$, Btu per pound.
J = Joule's equivalent (=778 ft-lb per Btu).
p = pressure, pounds per square inch (absolute).
P = pressure, pounds per square foot (absolute).
Q = energy transferred as heat (by conduction or radiation), Btu per pound.
S = entropy, per pound.
t = temperature, degrees fahrenheit.
T = temperature, degrees Rankine (fahrenheit absolute).
U = velocity, feet per second.
V = specific volume, cubic feet per pound mass.
W = shaft work, foot-pounds per pound mass.
x = quality of a vapor-liquid mixture; also a subscript to any property to characterize it as that of a vapor-liquid mixture.

15. PHYSICAL CONDITIONS

A liquid and its vapor may exist in several conditions defined as follows:

(a) **Saturated Liquid.** If heat is added to a liquid which is maintained at a certain constant pressure, the liquid will not boil until a certain temperature is reached. This temperature is called the saturation temperature corresponding to the pressure on the liquid, and the liquid which is at the saturated temperature is called saturated liquid.

(b) **Compressed Liquid** is liquid at a temperature less than the saturation temperature corresponding to the pressure, or conversely it is liquid having an imposed pressure greater than the saturation pressure corresponding to the temperature of the liquid.

(c) **Saturated Vapor** is the dry vapor at the saturation temperature corresponding to the pressure. It is the vapor at the temperature and pressure of the saturated liquid from which it is formed. The saturated state represents an equilibrium condition between a liquid and its vapor.

(d) **Wet Vapor** is a physical mixture of saturated vapor and saturated liquid; the ratio between the mass of vapor and the mass of the mixture is known as the quality of the mixture, and is represented by the symbol x.

(e) **Superheated Vapor** is the state in which vapor is not in contact with the liquid and its temperature is above the saturated temperature corresponding to the pressure, the excess of temperature being known as the degrees of superheat.

16. PROPERTIES OF LIQUIDS AND VAPORS

The properties of liquids and vapors which are of use in engineering computations are pressure, temperature, specific volume, entropy, enthalpy, and internal energy. It becomes necessary to be able to obtain the numerical values of these properties for fluids in any of the conditions described above. For gases the relations among the several properties are given by relatively simple mathematical formulations known as characteristic equations, so that tables of properties are not required. For liquids and vapors, however, the characteristic equations are found to be entirely too complex in form for direct use in practical work. As a consequence it is the custom of the engineer to depend upon the physicist for the primary experimental determinations of the functional relations and to use for practical computations tabular statements of the properties of the liquids and vapors at a great variety of states.

Among the engineering fluids for which adequately complete and reliable tables of properties are available are steam and the refrigerants ammonia (NH_3) and carbon dioxide (CO_2); less complete tables exist for a number of other vapors. These tables are usually drawn up in sections which give separately the properties of saturated liquid and vapor and of superheated vapor, these generally being arranged variously with pressure or temperature or perhaps entropy as the major argument. An abridgment of the latest American tables of the properties of steam appears on pp. 7-33 to 7-39. The symbols are those which at this writing are accepted as standard and which are used throughout this section. It will be observed that the subscripts f and g are used to denote properties at the saturated liquid state and at the saturated vapor state respectively, and that the subscript fg denotes the change of a property between the same two states. The properties given in the columns of Table I are briefly described as follows:

Columns 1 and 2 state the saturation pressure of water and steam corresponding to the temperature. The published tables always present for convenience two tabulations identical in form except that one employs even units of the pressure as the major argument and the other even degrees of temperature. The pressures are invariably absolute pressures, in pounds per square inch, and not gage pressures. The temperatures are degrees Fahrenheit.

Columns 3, 4, and 5 give, respectively, the specific volume of saturated water, the increase of specific volume during evaporation, and the specific volume of (dry) saturated steam.

Column 6 records the enthalpy (formerly called total heat or heat content) of saturated water with respect to an arbitrarily assigned zero of enthalpy for saturated water at 32 deg fahr (and 0.0887 lb per sq in.). As the PV/J item in the enthalpy function, $E + PV/J$, is only 0.00026 Btu per lb for saturated water at 32 deg fahr, it follows that the placing of a zero enthalpy at that temperature is essentially equivalent to regarding the internal energy of water at 32 deg fahr as also relatively zero.

Column 7 records the increase of enthalpy during evaporation and thus in fact the energy supply per pound (normally supplied as heat) which is required to accomplish the evaporation.

* Reprinted from the Abridged Edition of Steam Tables and Mollier Diagram, by Professor J. H. Keenan, 1931, by permission of the publisher, The American Society of Mechanical Engineers.

Column 8 is the sum of the items in columns 6 and 7. It records the enthalpy of the vapor with respect to an arbitrarily assigned zero of enthalpy for saturated water at 32 deg fahr.

Column 9 gives the entropy of saturated water with reference to a zero of entropy for water at the customary reference temperature 32 deg fahr.

Column 10 gives the change of entropy during evaporation at constant pressure and temperature.

Column 11 is the total entropy of the saturated vapor and must equal the sum of the items of columns 9 and 10.

Properties of Superheated Vapor. Steam tables also provide extensive tabular data on the properties of superheated steam. In such tabulations, because a vapor which is not contiguous with its liquid may be superheated to any temperature above the saturation temperature corresponding to the pressure, the properties are given for a wide range of temperatures or of degrees of superheat at each pressure. An abridged edition of the superheated steam section of the Keenan table appears in Table II, pp. 7–36 to 7–39.

The properties listed are seen to be the specific volume, enthalpy, and entropy. For convenience there is repeated directly below the pressure item the corresponding saturation temperature; and in columns 3 and 4 are repeated the several properties for saturated water and saturated steam at the given pressure. The remaining columns give the properties at the temperatures which are noted at the head of the column.

Properties of Compressed Liquid and Wet Vapor. The tables described have provided means for the direct determination of all the necessary properties of saturated liquid, saturated vapor, and superheated vapor. The two additional conditions of fluids for which data are frequently required are those of compressed liquid and wet vapor. It will be found that the table for the saturated condition supplies the requisite primary data for determination of the properties at these latter conditions, but some computations are necessary. The following describes the procedures to be followed.

Compressed Liquid is defined as liquid at a temperature less than the saturation temperature corresponding to the pressure under which it may be placed. An equivalent but alternative and frequently useful definition is that of a liquid under an externally imposed pressure which exceeds the saturated vapor pressure corresponding to the temperature. Simple illustrative conditions would be that of water in an open stream under atmospheric pressure but at 70 deg fahr instead of at the saturation temperature of 212 deg fahr which corresponds to the pressure, or that of boiler feedwater at 328 deg fahr but under a pump pressure of 400 lb per sq in. instead of the saturation pressure of 100 lb per sq in. which corresponds to the temperature.

As regards the specific volume, internal energy, and entropy of compressed water, those items are predominantly dependent on and influenced by the temperature but are unquestionably influenced slightly by superpressure. Therefore, for accurate work, especially at high liquid processes, it becomes necessary to have data showing the effect of superpressure in the values of these properties. However, for most ordinary work the values of V, E, and S for compressed water are regarded as the same as those of saturated water at the specified temperature (not pressure) of the compressed water.

As regards the enthalpy of compressed water the situation differs, for the reason that the enthalpy property $(E + PV/J)$ contains directly the pressure property as an inherent component and so must be definitely influenced by any material superpressure. At a given temperature, it may be estimated from saturation data with good accuracy by adding to the value of the enthalpy of saturated water (H_f), as quoted in the saturated vapor table at the specified temperature (not pressure), the excess PV/J occasioned by the superpressure. More specifically,

$$H_{\text{compressed liquid at } t \text{ and } P} = H_{f,\text{ at } t} + (P - P_f)V_f/J \qquad (1)$$

In many practical instances in which P does not greatly exceed P_f the item $(P - P_f)V_f/J$ may be found to be relatively minor in magnitude and with adequate accuracy the enthalpy of the compressed liquid may be taken as that of saturated liquid at the temperature (not pressure) to which it is compressed.

Wet Vapor is a physical mixture of saturated vapor with droplets or fog of saturated but unvaporized liquid which is mechanically entrained with the vapor. The ratio of mass of vapor to the mass of the mixture of liquid and vapor is called the quality and is designated by the symbol x. For a wet vapor the temperature is the same as the saturation temperature corresponding to the pressure. The specific volume, enthalpy, and entropy may be computed as follows:

$$V_x = V_f + xV_{fg} \qquad (2)$$

$$H_x = H_f + xH_{fg} \qquad (3)$$

$$S_x = S_f + xS_{fg} \qquad (4)$$

17. GRAPHICAL REPRESENTATION OF VAPOR PROPERTIES

One may choose as coordinates any pair of properties of a fluid and depict graphically the manner of their joint variation as the fluid progresses through any characteristic sequence of states. Of the various diagrams which might be so devised those which have been found to be most generally useful are the P–V diagram, the T–S diagram and the H–S or Mollier diagram. These are described and discussed in the following paragraphs.

P–V Diagram. In the P–V diagram, as represented for a typical fluid in Fig. 1, the absolute pressure is employed as the ordinate and the specific volume as the abscissa. In the diagram the slightly oblique and curved line on the left which is labeled the *saturated liquid line* shows the manner of variation of the specific volume of saturated liquid as the pressure (and temperature) is progressively increased. The state of a compressed liquid at any given pressure (but a temperature less than saturation) would be represented by a point to the left of the saturated liquid line, this by reason of the lesser specific volume at the lesser temperature. Consequently the general region which lies to the left of the saturated liquid line is known as the *compressed liquid region.*

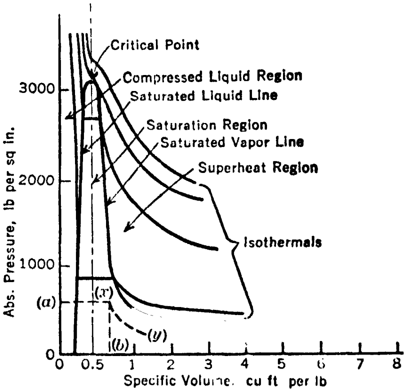

Fig. 1. P–V Diagram, Water and Water Vapor

The sloping line labeled the *saturated vapor line* similarly shows the relation between the pressure and specific volume of (dry) saturated vapor. The length of any horizontal line intercepted by the liquid and vapor lines thus represents the increase of specific volume during vaporization at constant pressure (V_{fg}). Therefore, since by the equation $V_x = V_f + xV_{fg}$, the state of a wet vapor mixture of quality x and at any given pressure would be represented by a point on that pressure line and lying at a distance xV_{fg} to the right of the liquid line. The region between the two saturation lines is known as the *saturation region.*

Since the superheating of a vapor at a given pressure effects an increase of the specific volume the state of a superheated vapor would be represented by a point to the right of the saturated vapor line, whence the region to the right of that line is known as the *superheat region.*

The saturated liquid and saturated vapor lines are observed to join at a *critical pressure,* which for water is at 3226 lb per sq in., and at which pressure the saturation temperature of water is 706.1 deg fahr. The saturation temperature at the critical pressure is similarly known as the *critical temperature.* The diagram indicates that a liquid under that pressure would on warming pass imperceptibly into a dense superheated vapor state without the appearance of the characteristic phase of vaporization at constant temperature.

The *isothermal lines* which appear in the figure are contour lines of constant temperature and indicate the specific volume of a fluid at any given temperature and pressure or, alternatively, the pressure corresponding to a given state as designated by the temperature and specific volume. Since the temperature is constant during vaporization at constant pressure the isothermals become straight horizontal lines within the saturation region. In the compressed liquid region the isothermals are very nearly vertical, showing the very slight change (decrease) of volume of a liquid as it is compressed at constant temperature. In the superheat region the isothermals are approximately hyperbolic curves, approaching that curve more exactly at very low pressures or considerable superheats.

For temperatures which are above the critical a vapor may not be condensed at any finite pressure. Some writers consider the critical temperature isothermal to provide an arbitrary line of demarcation between the *gas phase* (above the line) and the *vapor phase* (below the line) of a substance.

In addition to the isothermal lines one might draw contour lines of *constant quality, constant superheat, constant internal energy, constant enthalpy,* or *constant entropy,* which lines might be useful for various particular purposes. Also any sort of state change whatsoever may be represented by a suitable curve or line on the diagram.

In connection with the P–V diagram it should be remarked that the product PV corresponding to any state of a fluid is represented by the rectangular area bounded by the coordinates, by a constant pressure line through the state point, and by a constant volume line through the point, that is, by an area such as *oaxb* for state x. Also for any manner of state change as represented by the line xy, the $\int_x^y PdV$ is represented by the area between the line and the V-axis (that is, by the area *below* the line), and the $\int_x^y VdP$ is represented by the area between the line and the P-axis (the area *back of* the line).

T–S Diagram. In the T–S diagram (Fig. 2) *absolute* temperature is the ordinate, and entropy per pound mass (relative to liquid at 32 deg fahr) is the abscissa. The saturated liquid line, the critical point, and the saturated vapor line have the same significance as in the P–V diagram.

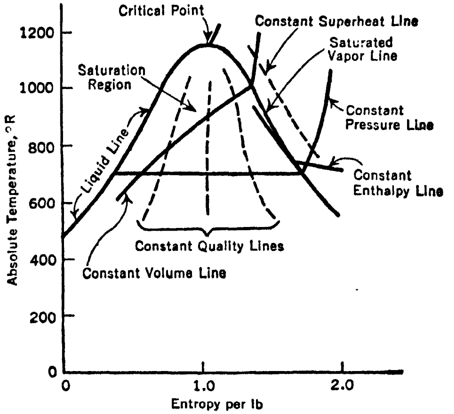

FIG. 2. T–S Diagram, Water and Water Vapor

Except at quite high pressures, constant pressure contour lines nearly coincide with the saturated liquid line up to the saturation temperature corresponding to a particular pressure, from which point that pressure line proceeds across the saturation region at the saturation temperature of vaporization. The compressed liquid region is a thin band along the saturated liquid line.

At any temperature (or pressure) the horizontal intercept between the liquid and saturated vapor lines measures the increase of entropy S_{fg} during vaporization, and, since for a wet vapor mixture $S_x = S_f + xS_{fg}$, the state of a wet vapor of quality x is represented by a point on the pressure line at a distance xS_{fg} to the right of the liquid line. Contour lines of constant quality will appear as in the diagram.

Typical contour lines of constant specific volume, constant enthalpy, and constant superheat also appear in the diagram.

The principal utility of the T–S diagram will be recalled to arise from the facts that for any process

$$Q_R = T_R \, \Delta S$$

and for any reversible process

$$Q = \int TdS$$

Thus for any state change of a fluid, as plotted on T–S coordinates, the change of the unavailable energy (Q_R) with reference to a receiver temperature T_R and chargeable to a pound mass of the fluid is represented by the area bounded by the S-axis below, by the T_R line above, and on the sides by the initial and final entropy lines. Likewise the heat energy reception or departure which accompanies a *reversible* state change is represented by the area between the state change curve and the S-axis (*below* the curve). A reversible adiabatic process is an isentropic (constant entropy) one and is represented by a straight vertical line.

H–S (" Mollier ") Diagram. The coordinates of the Mollier diagram are the enthalpy and entropy of the fluid, each per pound mass and each with reference to zero relative values of those properties for a liquid at 32 deg fahr. By reason of the intimate utility of the enthalpy property for all circumstances in which steady-flow processes occur, a portion of the diagram is invariably incorporated with the formal tables of vapor properties.

Referring to Fig. 3, the saturated liquid line, the critical point, and the saturated vapor line have the same significance as in the P–V and T–S diagrams. The compressed liquid region is practically restricted to a rather narrow band immediately above the saturated liquid line.

Constant pressure lines in this compressed liquid band approach the saturated liquid line as the excess of their pressure over the saturation pressure approaches zero. Within the saturation region the constant pressure lines are straight lines and are also constant temperature contours. The vertical distance between the intersections of a constant pressure line with the saturated liquid and saturated vapor lines measures the increase of enthalpy during vaporization, and the horizontal distance measures the entropy of vaporization.

On entering the superheat region the constant pressure lines veer upward, and the constant temperature contours approach constant H lines with increase of superheat.

Contour lines of constant quality and of constant superheat are also drawn in Fig. 3, and other contour lines might be shown. However, the two noted are usually the ones which appear. It may be remarked that the common Mollier chart, as used for many practical purposes, shows to larger scale only a small region around the saturated vapor line, such as that enclosed by dotted lines in the upper portion of Fig. 3.

18. STATE CHANGES AND PROCESSES

In the consideration of the various actual processes which are encountered in engineering thermodynamics certain classes of state changes of fluids occur with marked frequency. Several of these will be examined in detail.

For the analysis of any process it is the first requisite that the initial state of the fluid be adequately specified. For the fluids and the states which are encountered in engineering thermodynamics information concerning any two properties is, in general, sufficient for designation of the state. In practice it is commonly found that one or more of the specified properties will be those which we are best equipped to measure readily, that is, the pressure or temperature or perhaps the specific volume.

A second requisite is the specification of the character of the state change. In this connection it will be found that many of the actual processes are characterized by the actual or effective constancy of some property of the fluid during the state change. To illustrate, a state change taking place in a fluid which is retained within a closed and non-extensible vessel is one in which the specific volume remains constant or is a constant volume process; one taking place during the passage of a fluid through a device such as a boiler or superheater may closely approach constant pressure conditions and be taken as effectively such; the ideal state change taking place during the expansion of a fluid in an engine or turbine is the reversible adiabatic, which is characterized by a constant entropy of the fluid.

As a third feature it will be observed that, as the result of such constancy of one property of the fluid during a change of its state and thus a change of its other properties, this particular property is known at the cessation of the process. Therefore, to designate the final state of the fluid and thus to complete the description of the process, it will in general be necessary to specify the magnitude of one additional property at the final state. With sufficient information thus available for fixing that state, all the other properties may then be determined.

A fourth feature of most process analyses is the desirability or necessity for determining the energy transformations and transitions accompanying the processes.

The following representative processes with steam vapor will be analyzed: (*a*) constant volume process, (*b*) constant pressure process, (*c*) reversible adiabatic process, and (*d*) throttling process. Each analysis is illustrated and to a large extent developed by the use of an example.

Constant Volume Process. The simplest circumstance under which a constant volume process may take place is that in which a fluid is retained within a closed container while the state change is effected through the transition of energy to or from the system as heat conducted through the walls of the container from or to the surrounding region.

Example. A tank of 20 cu ft capacity contains steam at 200 lb per sq in. abs and 500 deg fahr. The tank and contents are cooled to a temperature of 326 deg fahr. What will be the final pressure and quality of the steam, how much energy was emitted by the steam in cooling, and what was the change of enthalpy of the steam? At what pressure and temperature did the steam become (dry) saturated?

Solution. Saturated steam at 200 lb abs has a temperature of 382 deg fahr, whence at state (1) the steam had a superheat of 118 deg fahr. From Superheated Steam Tables, at 200 lb and 500 deg fahr, $V_1 = 2.72$ cu ft per lb, whence the mass of steam in the tank was

$$M = 20/2.72 = 7.35 \text{ lb}$$

After cooling to 326 deg fahr at constant volume *the specific volume V_2 must be the same.* From the Saturated Steam Tables the specific volume of (dry) saturated steam at 326 deg fahr is 4.534 cu ft per lb, whence a portion of the steam must have condensed and the fluid in the tank become a mixture of saturated liquid and saturated vapor (wet steam). The pressure of this saturated mixture at 326 deg fahr must be 97.5 lb per sq in. abs (from Saturated Steam Tables).

To find the quality x_2

$$x_2 = \frac{V - V_{f,2}}{V_{fg,2}} = \frac{2.72 - 0.0177}{4.517} = 0.60$$

The energy emitted as heat in cooling must have come wholly from the internal energy of the steam since no energy emission as shaft work, flow work, or kinetic energy was possible. Therefore, for each pound of fluid,

$$\begin{aligned}
Q_{\text{out}} &= E_1 - E_2 \\
&= [H_1 - P_1 V_1/J] - [(H_{f,2} + x_2 H_{fg,2}) - P_2 V_{x,2}/J] \\
&= \left[1267.9 - \frac{200 \times 2.72}{5.4}\right] \\
&\quad - \left[(296.4 + 0.60 \times 889.7) - \frac{97.5 \times 2.72}{5.4}\right] \\
&= 1167.0 - 780.1 = 386.9 \text{ Btu per lb.}
\end{aligned}$$

Total energy emitted, as heat, $= 7.35 \times 386.9 = 2844$ Btu.

$$\begin{aligned}
\text{Change of enthalpy} &= H_2 - H_1 \\
&= (H_{f,2} + x_2 H_{fg,2}) - H_1 \\
&= 829.3 - 1267.9 = -438.6 \text{ Btu per lb.}
\end{aligned}$$

To find the pressure and temperature at which the steam became (dry) saturated it is necessary to search the Saturated Steam Tables for the state at which $V_g = 2.72$. This is found at a pressure of 166.7 lb per sq in. abs and a temperature of 366.8 deg fahr.

Note that in this non-flow, constant volume circumstance only the change of internal energy $(E_2 - E_1)$ measures or denotes an energy quantity, the change of PV becoming simply a change in that product of properties, *without an energy significance.*

Constant Pressure Process. A constant pressure process may readily be conceived to occur (*a*) without flow, as in a cylinder with piston, or (*b*) with steady flow, as in any vessel such as a steadily steaming boiler, a steadily operating condenser, etc., the state change being effected in either case by energy transition to or from the fluid, this usually as heat.

Example. A pound of water *in a cylinder (with piston)* is initially at 200 deg fahr and 235.3 lb per sq in. gage, and by energy reception as heat is transformed to steam of 98 per cent quality at the same pressure, the constancy of pressure being attained by permitting the piston to retreat as the fluid expands.

Compute the amount of energy required to effect the process and also that portion of this energy which is stored internally in the fluid.

Solution.

$$\begin{aligned}
JQ &= J(E_2 - E_1) - W \\
&= J(E_2 - E_1) + W_{\text{out}}
\end{aligned}$$

In this device the work output at the piston face equals $\int_1^2 P\,dV = P(V_2 - V_1)$, since the pressure P is constant. Therefore

$$\begin{aligned}
Q_{\text{in}} &= (E_2 - E_1) + P(V_2 - V_1)/J \\
&= (E_2 + PV_2/J) - (E_1 + PV_1/J) \\
&= H_2 - H_1, \text{ for a non-flow constant-pressure process.}
\end{aligned}$$

For the specific data of the problem:

$$H_1 = 167.9 + \frac{(250 - 11.5) \times 144 \times 0.0166}{778}$$
$$= 168.7 \text{ (exactly)} = 168.0 \text{ (approx.)}$$
$$H_2 = 376.0 + 0.98 \times 824.5 = 1184.0$$
$$Q = \Delta H = 1184.0 - 168.7 = 1015.3 \text{ Btu per lb}$$
$$E_1 = 167.9 - \frac{11.5 \times 144 \times 0.0166}{778} = 167.9$$
$$E_2 = 1184.0 - \frac{250 \times 0.98 \times 1.841}{5.4} = 1100.5$$
$$\Delta E = 1100.5 - 167.9 = 932.6 \text{ Btu per lb}$$

The difference between the energy supplied (ΔH) and that stored as molecular energy in the steam (ΔE) is transferred directly via the fluid to the piston face and is there delivered as work [$P(V_2 - V_1)$, = 1015.3 − 932.6 = 82.7].

The foregoing example has had to do with a non-flow constant pressure process. For the circumstance of steady flow at constant pressure through a device such as a boiler, since there is no shaft work,

$$Q_{\text{in}} = (H_2 - H_1) + (U_2^2 - U_1^2)/64.34\,J$$

As the change of kinetic energy in the usual device of this character would very rarely indeed exceed 1 Btu per lb and would usually be much less, this in comparison with a change of enthalpy which commonly would be some thousand Btu in magnitude, the kinetic energy term becomes effectively negligible and may be omitted. Thus for both a non-flow and a steady-flow constant pressure process the energy received by the fluid is measured by its change of enthalpy.

Reversible Adiabatic Process. Recalling that, by definition, *any process whatsoever in which no energy enters or departs from the system as heat is designated as an adiabatic process*, we may immediately write the following general energy equations for an adiabatic non-flow and an adiabatic steady-flow process:

$W = J(E_2 - E_1)$, for a non-flow adiabatic process

$W + (U_1^2 - U_2^2)/64.34 = J(H_2 - H_1)$, for a steady-flow adiabatic process

These equations are universally applicable whether the adiabatic process may be ideal and reversible or actual and thus irreversible. For the further condition of a *reversible* adiabatic process there is introduced the additional feature that the entropy remains constant during the process, or the process is isentropic. It may well be remarked that the outstanding practical utility of the entropy property lies in this very feature of its constancy during a reversible adiabatic process. To denote such constancy we employ the letter S as a subscript attached to any change of properties of a fluid during an isentropic process. Thus, rewriting the above equations but now in the special form which is applicable to the reversible adiabatic,

$W = J(E_2 - E_1)_S$, for a non-flow reversible adiabatic

$W + (U_1^2 - U_2^2)/64.34 = J(H_2 - H_1)_S$, for a steady-flow reversible adiabatic

For an easy and accurate determination of the fluid properties after isentropic expansion from a given initial state to a specified final pressure the H–S (Mollier) chart obviously is useful. Also the final quality after expansion to a given pressure or temperature *within the saturation region* may be computed directly by the equation

$$x_2 = \frac{S - S_{f,2}}{S_{fg,2}} = 1 - \frac{S_{g,2} - S}{S_{fg,2}} \tag{5}$$

where S is the initial and constant entropy. The final quality being known, the other properties may be computed as required.

Example. Steam at 200 lb per sq in. abs and a quality of 0.995 is delivered to an ideal steam turbine, expands adiabatically and reversibly therein to a pressure of 14.7 lb per sq in. abs, and is discharged at that pressure.

Compute the entropy, quality, and enthalpy of the steam leaving the turbine and the shaft work which would ideally be obtainable per pound of steam used, assuming negligible kinetic energies entering and leaving the turbine.

Solution. $S_1 = S_{g,1} - (1 - x_1)S_{fg,1} = 1.5450 - 0.005 \times 1.0012 = 1.5400.$

$$S_2 = S_1 = 1.5400.$$
$$x_2 = \frac{1.5400 - 0.3119}{1.4446} = 0.850.$$
$$H_2 = 1150.2 - 0.15 \times 970.2 = 1004.7.$$
$$H_1 = 1197.8 - 0.005 \times 842.4 = 1193.6.$$
$$W = J(H_1 - H_2)_S = J(1193.6 - 1004.7) = 778 \times 188.9 = 147{,}000 \text{ ft-lb.}$$

Throttling Process. Technically, a pure throttling process is one in which a fluid expands adiabatically but thoroughly irreversibly through a labyrinthal or porous obstruction in a line, the arrangement being such that the velocities of the stream approaching, through, and departing from the obstruction shall be very small and their differences wholly negligible. No shaft work is performed.

This process is approached closely in practice in the "wire-drawing" of a vapor (or gas) through a constriction in a line such as a partially closed valve or small orifice. In such devices there is unquestionably an accretion of velocity and kinetic energy directly in the constriction, but this momentary unidirectional velocity is immediately dissipated by reason of the high degree of turbulence existing in the stream directly after the constriction, whereby the kinetic energy in the stream finally departing from the region $(U_2^2/64.34)$ is negligible or differs negligibly from that in the stream approaching the region $(U_1^2/64.34)$. (See Fig. 4.)

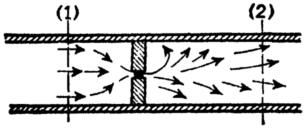

FIG. 4. Throttling Process

The process is also approached, but less exactly (owing to energy dissipation as heat), in the flow of a vapor through a long pipe line in which there is a distinct pressure drop due to friction.

To discern the working scheme for analyzing the throttling process, note that in fitting the general steady-flow energy equation (equation 5, Art. 4) to the conditions of the process the Q and W terms disappear and the kinetic energy terms are either negligible or effectively canceled, whence

$$H_1 = H_2$$

This equality of the initial and final enthalpy is the outstanding characteristic of the throttling process.

Example. Steam at 250 lb abs and 99 per cent quality is throttled to a pressure of 200 lb abs. What is the state of the steam after throttling, and what is the loss of available energy, assuming that the steam were being supplied to a reversible engine operating with a 70 deg fahr exhaust?

Solution.

$$H_1 = 1192.3 = H_2.$$

To ascertain the second state, since H_g at 200 lb abs is 1197.8 the fluid must still be a slightly wet mixture. To ascertain the quality,

$$H_2 = 1192.3 = H_{f,2} + x_2 H_{fg,2} = 355.3 + x_2\,842.4,\ x_2 = 0.9935$$

To ascertain the increase of unavailable energy:

$$S_1(\text{at 250 lb and 99\%}) = 1.5165;\ S_2(\text{at 200 lb and 99.35\%}) = 1.5385$$

$$\Delta S = 0.0220;\ \Delta Q_R = T_2\,\Delta S = (70 + 460) \times 0.0220 = 11.7 \text{ Btu per lb.}$$

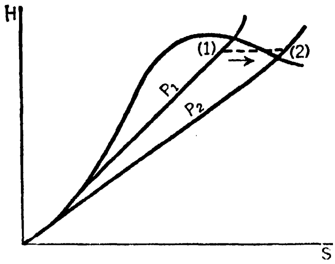

FIG. 5. *H–S* Diagram for Throttling Process

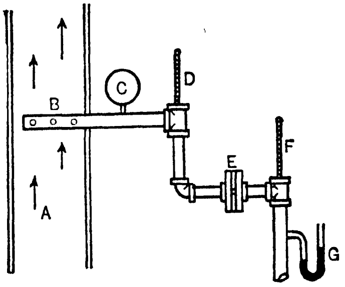

FIG. 6. Throttling Calorimeter

The Throttling Calorimeter. Both by reference to the above example and to a Mollier diagram (see Fig. 5) it becomes apparent that if a wet vapor passes through a throttling process the requisite equality of the initial and final enthalpies will in general produce an increase in the quality of the vapor.* Also if the initial quality of the vapor is sufficiently high and the pressure drop sufficiently great, some degree of superheat may well exist in the exit or lower pressure vapor. By reason of the latter circumstance and the additional facts (*a*) that *in the superheat region the pressure and temperature will suffice to determine*

---

* This statement must be made with some qualification. To illustrate, inspection of the Mollier diagram of steam (Keenan tables) shows that with initial pressures in excess of about 500 lb per sq in. a throttling through a moderate pressure range may in fact act to increase the moisture content.

the state and enthalpy of the fluid and (*b*) that these P and T properties are both directly measurable ones, the throttling phenomenon may be and is regularly employed in a device which is known as the *throttling calorimeter* and is used for ascertaining the enthalpy and quality of steam which contains a limited amount of moisture.

Referring to Fig. 6, a simple arrangement of such a device is there indicated. In the figure, A is a steam line through which is passing the steam the enthalpy and quality of which are desired. Pipe B is a *sampling tube* through which it is endeavored to draw a true sample of the steam in A. Gage C or thermometer D determines the saturation pressure or temperature of the steam supply. These obviously should "check" if the steam is saturated. Between the flanges at E is located a plate with a small ($^1/_{16}$ in. to $^1/_8$ in. diameter) orifice through which the sample is throttled to the discharge pressure, which is usually about atmospheric. Thermometer F, and mercury manometer G, together with data on the barometric pressure, provide the requisite data on the temperature and pressure of the throttled fluid by which its state may be ascertained from the Superheated Steam Tables. Thus the enthalpy of the leaving steam and thereby that of the entering steam is determinable.

The quality of the steam sample is found by solving for x in the expression for the enthalpy of wet steam:

$$H_2 = H_1 = H_{f,1} + x_1 H_{fg,1}; \quad \text{or} \quad x_1 = (H_2 - H_{f,1})/H_{fg,1}$$

An alternative method is to enter the Mollier chart at the intersection of the P_2 and t_2 lines, pass across at constant H to P_1, and read the quality directly.

This device if properly constructed and operated will give the enthalpy and quality of the sample with good accuracy, although a slight correction for radiation may be desirable. A serious practical difficulty lies in the securing of a truly representative sample of the steam in line A. Also its use is limited to fairly dry and fairly high-pressure steam since an excess of moisture or low steam pressure will prevent the superheating, and *its whole utility depends on the possibility of fixing the state of superheated steam from knowledge of its pressure and temperature.*

19. FLOW OF VAPORS THROUGH NOZZLES AND ORIFICES

The general energy equations for a nozzle are invariably applicable whether the fluid flowing is a gas or a vapor, whence we may refer immediately to the basic energy equations. Those equations are repeated here for convenience:

$$\frac{U_x^2 - U_1^2}{64.34} = J(H_1 - H_x) \tag{6}$$

$$M' = \frac{U_1 A_1}{V_1} = \frac{U_x A_x}{V_x} \quad \text{(continuity equation)} \tag{7}$$

$$U_x = 223.7\sqrt{\frac{H_1 - H_x}{1 - \left(\dfrac{A_x}{A_1}\right)^2 \left(\dfrac{V_1}{V_x}\right)^2}} \tag{8}$$

where the factor $\sqrt{\dfrac{1}{1 - \left(\dfrac{A_x}{A_1}\right)^2 \left(\dfrac{V_1}{V_x}\right)^2}}$ is to be considered the correction factor for initial velocity.

$$\frac{M'}{A_x}\,\text{(ideal)} = 8.02\sqrt{\frac{k}{k-1}}\,\frac{P_1}{\sqrt{RT_1}}\sqrt{\left(\frac{P_x}{P_1}\right)^{2/k} - \left(\frac{P_x}{P_1}\right)^{(k+1)/k}} \tag{9}$$

which does not include the correction factor for initial velocity.

In actual flow the nozzle efficiency and the coefficient of velocity are introduced, e_n and C_v, respectively:

$$e_n = \frac{(U_x^2 - U_1^2)_{\text{actual}}}{(U_x^2 - U_1^2)_{\text{ideal}}} = \frac{(H_1 - H_x)_{\text{actual}}}{(H_1 - H_x)_S} \tag{10}$$

$$C_v = \frac{U_{x,\,\text{actual}}}{U_{x,\,\text{ideal}}} = \sqrt{e_n} \tag{11}$$

Quite as it was with the flow of a gas, given the state of the fluid as supplied, the problem of applying these equations in developing either the ideal or the actual nozzle form is that of ascertaining the simultaneous values of H_x and V_x as expansion proceeds to successively lower pressures. However, as may be anticipated, the detailed procedure in ascertaining these values may differ in the cases of the gas and of the vapor, particularly if the vapor is one for which tables of properties are available. Such tables being available for the vapors of major engineering importance, it is the practice (at least among engineers of the United States) to utilize them, although it will appear subsequently that in considerations of actual flow certain difficulties are encountered in that procedure.

For the circumstance of the ideal expansion the values of the desired properties are easily obtained by recognizing the isentropic character of the expansion and then following the methods of the example on p. 7–45, using either the vapor tables alone or those jointly with a Mollier (H–S) chart. The appearance of an ideal state change as represented on H–S coordinates would be that of a line such as AB in Fig. 7. The essential characteristic of the line is the ideal constancy of the entropy.

The procedure in investigating the nozzle form for ideal expansion is perhaps shown to best advantage by an illustrative example.

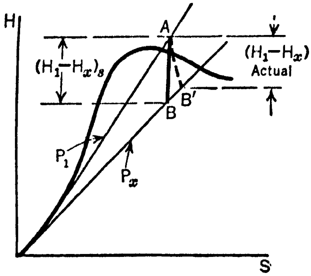

Fig. 7 H–S Diagram of Nozzle Flow Process

Example. Determine the characteristic form and dimensions of a steam nozzle which shall provide for the flow and reversible expansion of 2 lb of steam per second from an initial state of 200 lb per sq in. abs and 420 deg fahr to a discharge region at a pressure of 60 lb abs. Do this by computing the areas required upon expansion to successive pressures of 160, 120, 115, 109, 85, and 60 lb. Assume the ideal case of reversible adiabatic expansion and also assume negligible entrance velocity.

Solution for P_x of 160 lb per sq in.

$$H_1 = 1222.3;\ V_1 = 2.436;\ S_1 = 1.5735.$$

$$S_x = S_1 = 1.5735;\ t_x \text{ (from Superheat Table)} = 376.4 \text{ deg fahr.}$$

$$H_x = 1202.7;\ \Delta H = 19.6;\ U_x = 223.7\sqrt{19.6} = 990 \text{ ft per sec.}$$

$$V_x = 2.894;\ M'/A_x = 990/2.894 = 342;\ A_x = 0.00585 \text{ sq ft.}$$

Solution for P_x of 120 lb per sq in.

$$S_x = S_1 = 1.5735;\ x_x = 1 - \frac{1.5874 - 1.5735}{1.0956} = 1 - 0.0127 = 0.987.$$

$$H_x = 1189.8 - 0.0127 \times 877.4 = 1178.7;\ \Delta H = 43.6;\ U_x = 1480.$$

$$V_x = 3.725 - 0.0127 \times 3.707 = 3.678.$$

$$M'/A_x = 1480/3.678 = 401.5;\ A_x = 0.00498.$$

The major results at these and the other specified pressures are tabulated below.

Tabular Results

p_x (lb per sq in.)	t, or x	H_x	ΔH	U_x	V_x	M'/A_x	A_x (sq ft)
200	420	1222.3	......	......	2.436	......	....
160	376	1202.7	19.6	990	2.894	342	0.00585
120	0.987	1178.7	43.6	1480	3.678	402	0.00498
115	0.984	1175.3	47.0	1530	3.817	402	0.00498
109	0.981	1171.1	51.2	1600	4.001	400	0.00500
85	0.964	1151.1	71.2	1890	4.978	379	0.00528
60	0.943	1124.4	97.9	2210	6.7605	327	0.00612

Scrutiny of the above tabular results indicates that:

(*a*) For a given initial state a particular enthalpy, specific volume, and area (per unit mass-rate of flow) are again associated with each successive pressure.

(*b*) The critical pressure phenomenon is again evidenced by the minimum area, or throat, which occurs in the above example upon expansion to about 57 per cent (115/200) of the supply pressure.

(*c*) For expansion to any pressure equal to or less than the critical a convergent passage is proper.

(*d*) A subsequent divergent passage is required in order to provide properly for a controlled and directed expansion to a pressure which is less than the critical.

(*e*) For expansion to a discharge region pressure which is greater than the critical the required exit area for a given mass-rate of flow will depend on both the supply state and the discharge region pressure or, conversely, the mass-rate of flow at given supply and discharge region pressures will be proportional to the exit area.

(*f*) On the contrary, for expansion to a discharge region which is at a pressure equal to or less than the critical the invariable existence of the critical pressure at the throat and a fixed value of the critical ratio will act to cause the required throat area for a given mass-rate of flow to depend only on the state of the fluid supply or, conversely, the mass-rate of flow obtained with a given supply state depends only on the throat area and is independent of the discharge region pressure (although the proper final exit area for suitable accommodation of the entire expansion must depend also on the discharge region pressure).

One feature in which vapor flow and gas flow will differ slightly is that the critical ratio for a vapor does not appear to be strictly a constant. Thus, in the example, in which the steam supply was moderately superheated, the critical ratio appears to have the value of about 0.57. By similar investigation it would be found that the critical ratio for steam would apparently range from about 0.55 for highly superheated steam supply to about 0.58 for saturated steam supply. However, this variation does not require much concern, owing to the very slight change of the cross-sectional area of the nozzle at pressures between about 55 and 60 per cent of the supply pressure.

An important characteristic of this ideal expansion, which is clearly indicated in the above tabulation and was evident in Fig. 7, is the progressive condensation of a portion of the vapor with progressive expansion. Quoting specific figures, the reversible adiabatic expansion of the initially superheated supply would require the actual condensation of about 2 per cent of the vapor prior to reaching the throat and about 6 per cent prior to reaching the 60 lb exit pressure, and the example above would indicate that 13 per cent should condense if the expansion were continued to atmospheric pressure. In making these quality computations it was inherently assumed that a stable thermal equilibrium was maintained between the liquid and the vapor as the expansion proceeded, whence the expansion would be designated as being of the equilibrium type. A further consideration will be given to the possibility of an actual expansion of this type.

Actual Expansion of a Vapor. Any actual expansion through a nozzle is necessarily irreversible by reason of the unescapable friction and turbulence accompanying the high-velocity flow. The influence of such irreversibility and the general manner of accounting for it in air-nozzle design has been considered above. It will similarly be considered for steam-nozzle design in the following paragraphs, but first it needs be noted that without question additional causes for irreversibility exist in the case of vapor flow, or more particularly in the case of a vapor which is supplied in a saturated or only slightly superheated state. This additional irreversibility is occasioned by a temporary unstable condition which has been found to exist in rapidly expanding vapor. The condition is that known as supersaturation and is characterized by a retarding or deferring of the partial condensation which we have seen would accompany the equilibrium type of expansion. Experiments indicate that complete supersaturation and action like a superheated vapor persist until a pressure is reached which is about one-half of that at which condensation would normally begin. This is approximately equivalent to stating that for initially dry and saturated steam complete supersaturation persists down to and somewhat beyond the critical pressure. Assuming superheated and supersaturated steam with frictionless adiabatic expansion having the basic property relation

$$PV^{1.3} = \text{a constant} \tag{12}$$

the following relations are derived:

$$\frac{M'}{A_x}\,(\text{ideal}) = 16.7\sqrt{\frac{P_1}{V_1}\left[\left(\frac{P_x}{P_1}\right)^{1.54} - \left(\frac{P_x}{P_1}\right)^{1.77}\right]} \tag{9a}$$

or, if $(P_1 - P_x)/P_1$ does not exceed about 0.33,

$$\frac{M'}{A_x}\,(\text{ideal}) = 8.02\,\frac{1}{\sqrt{P_1 V_1}}\,\sqrt{P_x(P_1 - P_x) - 0.15(P_1 - P_x)^2} \tag{9b}$$

or, if $(P_1 - P_x)/P_1$ does not exceed about 0.1,

$$\frac{M'}{A_x}\,(\text{ideal}) = 8.02\sqrt{\frac{P_x(P_1 - P_x)}{P_1 V_1}} \tag{9c}$$

or, if $(P_1 - P_x)/P_1$ does not exceed about 0.01,

$$\frac{M'}{A_x}\,(\text{ideal}) = 8.02\sqrt{\frac{P_1 - P_x}{V_1}} \tag{9d}$$

Also for the special consideration of a value of P_x equal to the critical pressure, in which circumstance the flow rate per unit area is recalled to be the maximum,

$$\frac{M'}{A_{\text{throat}}}\,(\text{ideal}) = 3.78\sqrt{P_1/V_1} \tag{9x}$$

The critical ratio for the flow of superheated and supersaturated steam becomes

$$\frac{P_{\text{critical}}}{P_1} = \left(\frac{2}{1.3+1}\right)^{1.3/0.3} = 0.545 \qquad (13)$$

Diffuser and Ejector. The diffuser is in principle the reverse of a nozzle and is a device by which a lower pressure, high-velocity jet may deliver itself at a low velocity at and against a higher pressure. Referring to the Mollier diagram of Fig. 8, a fluid passing reversibly through a nozzle from pressure P_1 to the lower pressure P_2 would change state along the path *ab*, at constant entropy, decreasing enthalpy, increasing specific volume, and increasing velocity. A diffuser in which the action was wholly reversible would take the high-velocity fluid under the conditions existing at the nozzle outlet, *b*, and return it along state path *ba* to its original state and to a region of the higher original pressure P_1. All the state changes which occurred in the ideal nozzle would occur in the ideal diffuser in the reverse order.

The contour of the channel required by the diffuser is determined from exactly the same considerations which determine the contour of a nozzle, namely, consideration of the steady-flow energy equation and the continuity of flow principle. Parallel features of the two devices would be that, just as expansion in a nozzle to a lower pressure which exceeds about one-half of the higher calls for a converging section only, so a compression in a diffuser from a lower pressure in excess of one-half of the higher would require only a diverging section. Similarly, if the stream velocity to the diffuser were sufficient to enable discharge to a region the pressure of which exceeded twice that of the lower-pressure supply region, the diffuser channel would be initially convergent and then divergent from a throat. The general form of a diffuser for operation under the latter condition is shown in Fig. 9. Below the diffuser are depicted the decreasing velocity and specific volume and the increasing pressure and enthalpy as the fluid flows from the lower-pressure to the higher-pressure region.

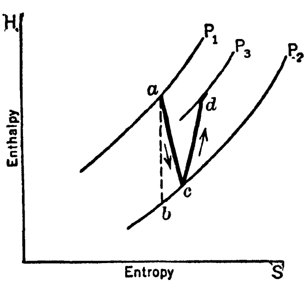

FIG. 8. *H–S* Diagram of Diffuser Process

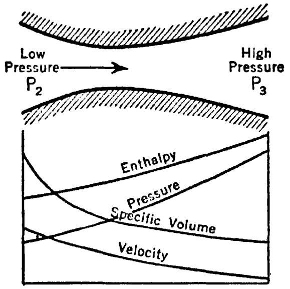

FIG. 9. Form of Diffuser and Characteristic Curves

In Fig. 8 there is also shown the character of the *actual* processes in a serial arrangement of nozzle and diffuser. The line *ac* represents the actual expansion in the nozzle from pressure P_1 to pressure P_2, and the line *cd* represents the recompression in the diffuser. The paths are both of increasing entropy and so, if in general the recompression may be one to a final enthalpy H_3 equal to the original enthalpy H_1, the final pressure P_3 must be less than the original pressure P_1 by an amount which depends on the degree of irreversibility of the two processes.

For the compression of a gas in a diffuser, if the stream were carried to a negligible exit velocity U_3, the pressure to and against which it might be delivered would depend on the pressure, temperature, and velocity of the supply stream. Thus, by a development of the energy equation,

$$\frac{U_2^2}{64.34} = \frac{k}{k-1} RT_2\left[\left(\frac{P_3}{P_2}\right)^{(n-1)/n} - 1\right]$$

or

$$P_{3,\max} = P_2\left[\frac{k-1}{kRT_2}\,\frac{U_2^2}{64.34} + 1\right]^{n/(n-1)} \qquad (14)$$

in which [$P_{3,\max}$ = maximum discharge pressure against which the stream could be delivered from diffuser after deceleration to a negligible velocity.
P_2 = pressure of the region of the supply stream.
U_2 = velocity of the supply stream, feet per second.
T_2 = supply region temperature, degrees Rankine.
$k = c_p/c_v = 1.40$ for air.

n = the effective P–V exponent of the more or less irreversible adiabatic compression process, the value of which exponent would equal k for ideal reversible compression, would exceed k for irreversible compression, and would be an index of the character of the diffuser performance.

Common applications of the diffuser are found in the downstream section of the Venturi meter and in centrifugal pumps and compressors. In the latter, high-velocity streams are created at the periphery of a rotating element and stationary diffusers are employed to utilize the kinetic energy of the streams for delivery to discharge regions of higher pressure.

The diffuser forms an essential component of the *ejector*, which is a device in which the kinetic energy of one fluid is used to pump another fluid from a region of lower to one of higher pressure. In the steam air ejector, Fig. 10, a high-velocity jet of steam is produced by the steam nozzle AC. Air drawn into the ejector from a region of low pressure D mixes with the jet, and the mixture is compressed in the diffuser EG and discharged into a region of higher pressure beyond G. The changes in pressure, velocity, enthalpy, and entropy occurring throughout the ejector are shown graphically in Fig. 10. The steam is supplied to the nozzle at a pressure P_1 considerably higher than the pressure P_3 at which the air is to be discharged. Along AC occurs the increase of velocity in the nozzle. Along DC' is a slight increase in velocity as the air is drawn into the ejector. Between C and some indefinite point E the steam and air mix at nearly constant pressure and with an increase in air velocity and decrease of steam velocity. This mixing is considered to occur by a wholly irreversible process described as inelastic impact, but with conservation of momentum of the streams of fluid. From E to G the mixture is compressed with decreasing velocity and increasing entropy and enthalpy. The diffuser requires a minimum section at F if the absolute pressure at E is less than about half the pressure at G. Because of lack of knowledge of just what occurs during the mixing process and also of the efficiency of the compression process in the diffuser, no satisfactorily exact analysis of the complete ejector has been made. Design is largely by empirical methods. However, it is not difficult to compute the efficiency of an ejector from performance data.

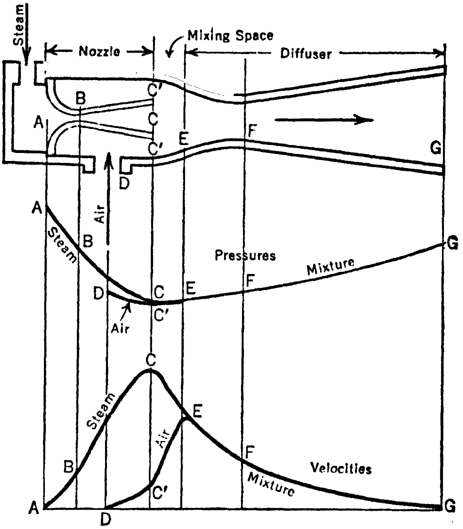

FIG. 10. Ejector and Characteristics

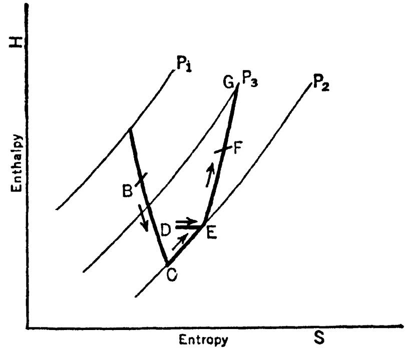

FIG. 11. H–S Diagram for Ejector Process

Let

M'_s = mass of steam used in unit time.

M'_a = mass of air handled in unit time.

$M'_s\,(H_1 - H_3)_S$ = adiabatic decrease in enthalpy of steam from nozzle supply pressure P_1 to air discharge (not suction) pressure P_3.

$M'_a\,W_a$ = adiabatic work of compression of air from air suction pressure P_2 to air discharge pressure P_3.

Then efficiency of ejector = work required to compress air adiabatically, divided by available energy supplied by steam above discharge pressure, or

$$\text{Ejector eff.} = \frac{M'_a\, W_a}{JM'_s(H_1 - H_3)_S} \tag{15}$$

The efficiency computed in this manner corresponds to the efficiency which should be used if the air were compressed in a steam-driven piston or centrifugal air pump directly by the use of mechanical work. The additional kinetic energy obtained in the steam jet by expansion from P_3 to P_2 is not charged to the ejector, since exactly that amount of energy is ideally required to compress the same steam back from P_2 to P_3 in the diffuser.

Example. A steam-air ejector is operated with dry saturated steam at a gage pressure of 100 lb per sq in. Air is discharged into the atmosphere from a vessel under a vacuum of 24.4 in Hg and at a temperature of 70 deg fahr. The barometer is 30.5 in. Hg. Three pounds of steam are used per pound of air discharged. Compute:

(*a*) Ideal velocity of discharge from steam nozzle.
(*b*) Ideal velocity of mixture of steam and air at entrance to diffuser.
(*c*) Efficiency of ejector.

Solution. (*a*) Atmospheric pressure, P_3 = 15.0 lb per sq in. abs.
Steam pressure, P_1 = 115 lb per sq in. abs.
Air pressure in vessel, P_2 = 3 lb per sq in. abs.
Ideal enthalpy drop in entire nozzle, 115 to 3 lb = 1189 − 945 = 244 B.t.u.
Corresponding jet velocity = $223.7\sqrt{244}$ = 3485 ft per sec.

(*b*) Assume velocity of air at point *c*, just before mixing, to be 200 ft per sec. Applying principle of equal momenta before and after mixing $(3485 \times 3) + 200$ = velocity of mixture × 4. Ideal velocity of mixture = 2664 ft per sec.

If the mixing occurred without loss of kinetic energy the velocity of mixture would be 3030 ft per sec. As stated, little is known as to what actually occurs at this point.

(*c*) The work required to compress the air is computed on the basis of reversible adiabatic compression from a pressure of 3 lb per sq in. abs to a pressure of 15 lb per sq in., which gives 57,000 ft-lb per lb of air. The adiabatic enthalpy drop in the steam nozzle from 115 lb to 15 lb is 148.8 Btu per lb. This is the energy available to produce the compression of the *air* in the diffuser. The overall efficiency of the ejector is then:

$$\frac{\text{Ideal energy required for air compression}}{\text{Ideal energy available in steam nozzle}} = \frac{57{,}000}{148.8 \times 778 \times 3} = 0.164 = 16.4 \text{ per cent}$$

In steam condenser applications, the air withdrawn from the condenser is saturated with water vapor at the temperature of the air-vapor mixture. In computing the work of compression it is this mixture which must be considered. For high vacuum in condensers it becomes necessary to use two or three stages of ejectors in series, condensing the steam between stages to reduce the amount of steam which otherwise would need to be compressed in the diffusers.

Flow of a Vapor through an Orifice. An orifice will perform the function of only the convergent portion of a nozzle. Therefore, a vapor will expand in the actual zone of the orifice to any discharge region pressure which is greater than or equal to the critical pressure, but not to any lower pressure. Any further expansion must take place beyond the orifice.

It follows that we again encounter the two general conditions of:

(*a*) Flow with the discharge region pressure greater than the critical, when computation of the ideal rate of discharge may be based upon expansion in the orifice to the lower pressure, and

(*b*) Flow with the discharge region pressure equal to or less than the critical, when computation of the ideal rate of discharge must be based upon expansion in the orifice only to the critical pressure.

THE STEAM POWER PLANT

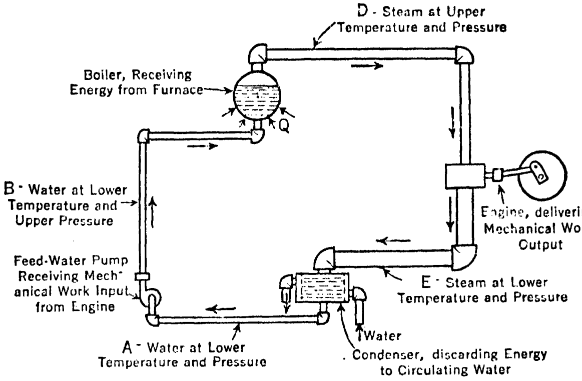
20. THE RANKINE CYCLE

Symbols

e = efficiency.
f = a subscript designating the saturated liquid state.
g = a subscript designating the dry saturated vapor state.
H = enthalpy, Btu per pound of fluid.
J = Joule's equivalent, 778 (ft-lb per Btu).
M = proportional mass of vapor passing to a particular heater in a regenerative cycle.

P = pressure (absolute), pound per square foot.
p = absolute pressure, pounds per square inch.
Q = energy transferred as heat, Btu per pound of fluid.
S = entropy per pound mass, and also a subscript designating constancy of entropy, during a process.
T = absolute temperature, degrees Rankine (=degrees fahrenheit absolute).
t = temperature, degrees fahrenheit.
U = linear velocity, feet per second.
V = specific volume, cubic feet per pound.
W = energy in transition as shaft work, foot-pounds per pound of fluid.

Two general methods are at present available for the production of power from the energy stored in the fuels. These are the internal-combustion engine and the type of composite device familiarly exemplified by the *steam power plant*. The thermodynamic principles which underlie the steam power plant cycles are presented here.



D - Steam at Upper Temperature and Pressure
Boiler, Receiving Energy from Furnace
Q
B - Water at Lower Temperature and Upper Pressure
Engine, delivering Mechanical Work Output
Feed-Water Pump Receiving Mechanical Work Input from Engine
E - Steam at Lower Temperature and Pressure
Water
A - Water at Lower Temperature and Pressure
Condenser, discarding Energy to Circulating Water

Fig. 1. Elementary (Rankine Cycle) Steam Power Plant

The Carnot Cycle is the classical example of a wholly reversible temperature-engine cycle in which energy that is being supplied at an elevated temperature is reduced to a lower temperature, in which process the maximum possible portion of that energy is converted into work. Also this cycle, notwithstanding its impracticability and unattainability, is in certain features the prototype of the various steam power plant cycles

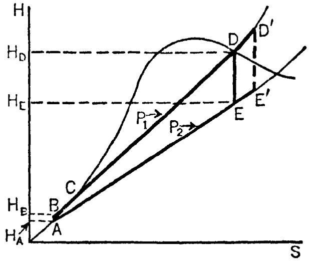


Fig. 2. H–S Diagram of Rankine Cycle

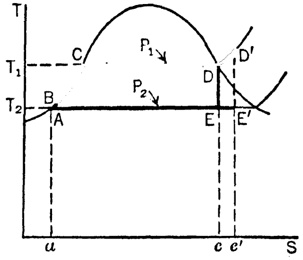

Fig. 3. T–S Diagram of Rankine Cycle

and in all cases it acts as an invaluable guide in the selection and development of those cycles. The Carnot cycle is described on p. 7-07.

The Rankine Cycle, of the actual steam plant cycles, is of concern not only because of its simplicity, practicability, and historical importance but also because the other, more complex cycles may in a sense be regarded as refinements of the Rankine. The ideal Rankine cycle consists in general of (a) the warming, constant temperature vaporization and, perhaps, further superheating of the working fluid of the cycle at a constant upper pressure, this through the addition of energy from the source whereby the fluid is brought from the lower to the upper temperature limit of the cycle; (*b*) the isentropic expansion of the fluid to the lower temperature and pressure limits of the cycle; (*c*) the complete condensation of the fluid by the emission of energy at the lower temperature and pressure, this energy departure constituting the rejection of the unavailable energy to the receiver; and (*d*) the return of the condensed fluid to the upper pressure by reversible adiabatic compression, whereupon the fluid cycle may be repeated. These processes take place successively in the boiler and superheater, the engine, the condenser, and the feed pump.

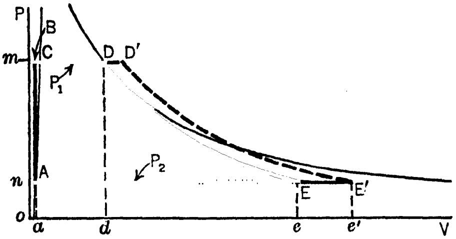

FIG. 4. *P–V* Diagram of Rankine Cycle

To facilitate the description and analysis of the cycle, reference will be made to Fig. 1, which is a diagrammatic representation of the arrangement of the essential pieces of apparatus in which the processes are carried out, and to Figs. 2, 3, 4, in which the state changes which occur progressively in the cycle are depicted respectively on *H–S*, *T–S*, and *P–V* coordinates.

There is selected arbitrarily as a starting point in the cycle the point and state *A* at which the water exists as saturated liquid at the lowest pressure and temperature of the cycle. This state occurs in the suction line of the *pump* which acts to raise the pressure of the water from this lowest pressure to the highest pressure of the cycle.

From this initial state, the fluid passes progressively through the following series of processes:

(1) The pressure of the water is raised by a reversible adiabatic compression in the *pump* from the lower pressure P_2 to the upper pressure P_1, causing a change from the saturated liquid state *A* to a subcooled liquid state *B*. The compression is not accompanied by any appreciable change of temperature, internal energy, specific volume, or entropy.

The energy required for the pumping process is nearly:

$$W_{\text{pump}} = (P_1 - P_2)V_{f,2}$$

where $V_{f,2}$ = specific volume of saturated liquid of temperature T_2. In Fig. 4 the product $(P_1 - P_2)V_{f,2}$ is represented by the area *mBAnm*, which area thus represents the pump work.

(2) The second distinctive process of the Rankine cycle is the warming, vaporizing, and perhaps superheating of the fluid, all occurring under a virtually constant pressure. The energy supply for accomplishing these several phases of the cycle is provided by heat conduction through the heating surfaces of the boiler and the superheater (if the latter is supplied) and is furnished directly or indirectly from the primary high-temperature energy source, namely, the hot products of combustion of the fuel in the furnace.

In the feedwater heating portion of the process, the water is warmed at P_1, from temperature T_2 up to the saturation temperature which corresponds to that pressure, whence the state of the liquid after completion of the heating is represented by the saturated liquid state point *C*. If the boiler is assumed to accomplish a complete vaporization of the water, the state of the fluid leaving the boiler is represented by the dry saturated vapor state point *D*. If in addition a superheater is supplied the fluid leaves that device at the superheated state point *D'*, which point must lie on the P_1 line in the superheat region.

The heat required for this complete process of energy supply as heat is

$$Q_{\text{supplied}} = H_{D\ (\text{or } D')} - H_B, \text{ Btu per lb}$$

Referring to the figures, the total energy supply as heat is measured directly on the *H–S* diagram by the vertical distance of point *D* (or *D'*) above *B* and on the *T–S* diagram by the area *aBCDea* (or *aBCDD'e'a*). The inherently unavailable portion of the heat energy supply is represented by the area *aAEea* (or *aAE'e'a*) on the *T–S* diagram.

(3) The next state change in the ideal Rankine cycle is the reversible adiabatic expansion of the fluid from the upper temperature and pressure to the lower. To accomplish this the fluid is delivered to the *engine* at constant pressure and expands therein, after which it departs from the engine at a constant lower pressure. The term engine is here used in a generic sense to designate the main prime mover of the plant, whether that be actually a reciprocating engine or turbine engine. It is in this composite delivery, expansion, and rejection process which takes place in the engine that the available portion of the previously supplied heat energy is transformed to shaft work.

Because the property characteristic of a reversible adiabatic state change is the constancy of the entropy, the expansion through the ideal engine is represented on the H–S and T–S diagram by the vertical isentropic line DE (or $D'E'$). The line DE in the P–V diagram portrays the typical appearance of this reversible adiabatic state change on those coordinates.

The work delivered by the engine is

$$W_{\text{engine}} = J(H_D - H_E)[\text{or } J(H_{D'} - H_{E'})] \text{ ft-lb per lb}$$
$$= J(H_1 - H_2)_S$$

where the subscript $_S$ indicates constant entropy.

The work output of the ideal engine is measured on the H–S diagram by the vertical distance of point D above E. The method of computing the enthalpy at E, given the entropy and pressure, has been given on p. 7–40.

The engine work is represented on the P–V diagram by the area back of the expansion line, or

$$W_{\text{engine, ideal}} = \text{area } mDEnm, \text{ or } = +\int_1^2 V\,dP$$

It is to be emphasized that this expression for the engine work applies to any ideal engine, whether of the reciprocating or turbine type.

(4) The closing process of the cycle is a condensation of the exhaust steam from the engine, by which the fluid is returned at constant pressure from the state E to the initial saturated liquid state A and during which there occurs the discarding of the inescapably unavailable residue of the previously supplied heat energy. In the ideal cycle and in many practical installations this process is accomplished during passage through a *condenser* in which the energy departure and the condensation are effected by energy transfer as heat conducted from the steam through the condenser structure to circulating water. The same state change and energy rejection may be accomplished, however, in various other practical manners, as by condensation in the atmosphere, in a heating system, or in any other process in which the low temperature energy of the exhaust steam may be employed to advantage.

The heat rejected in the condensation process is

$$Q_{\text{condenser}} = H_E - H_A \ (\text{or } H_{E'} - H_A), \text{ Btu per lb}$$

On the H–S diagram the vertical distance between state points E and A measures the energy rejected in the condensation.

On the T–S diagram this energy discard as heat $= T_2\,(S_A - S_E)$ is represented by the area $aAEea$ (or $aAE'e'a$). Therefore, as the area $aBCDea$ measured the amount of energy supplied from the source as heat, the difference between these two areas, or the area $ABCDEA$, measures the net amount of work obtainable from the operation of the cycle, that is, the net amount after debiting the engine output with the portion of its work which must be employed to drive the pump.

The cycle is thus completed.

21. MEASURES OF EFFICIENCY AND PERFORMANCE

The Thermal Efficiency of a Heat Engine Cycle, or of a heat engine alone, is defined as the ratio between the amount of work output and the amount of heat energy which must be supplied in order to accomplish that output, or

$$\text{Thermal efficiency } (e_t) = \frac{\text{Work output from system}}{\text{Heat supplied to system}}$$

The thermal efficiency of the Rankine cycle $= \dfrac{(H_1 - H_2) - (P_1 - P_2)V_{f,2}/J}{(H_1 - H_{f,2}) - (P_1 - P_2)V_{f,2}/J}$. This is a very nearly exact value. An approximation is

$$\frac{(H_1 - H_2)_S}{H_1 - H_{f,2}}$$

where H_1 = enthalpy of the steam as supplied at P_1.
$(H_1 - H_2)_S$ = decrease of enthalpy by isentropic expansion to P_2.
$H_{f,2}$ = enthalpy of saturated water at P_2.
$V_{f,2}$ = specific volume of saturated water at P_2.

The error arising from use of the approximation is usually regarded as negligible except when the modern higher boiler pressures (500 lb per sq in. and up) are employed.

In order to measure the effectiveness with which a cycle might ideally utilize the temperature range encountered in the cycle and thus to designate the degree to which the ideal cycle efficiency approaches the Carnot efficiency for that temperature range there is employed a figure of merit which is known as the *type efficiency* of the cycle. This is defined as the ratio between the ideal thermal efficiency of a cycle and the thermal efficiency of a Carnot cycle operating between the extremes of temperature found in the cycle under consideration, or

$$\text{Type efficiency} = \frac{\text{Ideal thermal efficiency of cycle}}{(T_1 - T_2)/T_1}$$

No actual engine can attain a performance equal to that of an ideal engine operating on the same cycle, because of the numerous irreversible actions which will inescapably occur in any real process. Heat will be radiated or otherwise dissipated from higher to lower temperature levels without full realization of its available energy; and mechanical irreversibility will occur owing to fluid friction, throttling and turbulence, and to the friction of moving parts of the engine mechanism, etc. The result must be less actual work output per pound of fluid than that ideally obtainable in the ideal cycle upon which the engine operation is based.

In order to evaluate the relative effectiveness of an actual engine and the degree to which it approaches ideal performance there is employed a measure of performance which is known as the *engine efficiency** and which is defined as the ratio between the output actually obtained per pound of steam supplied to the engine and the output ideally obtainable upon isentropic expansion of that steam, or

$$\text{Engine efficiency} = \frac{\text{Actual output per pound of steam supplied to engine}}{\text{Work ideally obtainable by isentropic expansion}}$$

$$= \frac{\text{Actual efficiency}}{\text{Ideal efficiency}}$$

The actual output of an engine is necessarily determined by test. Such a test requires a determination of the actual power output of the engine and the mass of steam supplied per unit time.

The power delivered to the piston face of a reciprocating engine may be measured by the engine indicator, the shaft horsepower output of any engine may likewise be measured by a suitable dynamometer, or for a direct-connected engine-generator set the electrical power output may be determined by proper electrical instruments. The mass-rate of steam supply may be determined by condensing and weighing the steam or by various types of steam flow-meters or calibrated orifices. The state of the steam is determined by its absolute pressure and its quality (ascertained by means of a calorimeter) or its temperature, if superheated. The various pressures are found by gages or manometers.

By reason of the variety of manners and positions which may be selected in designating the output of an engine a like variety of engine efficiencies may be assigned to a given machine. Each output mentioned above is successively less than the preceding one by reason of the progressive energy dissipation through mechanical and electrical losses. It is obvious that due attention must be given to this condition in quoting values of engine efficiency or in interpreting quoted values.

If adequate test data are available on the actual steam requirements and the power output of an engine, these data may be combined with the factors 2545 (Btu per horsepower-hour) or 3413 (Btu per kilowatthour), and the numerator of the efficiency equation may thereby be evaluated. Thus

Actual output per pound of steam supplied, Btu,

$$= \frac{\text{Power output, hp (or kw)} \times 2545 \text{ (or 3413)}}{\text{Steam supplied, pounds per hour}}$$

The denominator of the efficiency equation, that is, the output ideally obtainable per pound of steam supplied, may be computed for an engine according to the conditions of the particular type of cycle upon which the system operates. For the Rankine cycle the work ideally obtainable per pound of steam is $(H_1 - H_2)_s$. This is called the *adiabatic enthalpy drop*.

The ratio between the steam supplied per hour and the power output is known as the *steam rate* of an engine and is commonly expressed in terms of the pounds of steam supplied per horsepower-hour (or kilowatthour) or

$$\text{Actual steam rate} = \frac{\text{Pounds of steam supplied per hour}}{\text{Output in hp (or kw)}}$$

---

* Unfortunately various terms have been used to designate this efficiency: "efficiency ratio," "relative efficiency," "Rankine efficiency," and "turbine efficiency." *Engine efficiency* is the term employed in the Power Test Codes of the American Society of Mechanical Engineers.

The engine efficiency may be expressed concretely in the form:

$$\text{Engine efficiency} = \frac{2545/\text{Actual steam rate, lb per hp-hr}}{\text{Output ideally obtainable, Btu per lb}}$$
$$= \frac{3413/\text{Actual steam rate, lb per kwhr}}{\text{Output ideally obtainable, Btu per lb}}$$

The Actual Thermal Efficiency is a figure which in its basic significance is quite parallel to the ideal thermal efficiency of a cycle or an engine, which is broadly defined as the fraction $\frac{\text{Work output from system}}{\text{Heat supplied to system}}$. However, in evaluating this actual efficiency for an operating engine or engine-generator unit or for a complete operating plant the useful output may in practice be variously regarded as the indicated power output of a reciprocating engine, or as the shaft power output of any engine, or as the electrical power output of an engine-generator unit, or as the net electrical output at the bus-bars of a complete plant. Also in ascribing a value to the energy supply, that quantity may be taken variously as the energy supplied as heat (at the boiler), that supplied as chemical energy in the fuel, etc. It is thus apparent that a considerable variety of interpretations may be applied to the term without need for confusion if due care is employed in making the interpretation. In any individual case, and irrespective of its particular interpretation, the thermal efficiency may invariably be regarded as a ratio between the useful output delivered and the energy supplied for the procuring of that output, or

$$\text{Actual thermal efficiency} = \frac{\text{Useful output from system}}{\text{Energy supplied to system}}$$

In utilization of actual test data, it is commonly more convenient to express it in terms of a specific output or supply, that is, an output (or supply) per unit time, per unit mass of steam supplied to an engine or per unit mass of fuel supplied to a plant. For example, the specific output per pound of steam to an engine is expressed by the relation

$$\text{Actual output, Btu per lb of steam to engine} = \frac{2545 \text{ (or } 3413)}{\text{Actual steam rate, lb per hp-hr (or kwhr)}}$$

A parallel relation for the complete plant, in terms of the fuel rate, is

$$\text{Actual output, Btu per lb of fuel to plant} = \frac{2545 \text{ (or } 3413)}{\text{Actual fuel rate, lb per hp-hr (or kwhr)}}$$

Either of these relations may be employed directly as the numerator of the efficiency fraction of the above equation.

Several distinctive practices are followed in interpreting the denominator of the efficiency fraction in the various circumstances in which efficiency is to be determined. For the simple Rankine cycle it is the established practice to regard the energy supply which is assignable to each pound of steam and is chargeable against the engine as the enthalpy difference between that of saturated liquid at the temperature of the engine exhaust and that of the steam as supplied to the engine. It is to be observed that for this case no concern is given to the actual temperature at which the condensate may be leaving the condenser; this is in order to avoid penalizing the engine for any subcooling of the condensate which may occur by reason of unfavorable characteristics of the condenser. For the engine of the Rankine cycle, the efficiency thus becomes

$$\text{Actual thermal eff. of engine} = \frac{2545 \text{ (or } 3413)/\text{Steam rate}}{H_1 - H_{f,2}}$$

For the entire power plant it is the established practice to regard the chemical energy released by a complete combustion of the fuel as the energy supply. That energy when evaluated per pound of fuel is known as the calorific value or heating value of the fuel. It is determined by calorimetric measurement made upon representative samples of the fuel. Introducing this quantity in the efficiency fraction,

$$\text{Actual thermal eff., complete plant} = \frac{2545 \text{ (or } 3413)/\text{Fuel rate}}{\text{Heating value of fuel, Btu per lb}}$$

The *heat rate of an engine or of a plant* is defined as the amount of energy actually to be supplied per horsepower-hour (or per kilowatthour) of useful output. This may readily be expressed in terms of the steam rate, or the fuel rate, and the energy supply per pound of steam or of fuel, or

Actual heat rate, Btu per hp-hr (or kwhr)

= Steam rate of engine × Energy supplied per lb of steam

or = Fuel rate of plant × Heating value, Btu per lb of fuel

Example 1. A Rankine cycle type of steam plant is operating with a boiler pressure of 300 lb per sq in. abs and a 20 lb per sq in. abs back pressure. There is no superheater, and the steam delivered by the boiler has a 99 per cent quality. Compute the properties of the steam or water at each significant point of the ideal cycle, the ideal feed pump work (in foot-pounds and in Btu per pound of steam), the requisite heat supply, and the ideal minimum energy discard per pound of steam.

How many pounds of steam would be required in the ideal Rankine plant per net horsepower-hour output? Compute the Rankine cycle thermal efficiency and the type efficiency.

Solution.

Water leaving condenser: $P_A = P_2 = 20 \times 144$; $V_A = V_{f,2} = 0.0168$; $t = 228.0$ deg fahr; $H_A = H_{f,2} = 196.1$; $S_A = S_{f,2} = 0.3356$.

Water leaving pumps: $P_B = P_1 = 300 \times 144$; $V_B = V_{f,2} = 0.0168$; $t = 228.0$ deg fahr; $H_B = 196.1 + 144 \times (300 - 20) \times 0.0168/778 = 197.0$; $S_B = S_A = 0.3356$.

Steam leaving boiler: $P_D = 300 \times 144$; $V_D = 0.99 \times 1.541 = 1.526$; $t = 417.3$ deg fahr; $H_D = 393.9 + 0.99 \times 808.5 = 1194.2$; $S_D = 0.5883 + 0.99 \times 0.9220 = 1.5010$.

Steam leaving engine: $P_E = 20 \times 144$; $t = 228.0$ deg fahr; $S_E = S_D = 1.5010$; $x_E = (1.5010 - 0.3356)/1.3960 = 0.835$; $H_E = 196.1 + 0.835 \times 959.9 = 997.6$; $V_E = 0.832 \times 20.10 = 16.73$.

Pump work $= 144(300 - 20) \times 0.0168 = 680$ ft-lb $= 0.87$ Btu per lb.

Engine work $= 778(997.6 - 1194.2) = -153{,}000$ ft-lb $= -196.6$ Btu per lb.

Net work output $= -153{,}000 + 680 = -152{,}300$ ft-lb $= -195.7$ Btu per lb.

Energy supplied as heat $= 1194.2 - 197.0 = 997.2$ Btu per lb.

Energy discard $= 196.1 - 997.6 = -801.5$ Btu per lb.

Steam ideally required per horsepower-hour of plant output $= (33{,}000 \times 60)/152{,}300 = 13.00$ lb (or $= 2545/195.7$), = the ideal "steam rate" of cycle.

Rankine cycle efficiency $= 195.7 \div 997.2 = 0.196$ or 19.6 per cent.

Carnot cycle thermal efficiency $= (417.3 - 228.0) \div (417.3 + 460) = 0.216$ or 21.6 per cent.

Type efficiency $= 0.196 \div 0.216 = 0.907$ or 90.7 per cent.

Example 2. The engine of the cycle of Example 1 develops 300 hp and uses 6000 lb of steam per hour. Compute actual thermal efficiency, heat rate, and engine efficiency.

Solution.

Steam rate $= 6000 \div 300 = 20$ lb per hp-hr.

Actual thermal efficiency $= 2545 \div (20 \times 997.2) = 0.128$ or 12.8 per cent.

Heat rate $= 20 \times 997.2 = 19{,}944$ Btu per hp-hr.

Engine efficiency $= (2545/20) \div 195.7 = 0.653$ or 65.3 per cent, also
$= 0.128 \div 0.196 = 0.653$ or 65.3 per cent.

22. THE ENERGY ("HEAT") BALANCE

In the thermodynamic design of a steam power plant and in the analysis of its actual operation attention is very commonly given to what is known as the "*heat*" *balance* of the plant. By this is meant, more exactly, a comprehensive energy analysis and energy accounting for the purpose of ascertaining the ultimate destination of all portions of the original energy supply in the fuel and also for the more important purpose of correcting in so far as may be practicable any wastage of available energy.

Two viewpoints are available in the development of such an energy analysis. On the simpler but less valuable basis concern is given only to the distribution of the energy with regard to its physical location and destination, ascribing losses only as energy may obviously be dissipated by radiation to the atmosphere from hot pipes or surfaces, in the hot stack-gases from the furnace, by conduction to the circulating water, or by mechanical friction in the moving parts of machines. Because the development of such an accounting is dependent only on the conservation of energy principle it may be designated as a *first law energy balance*.

The evolution of a first law balance must proceed from specific information concerning the type, arrangement, and interconnections of all steam-using equipment which is installed in the plant and from concrete data or estimates concerning operating conditions and operating efficiencies obtaining in the numerous individual units which comprise the plant. From such information a detailed bookkeeping account may be developed which shall record specifically the amount and character of all energy entering or departing from each device and shall permit a summarization portraying the direction, magnitude, and destination of all component parts of the energy stream en route through the plant.

Such a summarization of the energy account may, as usual, be presented to advantage graphically. Either one of two general types of procedure is commonly employed in the graphic representation. One is illustrated in Fig. 5, in which are depicted diagrammatically the primary components of a simple steam power plant, the interconnecting pipes joining the several devices, the direction of flow between them, the amount of fluid flowing per hour, and pertinent properties of the fluid en route. In the figure there are intentionally presented a plant character and performance which are *not* representative of better modern practice, in order that certain unfortunate features of the plant may the better be recognized. It is observed that the plant is so devised that the various *auxiliary* engines exhaust at about atmospheric pressure and that the exhaust steam from those engines is condensed as far as possible in a heater in which some degree of feedwater heating is thus accomplished.

The second method of presentation of the first law balance appears in Fig. 6. In that figure the character of the interconnections between parts or the fluid properties at specific points are not emphasized but instead there is shown graphically the relative magnitude of the energy quantities at each significant stage in the energy stream. The energy magnitudes are in general expressed in terms of the total enthalpies of the mass of fluid passing a given section in a unit time. The enthalpies are those with respect to a relative zero of enthalpy for water at 32 deg fahr, and in that feature the diagram may be to an extent misleading as the fluid does not and practically could not attain that temperature at any point in the cycle. This procedure is followed because it is the conventional and more convenient one. The figure portrays with maximum clarity the general directions of the energy stream through the plant, the manner of distribution of the energy en route, and the unfortunately small proportion of the initial energy from the fuel which actually is made available as work output.

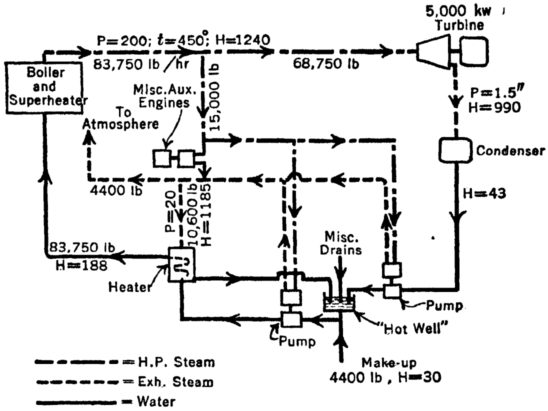

FIG. 5. Diagram for First Law Energy Balance

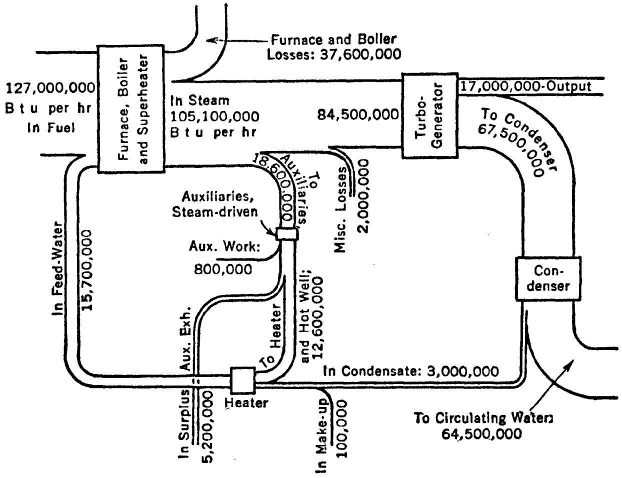

FIG. 6. Diagram for First Law Energy Balance

It is to be observed that in Fig. 5 the combined steam exhaust from the various auxiliary engines is shown to be in excess of that which can practicably be condensed in the feedwater heater, whereby there exists a surplus of auxiliary exhaust which must be rejected to the atmosphere. This condition would obviously be an inefficient one. To avoid its existence, as well as to avoid the opposite circumstance of an exhaust steam supply which is insufficient for adequate feedwater heating, is one frequent objective of the development of an energy balance in the design of a plant. Also, in recognition of the necessity of assuring a proper balance between the amount of auxiliary exhaust steam and the amount which can profitably be employed for the purpose of feedwater heating, the notion of energy balancing and the terms *heat-balance design, heat-balance arrangement, heat-balance diagram,* etc., are frequently employed in a somewhat limited sense referring only to the arrangement and character of the auxiliary machinery as that influences the proper balance between the exhaust steam supply and the possibility for its utilization.

The maintenance of such a suitable balance under all normal operating conditions in the large and complex power plant becomes a very nice problem indeed and one offering many varieties of solution. It becomes still more important that the designer adequately recognize the requirement of avoiding to the maximum practicable limit the *dissipation of available energy to unavailable* by reason of any serious degree of irreversibility in any of the numerous energy transition processes which take place in the plant. A valuable device for the detection and avoidance of such irreversibilities is what is known as a *second law energy balance.*

Heater

FIG. 7. Diagram for Second Law Energy Balance

The general procedure in the development of a second law balance is first that of determining the energy quantities throughout the energy stream, quite as in the first law balance, and then the separation of the energy passing each significant point in the stream into its inherently unavailable and ideally available portions. The results of such a subdivision of the energy stream of Fig. 6 are presented in Fig. 7.

The features which are perhaps of more outstanding significance in the figure are (*a*) the pronounced dissipation of available energy which occurs in the energy transition from the high-temperature furnace region to the relatively moderate-temperature steam and (*b*) the quite appreciable dissipation of available energy and consequent loss of overall plant efficiency which result from inefficient auxiliary machinery and thermally irreversible heat transmission occurring in the feedwater heating equipment.

23. MODERN VAPOR CYCLES *

From consideration of the Carnot cycle and its efficiency fraction, $(T_1 - T_2)/T_1$, it is evident that the efficiency of a temperature-engine cycle may be increased by increase of the temperature at which the fluid receives its energy from the source, or by decrease of the temperature to which the fluid expands reversibly in the engine and at which therefore it discards the unavailable residue of energy to the receiver. In a vapor cycle such as the

---

* For a more complete discussion of this subject see Heat Power Engineering, Barnard, Ellenwood and Hirshfeld. Part I, Chap. XVIII, John Wiley & Sons, 1926.

Rankine the temperature of energy rejection is established primarily and practically by that of the atmosphere or of the natural supplies of water in the streams, lakes, or seas. The attainment of suitable cyclic efficiency requires that the fluid shall expand as closely as practicable to this temperature. With water as the working fluid, this requires that a very low pressure (high vacuum) be maintained in the condenser. In order to gain efficiency by increase of the temperature of energy reception in the Rankine vapor cycle the temperature of vaporization may be raised by increase of vapor pressure or the average temperature of energy reception may be raised moderately by superheating after vaporization is completed.

For a like temperature range in each, the Rankine cycle may not attain the thermal efficiency of a wholly reversible cycle such as the Carnot. For a cycle operating without superheat this is in one sense due to the lower average temperature of the liquid during warming from the condensing to the vaporizing temperature. From an alternative and perhaps more fundamental viewpoint the reduced efficiency is due to thermal irreversibility associated with the liquid-warming phase of the cycle. This irreversibility may be reduced by the use of *stage* or *regenerative* feed-heating, and the cyclic efficiency may thereby be sensibly bettered. The improvement of efficiency resulting from superheating may be doubly realized by the expedient of *resuperheating* the vapor after partial expansion through the engine. The benefits of high vaporization temperatures may be obtained without the disadvantage of high attendant pressures by the use of a fluid of lower vapor pressure than water. All these expedients are employed in modern power plant practice.

Fig. 8. Binary-fluid (Mercury-water) Cycle

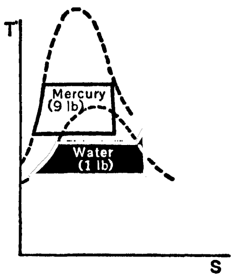

Fig. 9. T–S Diagram for Mercury-water Cycle

The Regenerative Feed-heating Cycle employs a method of progressive liquid warming in a series of heaters which are activated by steam extracted from the engine after more or less complete expansion therein. Thermal irreversibility is thus reduced by accomplishing the first portion of the warming with lower-temperature steam the available energy of which has been well realized in the engine, by similarly accomplishing the next step in the warming of the liquid by medium-temperature steam, and so on. This particular method of efficiency betterment by reduction of thermal irreversibility in the feed-heating is simply illustrative of the gains invariably to be secured by the reduction of any irreversible features. The cycle is best analyzed in detail by writing and solving the energy equation for each successive heater in order from the highest-pressure heater down. Thereby the relative amount of steam to be extracted for each heater may be computed, whereupon the available energy output obtainable in each successive portion of the engine may be determined.

The Reheating Cycle may effect an ideal efficiency betterment only if the resuperheating of the partially expanded steam is accomplished by energy supplied directly from the primary source (the hot furnace gases) and if the resuperheating serves to raise the average temperature of energy reception by the fluid from that source. The analysis of the cycle is quite like that of the Rankine cycle except in the necessity for recognizing the two-stage character of the expansion in the engine and for properly accounting the additional energy supplied to the fluid in the resuperheater. The cycle lends itself well to the addition of regenerative feed-heating.

Binary-Fluid Cycles are employed for the purpose of permitting high average temperatures of energy reception from the source without the handicap of difficultly high fluid pressures in the higher-temperature portion of the cycle. This is accomplished by employing in that portion of the cycle a fluid which has favorable vapor pressure-temperature characteristics. Such advantageous pressure-temperature characteristics may be utilized by employing a fluid of relatively lower vapor pressure in a higher-temperature section

of the composite cycle and a fluid of higher vapor pressure in a lower-temperature section. A compound cycle of this character which employs the two fluids mercury and water is in successful use at this writing. The general scheme of arrangement of the apparatus of this binary-fluid cycle is shown in Fig. 8. Observe that the energy rejected from the condensing mercury forms the energy source for the vaporizing water. In Fig. 9 there is shown a *T-S* chart for 9 lb of mercury and for 1 lb of water. These are about the requisite proportions between the rates of mercury and water circulation in the cycle, because the relative latent heats are such that the heat delivered in condensing 1 lb of mercury after expansion through the mercury turbine is about one-ninth of the heat required to evaporate 1 lb of water.

24. THE STEAM GENERATING UNIT*

Steam Generating Unit is the modern name used to describe the combined equipment required in the steam power cycle for the addition of heat to the working fluid, water. This consists not only of a furnace and boiler but, in the more modern plants, may include some or all of other heat-absorbing elements such as a superheater, economizer, air preheater, steam reheater, and air- or water-cooled furnace walls.

The Steam-Generating Capacity of the unit may be expressed either in terms of

(1) The maximum rate of heat absorption by the unit, expressed either in *kilo Btu* (kB) *per hour*, or in *mega Btu* (mB) *per hour* (kB = 1000 Btu, mB = 1000 kB = 1,000,000 Btu), or

(2) The maximum rate of steam formation, in *pounds per hour*, or multiples thereof, together with a statement of the pressure and temperature of the steam and of the feedwater.

The Efficiency of a Steam-generating Unit is the fraction that shows what portion of the heat supplied by the fuel used in a definite time has been absorbed by the water and steam passing through the unit in the same time. When a true measure of the performance of a unit is required, the energy consumption of its auxiliaries must be deducted from the gross output. The ratio of the resulting net output of the unit to the energy supplied in the form of fuel is the true efficiency of the steam generating unit.

$$\text{Eff.} = \frac{w_n(h_2 - h_1)}{w_f(\text{H.V.})}$$

in which h_1 = the enthalpy of the feedwater at the inlet to the first heating element of the unit (e.g., to the economizer when installed, otherwise to the boiler itself), in Btu per pound.

h_2 = the enthalpy of the steam at the outlet from the superheater (or from the boiler if no superheater is installed), in Btu per pound.

H.V. = the heating value of the fuel, *as fired*, in Btu per pound.

w_f = weight of fuel fired, in pounds per hour.

w_n = net weight of steam delivered by the superheater, in pounds per hour.

= gross weight − auxiliary steam.

The Energy Used by the Auxiliaries may be consumed by steam jets, steam engines, turbines, or electric motors needed to operate the various pieces of equipment which comprise the generating unit. The electric energy consumed should be converted into its steam equivalent. The total steam equivalent of all auxiliaries should then be deducted from the total weight of steam produced in order to determine the net energy output of the generating unit. The weight of auxiliary steam equivalent to the electrical energy consumption of the auxiliaries, in pounds per hour, is

$$w_s = (F_n)(1 - E_a)\left(\begin{array}{l}\text{Rate of}\\ \text{firing,}\\ \text{tons}\\ \text{per}\\ \text{hour}\end{array}\right)\left(\begin{array}{l}\text{Auxiliary}\\ \text{energy of the}\\ \text{steam-generating}\\ \text{unit, kilowatthours}\\ \text{per ton of fuel}\end{array}\right)\left(\begin{array}{l}\text{Actual}\\ \text{evaporation,}\\ \text{pounds of}\\ \text{steam per}\\ \text{pound of fuel}\end{array}\right)$$

or

$$w_s = (F_n)(1 - E_a)\left(\begin{array}{l}\text{Auxiliary power of}\\ \text{the steam-generating}\\ \text{unit, in kilowatts}\end{array}\right)\left(\begin{array}{l}\text{Actual}\\ \text{evaporation,}\\ \text{pounds of}\\ \text{steam per}\\ \text{pound of fuel}\end{array}\right),$$

in which F_n = net fuel rate of the station, in pounds of fuel fired per kilowatthours sent out from the station.

E_a = fraction of the main generator gross output required to operate all the station auxiliaries, as determined by test.

*** This section is reprinted in a modified form, by permission, from Barnard, Ellenwood, and Hirshfeld, Heat-Power Engineering, Part II, John Wiley & Sons.**

The Losses of Energy that Occur in a Steam-generating Unit and thereby affect its efficiency are the following:

(1) *Loss from the incomplete combustion of the fuel* as evidenced by the presence of:
  (*a*) combustible in the refuse collected in the ash pit;
  (*b*) combustible, such as solid carbon, carbon monoxide, hydrogen, and hydrocarbons, in the exit gas.
(2) *Loss to the stack not caused by incomplete combustion but due to*:
  (*a*) the dry exit gases leaving the last heating surface at a higher temperature than that of the atmosphere;
  (*b*) the water vapor, which accompanies the dry gas, leaving the last heating surface at a higher temperature than that of the air and fuel from which it came.
(3) *Loss by heat transfer from the entire unit to the surrounding air.*

The magnitudes of these losses are variables which depend upon the type and quality of fuel used, size and type of equipment, load on the unit, and the manner in which the plant is operated.

The Boiler Energy Balance

A study of the magnitudes of the losses is of importance to the operating engineer. It serves as a basis for comparison of the performance of different steam-generating units. Any tabulation prepared with the object of evaluating the various energy items of a plant constitutes an energy balance. Such a tabulation applied to a steam-generating unit is usually called a boiler energy balance. The items generally found in such a statement are:

1. Energy absorbed by steam in the boiler.
2. Energy carried away by the dry flue gas.
3. Energy loss due to unburned combustible in refuse.
4. Energy loss due to incomplete combustion of C to CO instead of to CO_2.
5. Energy carried away by surface moisture in the fuel.
6. Energy carried away by moisture resulting from combustion of hydrogen.
7. Energy carried away by moisture in the air used for combustion.
8. Radiation and unaccounted-for losses.

Convenient methods for determining each of these items will be outlined briefly in the succeeding paragraphs.

1. Energy Absorbed by Steam in Boiler.

$$Q = (H_2 - H_1)W \tag{1}$$

where H_2 = enthalpy of steam at exit, Btu per pound.
H_1 = enthalpy of water at entrance, Btu per pound.
Q = heat absorbed by steam, Btu per pound of fuel.
W = pounds of steam per pound of fuel as fired.

2. Energy Carried away by Dry Flue Gas. The weight of dry flue gas per pound of fuel may be found in the following manner: The gases found in the analysis of a sample of the dry products of combustion of a fuel are CO_2, CO, O_2 and N_2. These constituents are determined as volumetric percentages, or the analysis gives the volume of each constituent per 100 volumes of mixture.

Therefore since a molecular weight in pounds of any gas occupies approximately 358 cu ft at 32 deg fahr and atmospheric pressure, the relative weight of the percentage volume of each gas in the mixture will be its percentage volume multiplied by *molecular weight in pounds.*

If the carbon balance is used as a basis of calculation, it is assumed that all the carbon appearing in the flue gas in the form of CO_2 and CO has come from the carbon in the fuel *that was burned.*

Hence

$$\frac{\text{Lb of dry flue gas}}{\text{Lb (CO}_2\text{ and CO)}} = \frac{{}^{44}/_{358}\,CO_2 + {}^{28}/_{358}\,CO + {}^{32}/_{358}\,O_2 + {}^{28}/_{358}\,N_2}{{}^{44}/_{358}\,CO_2 + {}^{28}/_{358}\,CO} = \frac{44\,CO_2 + 28\,CO + 32\,O_2 + 28\,N_2}{44\,CO_2 + 28\,CO}$$

But CO_2 is, by weight, $^{12}/_{44}$ carbon and $^{32}/_{44}$ oxygen, and CO is, by weight, $^{12}/_{28}$ carbon and $^{16}/_{28}$ oxygen; therefore

$$\frac{\text{Lb dry flue gas}}{\text{Lb carbon in fuel}} = \frac{44\,CO_2 + 28\,CO + 32\,O_2 + 28\,N_2}{{}^{12}/_{44} \times 44\,CO_2 + {}^{12}/_{28} \times 28\,CO} = \frac{44\,CO_2 + 28\,CO + 32\,O_2 + 28\,N_2}{12\,(CO_2 + CO)}$$

Since a pound of fuel does not contain a pound of carbon, and since, in any event, all the combustible is seldom burned, the above expression can be multiplied by the percentage of carbon in the fuel *actually burned*, C_g (equal to C in fuel − C in refuse), to get the weight of flue gas per pound of fuel. Thus

$$W_{fg} = \frac{\text{Lb dry flue gas}}{\text{Lb coal}} = C_g \times \frac{44\ CO_2 + 28\ CO + 32\ O_2 + 28\ N_2}{12\ (CO_2 + CO)} \tag{2}$$

Sulfur dioxide has been purposely omitted from the above expression since the quantity of this gas present in a sample of dry flue gas is generally quite small, and also since its presence can not be detected with the ordinary apparatus available for flue-gas analysis. The weight and volume of SO_2 can be computed easily if desired from the elementary combustion equation $S + O_2 = SO_2$.

Assuming specific heat and pressure each to be essentially constant, the energy carried away by the dry flue gas is

$$h_2 = W_{fg} \times C_p \times (t_c - t_1) \tag{3}$$

where t_c = gas temperature, at boiler outlet, degrees fahrenheit.
t_1 = air temperature at entrance to furnace, degrees fahrenheit.
C_p = mean specific heat of dry flue gas between t_1 and t_c, Btu per pound per degree fahrenheit.
C_p = 0.240–0.250 average value.

3. Energy Loss Due to Unburned Combustible in Refuse. The unburned combustible in the refuse consists of small amounts of unburned or incompletely burned fuel, and may be assumed to be essentially carbon. The energy loss involved is

$$h_3 = C_r \times 14{,}600 \tag{4}$$

where C_r = weight of combustible in refuse per pound of fuel.
14,600 = approximate heating value of this combustible per pound.

4. Energy Loss Due to Incomplete Combustion of C to CO. When insufficient air is supplied for combustion or when air and fuel are not intimately and thoroughly mixed, part of the carbon may burn to CO instead of CO_2. A pound of C burning to CO_2 releases 14,540 Btu per lb of carbon, whereas when a pound of carbon is burned to CO, only 4480 Btu are released per pound of carbon. The loss here, then, is 14,540 − 4480 = 10,160 Btu per lb C burning to CO.

The weight of C burning to CO can be determined from the flue-gas analysis by a method similar to that employed in paragraph 2.

$$\frac{\text{Weight of carbon monoxide}}{\text{Weight of carbon monoxide and dioxide}} = \frac{{}^{28}/_{358}\ CO}{{}^{44}/_{358}\ CO_2 + {}^{28}/_{358} \times CO} = \frac{28\ CO}{44\ CO_2 + 28\ CO}$$

where CO and CO_2 are percentages of carbon monoxide and carbon dioxide by volume.

Since all the carbon in the flue gas (present as CO_2 and CO) must have come from that carbon in the fuel *that was actually burned*, and since, by weight, carbon monoxide is ${}^{12}/_{28}$ carbon, and carbon dioxide is ${}^{12}/_{44}$ carbon, then the weight of carbon, W_c, present in the CO content of the flue gases is

$$\frac{{}^{12}/_{28} \times 28\ CO}{{}^{12}/_{44}\ CO_2 + {}^{12}/_{28}\ CO} \times C_g = \frac{CO}{CO_2 + CO} \times C_g$$

where C_g, CO_2, and CO are as in paragraph 2.

The energy loss resulting from the CO is

$$h_4 = W_c \times 10{,}160 = 10{,}160 \times \frac{CO}{CO_2 + CO} \times C_g \tag{5}$$

5. Energy Carried away by Surface Moisture in Fuel. Most of the surface moisture in a fuel probably evaporates between temperatures of 70 and 120 deg fahr. To accomplish this, energy must be supplied by the fuel in sufficient amount (*a*) to raise the moisture to the vaporization temperature, (*b*) to evaporate it at this temperature, and (*c*) to raise its temperature to that of the flue gas at exit from the boiler. Steam tables would be required for a scientific calculation of this item. In lieu of this rather elaborate method the following simplification can be used:

$$h_5 = W_{mf} \times (1090 - t + 0.46\ t_c) \tag{6}$$

where W_{mf} = pounds of surface water per pound of fuel.
t = temperature of fuel, degrees fahrenheit.
t_c = temperature of gases at boiler outlet, degrees fahrenheit.

6. Energy Carried away by Moisture Resulting from Combustion of H_2. At precisely what temperature the formation of water vapor takes place is unknown. It is generally assumed, however, that it occurs at the outset of combustion. Whence, the parenthetical quantity in the preceding equation can be used to determine the loss per pound of moisture, or since 9 lb of moisture result from the combination of 1 lb of H_2

$$h_6 = 9H(1090 - t + 0.46\,t_c) \tag{7}$$

where H = percentage of H_2 in fuel by weight; other symbols as in equation (6).

7. Energy Carried away by Moisture in Air. The moisture in the air used for combustion has already been raised in temperature to the vaporization point and has been completely vaporized. Hence the only energy absorbed by it within the furnace is that required to raise the temperature of this vapor to that of the flue gases at boiler outlet, or

$$h_7 = W_{ma}\,0.46(t_c - t_1) \tag{8}$$

where t_c = flue gas temperature at boiler outlet, degrees fahrenheit.
t_1 = air temperature at entrance to furnace.
W_{ma} = weight of moisture in air per pound of fuel.

8. Radiation and Unaccounted-for Losses. It is generally assumed that the preceding seven items constitute the principal manners in which the heating value of the fuel is distributed. Hence all other items are included under the head of radiation and unaccounted-for, or

$$h_8 = \text{H.H.V. of fuel} - \text{items 1–7 inclusive} \tag{9}$$

Example. The following typical problem will illustrate the determination of the various items of the boiler heat balance.

Given: Coal analysis, as fired, C, 65%; O, 8%; H, 5%; N, 1 %; ash, 13%; H_2O, 8%; heating value, 11,850 Btu per lb. Pounds of steam per pound of coal = 8.5.

Flue gas analysis (by volume) CO_2, 12.8%; CO, 0.6%; O_2, 5.4%; N_2, 81.2%.

Air and fuel enter furnace at 70 deg fahr; gas temperature at boiler outlet = 470 deg fahr; temperature of steam in boiler = 400 deg fahr; combustible in refuse = 20%; moisture in air = 0.5% of weight of dry air. Boiler pressure = 210 lb per sq in. abs. Feed water temperature = 180 deg. fahr.

Solution. Since Refuse = Ash + Carbon, Weight of refuse = $\frac{0.13}{0.80} \times 0.20 = 0.0325$ lb per lb coal, as fired.

Hence, carbon burned = $C_g = 0.65 - 0.0325 = 0.6175$ lb per lb coal, as fired.

Weight of dry flue gas, by equation (2) = 11.62 lb per lb coal, as fired.

Weight of dry air supplied = $DFG + H_2O + SO_2 + \text{Ash} - 1 = 11.2$ lb per lb coal as fired.

"*DFG*" signifies dry flue gas.

Boiler Energy Balance

Eq.	Energy Item	Calculation	Btu	%
1	Absorbed by boiler............	$(1207.9 - 147.87)8.5$	9,000	76.00
2	Absorbed by *DFG*............	$11.62 \times 0.24 \times (470 - 70)$	1,118	9.41
3	Loss due C in refuse..........	$0.0325 \times 14{,}600$	475	4.00
4	Loss due CO..................	$0.6175 \times 10{,}160 \times 0.6(12.8 + 0.6)$	280	2.36
5	Absorbed by H_2O in fuel.......	$0.08(1090 + 0.46 \times 470 - 70)$	99	0.83
6	Absorbed by H_2O from H_2.....	$9 \times 0.05(1090 + 0.46 \times 470 - 70)$	556	4.70
7	Absorbed by H_2O in air.......	$0.005 \times 11.2 \times 0.46(470 - 70)$	103	0.86
8	Radiation, etc.................	By difference	219	1.84
		Total......	11,850	100.00

Overall boiler efficiency = 9000 ÷ 11,850 = 0.76 = 76 per cent.

Interpretation of Boiler Balance. The energy balance as calculated gives the distribution of the *actual* energy quantities. Some of the losses can be reduced or eliminated entirely; others are always present and are *inherent* losses. An energy balance setting forth the inherent losses will enable the reader to tell at a glance where improvement may be made, and where no further gain will be possible. For instance, air supplied for combustion may be reduced, thus decreasing the excess air, and hence energy carried away by dry flue gas; but the air cannot be reduced below the theoretical requirements. Similarly, by suitable baffling and maintenance of optimum flue-gas velocity and rate of fuel firing, the temperature of the flue gas may be reduced, but it can never be reduced below the temperature of the steam leaving the boiler (without an economizer). The following tabulations will further clarify the point. All items are per pound of fuel as fired.

Distribution of Inherent Losses

Eq.	Name	Calculation	Btu	%
2	Absorbed by *DFG*	$9.26^* \times 0.24 \times (400 - 70)$	733.4	6.19
3	Loss due C in refuse		0.0	0.00
4	Loss due CO		0.0	0.00
5	Absorbed by H_2O in fuel	$0.08(1090 - 70 + 0.46 \times 400)$	96.3	0.81
6	Absorbed by H_2O from H_2	$9 \times 0.05(1090 - 70 + 0.46 \times 400)$	541.8	4.57
7	Absorbed by H_2O in air	$0.005 \times 8.92^* \times 0.46(400 - 70)$	67.7	0.57
8	Radiation, etc.		0.0	0.00
1	Absorbed by ideal boiler	By difference	10,410.8	87.86
		Total	11,850.0	100.00

* Theoretical, for perfect combustion.

Comparison of Actual and Inherent Losses

Item	Actual %	Inherent %
Absorbed by boiler	76.00	87.86
Absorbed by dry flue gas	9.41	6.19
Loss due C in refuse	4.00	0.00
Loss due CO	2.36	0.00
Absorbed by H_2O in fuel	0.83	0.81
Absorbed by H_2O from H_2	4.70	4.57
Absorbed by H_2O in air	0.86	0.57
Radiation, etc.	1.84	0.00
Total	100.00	100.00

25. STEAM ENGINES AND TURBINES

The engine of the steam cycle treated in Arts. 20–23 may be either of two general types, the reciprocating engine, commonly referred to as the *steam engine*, or the turbine engine, commonly referred to as the *steam turbine*. Given the same initial conditions of the steam and the same exhaust conditions the ideal thermal efficiencies of the steam engine and the turbine are exactly the same. The use of one or the other for a specific purpose is determined by practical or economic considerations. The measures of efficiency and performance developed in Art. 21 are applicable to both the steam engine and the steam turbine.

A Simple Steam Engine is one in which the expansion of steam is completed in one cylinder.

A Compound Steam Engine is one in which the steam progressively expands in two or more cylinders. The term *compound*, without qualification, refers to the two-cylinder arrangement. A *triple-expansion* engine means that the expansion is completed in three stages or cylinders, and a *quadruple-expansion* engine means that the expansion is completed in four stages or cylinders. Compound engines may have the cylinders arranged in various ways such as: tandem-compound, cylinders placed one behind the other in line; angle-compound, cylinder axes placed at right angles to one another; cross-compound, cylinders arranged side by side; and vertical triple expansion, three cylinders placed with axes vertical.

An engine may operate *non-condensing*, i.e., exhausting to the atmosphere, or *condensing*, i.e., exhausting into a condenser in which a vacuum is maintained.

A Single-acting Engine is one in which steam is admitted only to one side of the piston. A *double-acting* engine is one in which steam is admitted alternately to each side of the piston.

Valves. A *slide valve* is a valve which controls the inlet and exhaust of steam by sliding across the ports. A *poppet valve* is a disk, fitting a port, which is raised or lowered for the control of inlet and exhaust. A *Corliss valve* has a cylindrical surface which oscillates through a small angle to open or close the port. Each event is separately controlled. The main feature of this valve is the quick closure of the steam port, obtained by a trip-gear on the inlet valve. The more recent high-speed Corliss engine has positive control of the valves at all times.

The exhaust valve of the *uniflow engine* is the piston itself, which functions with

respect to the exhaust ports located at the middle of the cylinder. The inlet valves, located at the ends of the cylinder, may be of any type.

Steam Engine Speed is governed in two ways: by throttling the steam supply, or by varying the cut-off.

Indicator Diagram. An indicator diagram is a diagram (see Fig. 8), showing the steam pressure in the engine cylinder at each point of the stroke. Such a diagram may be actually obtained by means of a steam-engine indicator, which is an instrument which causes a pencil to record on paper the pressure in the cylinder at every point of the stroke. The diagram drawn by the pencil shows whether the valves are properly adjusted, and it is also used in figuring the power developed in the cylinder, and the approximate steam consumption. A diagram of a non-condensing engine in which the steam is cut off at about one-quarter of the stroke is shown in Fig. 10.

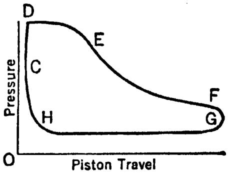

Fig. 10. Indicator Diagram of a Simple Steam Engine

The lines and points have the following significance.

Point of Admission, C, is the point at which the steam valve opens.

Admission Line, CD, shows the rise of pressure due to the admission of steam to the cylinder by opening the steam valve.

Steam Line, DE, is drawn when the steam valve is open and steam is being admitted to the cylinder.

Point of Cut-off, E, is the point where the admission of steam is stopped by the closing of the valve. It is often difficult to determine the exact point at which the cut-off takes place. It is usually located where the outline of the diagram changes its curvature from convex to concave.

Expansion Curve, EF, shows the fall in pressure as the steam in the cylinder expands doing work.

Point of Release, F, shows when the exhaust valve opens.

Exhaust Line, FG, represents the change in pressure that takes place when the exhaust valve opens.

Back-pressure Line, GH, shows the pressure against which the piston acts during its return stroke.

Point of Exhaust Closure, H, is the point where the exhaust valve closes. It cannot be located definitely, as the change in pressure is at first due to the gradual closing of the valve.

Compression Curve, HC, shows the rise in pressure due to the compression of the steam remaining in the cylinder after the exhaust valve has closed.

Initial Pressure is the pressure acting on the piston at the beginning of the stroke.

Terminal Pressure is the pressure above the line of perfect vacuum that would exist at the end of the stroke if the steam had not been released earlier. It is found by continuing the expansion curve to the end of the diagram.

The Indicated Mean Effective Pressure, found by dividing the diagram area by its length and multiplying the quotient by the pressure scale of the diagram, is in a broader sense that equivalent pressure which, if acting unopposed upon the piston face during the power stroke of a cycle, would produce the net amount of work output actually delivered per cycle.

Indicated Work per Cycle, ft-lb, $= \text{Imep} \times A \times L$

$$= P_m \times A \times L$$

where P_m = abbreviation for the mean effective pressure, pounds per square foot.
A = piston area, upon which the pressure acts, square feet.
P_mA = mean effective force acting on piston face, pounds.
L = length of piston stroke, feet.

The indicated horsepower is

$$\text{Ihp} = \frac{P_m ALN}{33{,}000}$$

where N = the number of power strokes per minute (2 per revolution for simple double-acting engine).

The Brake Horsepower of an engine is calculated by the use of

$$\text{Bhp} = \frac{2\,\pi rwn}{33{,}000}$$

where r = radius of brake arm, feet.
w = force acting at end of brake arm, pounds.
n = number of revolutions per minute.

The Brake Mean Effective Pressure, Bmep, useful for comparison purposes, is found by dividing the Bhp by the term $\frac{LAN}{33,000}$.

The mechanical efficiency of the engine may be stated,

$$\text{Mechanical efficiency} = \frac{\text{Bmep}}{\text{Imep}} = \frac{\text{Bhp}}{\text{Ihp}}$$

The Ideal Thermal Efficiency of the steam engine is the same as that for the Rankine cycle, Art. 21. The actual thermal efficiency of the steam engine is the same as that for the steam cycle, but may be based on either indicated horsepower or brake horsepower. Likewise the engine efficiency, heat rate, and steam rates of the steam engine are the same as for the steam cycle, and each may be based on either indicated horsepower or brake horsepower.

Tests. For detailed methods of tests of steam engines, as well as of all other power machinery, reference should be made to the Power Test Codes published by the American Society of Mechanical Engineers, New York.

The following summary represents briefly the generally accepted ideas regarding the cylinder action and the losses in the reciprocating steam engine.

A. The losses of available energy in the steam engine are due to the following causes arranged in the approximate order of magnitude of loss:

1. Initial or surface condensation.
2. Incomplete expansion and early release.
3. Throttling of steam flowing through partly open valves.
4. Leakage of steam past piston and closed valves.
5. Friction of moving parts.
6. Heat loss by radiation and conduction.
7. Compression and early admission.

B. Initial or surface condensation is increased by the following conditions:

1. Early cut-off and large ratio of expansion.
2. Large pressure and temperature range in a single cylinder.
3. Small cylinder diameters, because the exposed surface is large in comparison with the volume.
4. Steam supply saturated or wet.
5. Long valve passages and the use of the same passage for admission and exhaust steam.

C. Conditions favorable to reduction of initial condensation are:

1. Late cut-off and small expansion ratio (but this increases loss due to incomplete expansion in simple engines).
2. Superheat.
3. Separate valves for admission and exhaust, and short valve passages.
4. High compression.
5. Compounding.
6. Uniflow principle.

Types of Turbines

In the Turbine Engine, or steam turbine the energy conversion to work is accomplished by means of the conversion of the available portion of the internal energy of the steam into mechanical kinetic energy of a jet in stationary or moving nozzles, and then the conversion of this mechanical kinetic energy of the jet into work on a shaft by allowing the jet to change its direction of motion while passing over moving vanes or blades.

In the Impulse Turbine the steam pressure drop and consequent development of kinetic energy take place solely in the stationary nozzles, and the work is obtained by the conversion of this kinetic energy into work on moving blades. In the *reaction* turbine only a part (about half) of the kinetic energy conversion occurs in the stationary nozzle, the remainder of the kinetic energy conversion being accomplished by a pressure drop in the steam as it passes through the moving blades. The efficiencies and other performance of the steam turbine are the same as for the reciprocating engine except that for the turbine the items of indicated horsepower and mechanical efficiency are missing.

De Laval Turbine. The characteristic features of the *De Laval turbine* are the diverging nozzles which expand the steam to the back pressure in a single stage, and a single steel disk, mounted on a slender flexible shaft, carrying the blades on its periphery.

The Rateau Turbine consists of a number of De Laval elements in series. The steam expands in several pressure stages until completely expanded to the back pressure.

The Parsons Turbine is a reaction turbine in which there are a large number of rows of blades mounted on a rotor or revolving drum. Between each of these rows of blades is a row of stationary blades attached to the casing. The steam expands to a lower pressure in both sets of blades. A set of stationary blades and the following set of moving blades constitute what is known as a *stage*.

Several combinations of these different types are in use. A summary of the principal features of construction and the operating characteristics of several widely used types of turbines is given in Table I.

Table I *

Classification	Type	Characteristics	
		Physical	Operating
Impulse	De Laval	One nozzle or set of nozzles. Single disk with one row of blades. One passage of steam across blades.	High steam velocities. High wheel velocities. Large pressure drop in nozzle.
	Simple Curtis	One nozzle or set of nozzles. Single disk with two or more rows of blades. Intermediate reversing blades. One passage of steam across each blade row.	Moderate wheel speed. Large pressure drop in nozzle. Same pressure throughout stage.
	Re-entry (*a*) Axial flow (*b*) Tangential type	One nozzle or set of nozzles. Single row of blades or buckets. Reversing chambers to redirect steam on blades one or more times.	Usually moderate wheel speed. High wheel speeds in geared sets. Large pressure drop in nozzle.
	Rateau	Series of De Laval wheels with intermediate diaphragms carrying orifices. Usually, large number of stages.	Small pressure drop per stage. Most efficient ratio of wheel speed to steam speed can be secured.
	Multistage Curtis	Series of simple Curtis wheels separated by diaphragms carrying orifices. Usually relatively few stages.	Relatively large pressure drop per stage.
Reaction	Axial flow, Parsons	Series of alternate rows of converging fixed and moving blades. Moving blades mounted usually on several drums. Steam flows axially.	Small pressure drop per row. Large number of rows. Long spindles. Most efficient ratio of wheel speed to steam speed possible.
	Radial flow, Ljungstrom	Series of radial rings of converging reaction blades. Alternate rings revolve in opposite directions.	High ratio of blade speed to steam speed. Elaborate steam packing devices.
Combination Types	Curtis-Rateau	One Curtis stage followed by several simple-impulse stages.	Only moderate temperatures and pressures in casing due to large pressure drop in first nozzle.
	Curtis-Parsons	One Curtis stage followed by a series of Parsons stages. Usually disk and drum construction.	Temperatures in casing low, since steam is expanded in nozzle.

* Based on Kent.

26. STEAM CONDENSERS AND OTHER HEAT TRANSFER APPARATUS

Steam Condensers are either of the *jet* type, in which the condensate mixes with the cooling water and from which both are discharged together, or of the *surface* type, in which the two fluids are kept separate by thin metallic walls and are handled independently.

The Weight of Water necessary to condense a given weight of steam may be found for any type of condenser from the equation that expresses the energy balance for the condenser. Neglecting the effect of the presence of air, changes in velocity, and heat lost to the atmosphere,

$$w_s(H_s - H_c) = w_w(H_2 - H_1)$$

where w_s and w_w = the respective weights, in pounds, of steam and condensing water flowing through the condenser in a unit of time, usually the hour.
H_1 and H_2 = the respective enthalpies of the condensing water entering and leaving the condenser, in Btu per pound.
H_s = the enthalpy of the steam entering the condenser, in Btu per pound.
H_c = the enthalpy of the condensate leaving the condenser, in Btu per pound.

Then, the weight of condensing water per unit weight of steam becomes

$$\frac{w_w}{w_s} = \frac{H_s - H_c}{H_2 - H_1}$$

or, very closely,
$$\frac{w_w}{w_s} = \frac{H_s - (t_c - 32)}{t_2 - t_1} = \frac{H_s - (t_c - 32)}{t_s - (t_1 + \theta_b)}$$

where t_1 and t_2 = the respective temperatures of the condensing water entering and leaving the condenser, in degrees fahrenheit.
t_c = the temperature of the condensate leaving the condenser, in degrees fahrenheit.
t_s = the temperature of the exhaust steam (assuming no superheat), in degrees fahrenheit.
$\theta_b = t_s - t_2$ = terminal temperature difference.

With jet condensers, $t_c = t_2 = t_{\text{mix.}} = t_s - \theta_b$.

Therefore,
$$\frac{w_w}{w_s} = \frac{H_s - t_{\text{mix.}} + 32}{t_{\text{mix.}} - t_1} = \frac{H_s - t_s + \theta_b + 32}{t_s - (t_1 + \theta_b)}$$

Most problems of heat transmission in surface condensers can be solved by the use of the following:

$$w_s(H_s - H_c) = \frac{AU(t_2 - t_1)}{\log_e\left(\dfrac{t_s - t_1}{t_s - t_2}\right)} = w_w\, c_w(t_2 - t_1)$$

where A = the amount of condenser heating surface, in square feet.
c_w = the specific heat of the condensing water.
U = the thermal transmittance, in Btu per hour per degree fahrenheit per square foot of condenser heating surface.
e = Napierian base of logarithms = 2.71828.

The mean temperature difference

$$\frac{t_2 - t_1}{\log_e\left(\dfrac{t_s - t_1}{t_s - t_2}\right)}$$

is commonly called the *logarithmic mean temperature difference.*

Assuming c_w as unity, permissible for fresh water where extreme accuracy is not essential,

$$\log_e\left(\frac{t_s - t_1}{t_s - t_2}\right) = \frac{U}{(w_w/A)}$$

in which (w_w/A) is the number of pounds of circulating water used per hour per square foot of condensing surface.

$$t_s = t_1 + (t_2 - t_1) + \theta_b = t_1 + \frac{H_s - H_c}{(w_w/A)} + \theta_b$$
$$= t_1 + \frac{H_s - H_c}{(w_w/w_s)}\left[\frac{\theta_b}{t_2 - t_1} + 1\right]$$
$$= \frac{t_1 + (t_2 - t_1)}{1 - (e)^{-U/(w_w/A)}}$$

These equations are useful in showing how the steam temperature, and the corresponding absolute pressure, are influenced by the variations in each of the individual factors and ratios appearing in the right-hand members.

Feedwater heaters are either of the *open* type, in which the two fluids mix and from which both are discharged together, or of the *closed* type, in which the two fluids are kept separate and are handled separately.

Neglecting heat loss through the shell

$$w_s(H_a - H_b) = w_f(H_2 - H_1)$$

in which w_s and w_f = the quantities of steam and feedwater flowing through the heater, respectively.
H_a and H_b = the respective enthalpies of the hot fluid entering and leaving the heater, in Btu per pound.
H_1 and H_2 = the respective enthalpies of the feedwater entering and leaving the heater, in Btu per pound.

Since the condensate formed in the open-type heater mixes with the feedwater, H_b and H_2 are equal in this type of heater. For moderate feedwater temperatures c_p of water is near unity; the term $(t_2 - t_1)$ may be substituted for the term $(H_2 - H_1)$, where t_2 and t_1 are the respective temperatures of the feedwater leaving and entering the heater. The problems of heat transmission in the closed feedwater heater are treated the same as those of the surface condenser.

An economizer is an apparatus by which some of the heat from gases leaving the boiler is recovered and used principally to heat feedwater. For heat transmission in economizers,

$$\text{Mean temperature difference} = \frac{\theta_a - \theta_b}{\log_e \dfrac{\theta_a}{\theta_b}}$$

where θ_a = the initial temperature difference of the two fluids, degrees fahrenheit.
θ_b = the final temperature difference of the two fluids, degrees fahrenheit.

And

$$w_g\, c_g(t_a - t_b) = \frac{AU(\theta_a - \theta_b)}{\log_e \dfrac{\theta_a}{\theta_b}} = w_f\, c_f(t_2 - t_1)$$

where w_g = weight, in pounds, of flue gas through the economizer per unit time.
w_f = weight, in pounds, of feedwater through the economizer per unit time.
c_g and c_f = the respective specific heats of the flue gas and feedwater.

Air preheaters, used also to recover some of the heat from gases leaving the boiler, may be of two general types, recuperative and regenerative. For the recuperative type in which the heat is transferred from the flue gases to the air through thin metallic walls the principles of heat transmission are the same as for the economizer. In the regenerative type the heat-transmitting surfaces are exposed alternately to the heat-surrendering gases and to the heat-absorbing air.

THE INTERNAL-COMBUSTION ENGINE

27. GENERAL CHARACTERISTICS

The Internal-combustion Engine constitutes one of the two general types of devices for realizing as shaft work some portion of the available energy associated with the high-temperature products of the combustion of a fuel, the other device being represented by the composite arrangement of furnace, steam boiler, and steam engine or turbine treated in Arts. 20–26. It will be recalled that in the latter arrangement the stored chemical energy of the fuel is released by a process of combustion carried out in a furnace at high temperature levels but at constant atmospheric pressure, that the energy so released is then in part delivered by conduction to moderate-temperature steam which is formed in the boiler under high pressure, and that this steam acts as a carrier through the medium of which energy is delivered to the engine, in which there is finally accomplished a partial transformation of the energy to shaft work and from which the unavailable residue of energy is discarded at about atmospheric temperature. In distinction to this serial procedure in the steam plant the internal-combustion engine effects a more direct utilization of the chemical energy released by the combustion by so confining the burning fuel mixture that a *high pressure is produced (or maintained) in the hot combustion products themselves,* whereby through a suitable mechanism these products may act directly upon a piston to motivate a shaft against whatever resisting force may be imposed by the external load.

The Characteristic Conditions for which the internal-combustion engine must be designed may be summarized as follows:

(A) A major portion of the material which must be introduced into the engine cylinder is the atmospheric air which supplies the oxygen necessary for the combustion. The induction of air from the atmosphere to the engine cylinder may be accomplished in various ways. A very common method is to employ one complete piston stroke for this purpose. An engine which does so is said to operate upon a *four-stroke* cycle. That cycle is described in the following. The alternative or *two-stroke* cycle is considered briefly later.

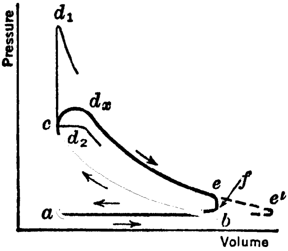

FIG. 1. Indicator Diagram of Internal Combustion Engines

In a continuous graphic record of (*a*) the pressure existing within the space enclosed by the cylinder and piston at any point of the piston travel and (*b*) the total volume of that space at the same piston position, such as is furnished by the engine *indicator*, this induction or *suction* stroke would be represented by a line such as the line *ab* in Fig. 1. During this entry of the fluid through the *intake* valve the pressure within the cylinder will be less than that at the entrance to the induction system by the amount of the pressure drop necessary to accelerate the fluid and to overcome fluid friction in the intake passages.

(B) For both practical and theoretical reasons it is necessary that prior to the combustion of the fuel the fuel mixture or at least the air portion of this mixture shall have been brought to a pressure and temperature materially above those of the atmosphere. This is accomplished by a compression which is caused to take place by a return or *compression* stroke of the piston with all valves closed. For this stroke the simultaneous fluid pressures and volumes would be represented by points on the line *bc*.

(C) For motivation of the engine it is necessary that during the next or *power* stroke of the piston the average fluid pressure shall be materially greater than that during the other strokes. This pressure increase is effected by a pronounced temperature increase of the fluid during and resulting from combustion while confined within the cylinder. This combustion is initiated at or about a point in the piston travel which would be represented by point *c* in the figure.

The rate of combustion (and thus the rates of energy release and of temperature and pressure rise as a result of combustion) is a characteristic which is in effect the major basis for classification of modern engine types. Suitable control of the conditions under which the combustion occurs might permit or cause it to be so rapid and explosive in character as to take place at virtually constant volume and produce a more or less " vertical " rise of temperature and pressure, such as indicated by the line cd_1 in Fig. 1. Alternatively the combustion might be caused to proceed with such lesser rapidity that it would continue through a portion of the power stroke, with the production of a somewhat lesser temperature and pressure rise than would occur under the first conditions. Lines cd_x or cd_2 would be representative of the latter condition.

The exact rate of energy release under this second schedule might be caused to be virtually anything from the one producing almost constant volume combustion to one so relatively slow as simply to maintain a constant temperature and thus to permit a gradual pressure drop following the initiation of the combustion. The line cd_x may be taken as a general one representing any sort of combustion conditions which might obtain. However, the prototype of one of the standard cycles which are employed in present-day internal-combustion engine practice, that is, the *Diesel cycle*, is one in which it is assumed that the pressure shall be maintained constant during and by the combustion, producing a combustion line as represented by cd_2 in the figure. The constant volume combustion of line cd_1 is a basic characteristic of the *Otto cycle*.

To permit the constant volume combustion of the Otto cycle it is necessary that at point *c* in the cycle the engine cylinder shall contain the fuel and air in intimate mixture and thus in effective condition for ignition (by electric spark) and *explosive* combustion. This condition is obtainable by (1) the use of either gaseous fuels or relatively volatile liquid fuels and (2) the atomization and intimate mixing of the fuel with the air in some portion of the cycle prior to the completion of the compression. This mixing is ordinarily done outside of the engine cylinder in a mixing valve or *carburetor* and during the induction of the air on stroke *ab*. It is to be noted, however, that this very presence of a combustible mixture in the cylinder during the compression stroke imposes certain definite limits on the extent of the compression which may be employed in the Otto cycle engine, because of the temperature rise produced by the compression and the resultant tendency toward spontaneous pre-ignition of the mixture, and also by reason of the tendency of numerous fuels toward an abnormally rapid combustion and the production of abnormally and seriously high combustion temperature and pressure if compression is carried beyond certain limits. This latter phenomenon is known as *detonation*.

The progressive, constant pressure combustion of the conventional *Diesel cycle* is securable (1) by withholding the fuel from the engine cylinder until about the completion of the compression stroke, which implies that only air shall have entered during the suction stroke, and (2) by a subsequent progressive injection of an atomized jet of the (liquid) fuel into the cylinder during the combustion period *at a properly controlled rate.* Except in various smaller engines operating on a so-called *semi-Diesel* cycle, the ignition of the fuel is accomplished by compression of the air to so high a pressure P_c that at the end of compression it shall have attained a temperature high enough to induce spontaneous ignition upon the fuel injection. Even under this condition, however, to accomplish suitable ignition and combustion requires that the fuel must be injected in a very finely atomized state.

(**D**) Returning to a consideration of the events of the cycle—except as there is some incompleteness of combustion at point *d* by reason of chemical equilibrium and thus a persistence of combustion, or *after-burning*, beyond that point, the *remainder* of the power or *expansion stroke* provides solely for an expansion of the high-temperature products of combustion. This continues until the end of the stroke is reached, at or somewhat before which point the exhaust valve is opened. Line *de* is representative of this expansion phase. It will be observed that an expansion to the same total volume as that at the beginning of compression (V_b) predicates a release of the combustion products at a pressure which is materially higher than the intake or atmospheric pressure, and also their rejection or exhaust at a temperature very considerably above atmospheric temperature. The available energy loss associated with this temperature and pressure excess might be reduced by arranging for a continuation of the expansion to some greater volume such as the volume $V_{e'}$ of the figure. Such cycles have been and are frequently proposed but have not been developed commercially.

(**E**) Directly upon opening of the exhaust valve there occurs a rapid drop of pressure within the cylinder due to the escape of a portion of the combustion products through the exhaust passages, and upon the following or *exhaust* stroke in a four-stroke cycle the remainder of the products are ejected by the returning piston, except as a portion is left in the *clearance space* between the piston and the head end of the cylinder. These two exhaust processes are represented by lines *ef* and *fa* in Fig. 1. During the exhaust stroke the pressure within the cylinder would exceed that of the exterior by the amount necessary to accelerate the fluid and to overcome fluid friction in the exhaust system. The particular mass of products which remains in the clearance space at the end of any given exhaust stroke is replaced by an equivalent mass at the end of the next cycle; this clearance residue may therefore be regarded as continuously entrapped within the cylinder.

The performance of a complete cycle has thus been described. Observe that for its accomplishment four strokes of the piston have been required, and therefore, as noted above, the cycle would properly be designated as a *four-stroke* cycle. An engine operating on this four-stroke schedule would be described as a *four-cycle* engine whether it might conform to the Otto cycle or the Diesel cycle or any modification of either as regards the degree of compression or the character of combustion.

In lieu of the four-stroke schedule it is possible and wholly practicable to accomplish the introduction of the air or the mixture into the cylinder, its compression, the combustion and expansion, and a sufficient clearing of the combustion products from the cylinder, in two piston strokes. A cycle so carried out is designated, as remarked above, as a *two-stroke* cycle, and an engine operating on the cycle is a *two-cycle* engine. The arrangements by which the cycle is accomplished differ in detail in various engines, but the general procedure is in effect (*a*) to cause the exhaust valves (or ports) to open rather early in the *expansion* stroke, thus facilitating as far as possible the escape of the combustion products without the provision of a separate exhaust stroke, and (*b*) to force the air (or the mixture) into the cylinder and jointly to sweep out the residual combustion products by the use of a low-pressure *scavenger* blower which is caused to discharge to the cylinder during the early portion of the compression stroke, thus eliminating a separate intake stroke. The general appearance of the pressure-volume diagram of a two-stroke

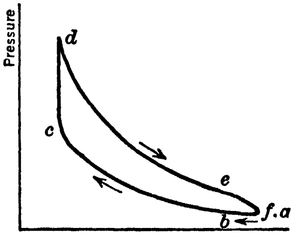

Fig. 2. Indicator Diagram of a 2-cycle Engine

cycle is shown in Fig. 2, in which equivalent phases in the two- and the four-stroke cycles are denoted by the same letters as were used in Fig. 1.

The idealized conditions of operation of an internal-combustion engine may be taken to involve the following general features:

(*a*) Zero resistance and thus zero pressure drop through the intake system, whereby the cylinder pressure during admission might be that of the atmosphere, P_a.

(*b*) A reversible adiabatic compression of the air or mixture, the adiabatic feature being in distinction to the actual condition of energy transfer as heat between the fluid and the water-cooled or air-cooled cylinder of the real engine.

(*c*) A reversible adiabatic combustion phase, which again is in distinction to the actual condition of energy escape as heat from the burning mixture to the cylinder during combustion.

(*d*) A reversible adiabatic expansion of the combustion products, with, however, the possibility of some persistence of combustion during and after expansion if conditions of chemical equilibrium were encountered during combustion.

(*e*) An instantaneous pressure drop upon opening of the exhaust valve *at the end* of the expansion stroke, and zero resistance and thus zero pressure drop through the exhaust system, whereby the cylinder pressure during exhaust might be that of the atmosphere, P_a.

28. THE OTTO CYCLE

A pressure-volume diagram for an Otto cycle conforming to the above-mentioned ideal features would be like that of Fig. 2. The extent of the compression and expansion employed is a feature which affects the final products' temperature and thus the efficiency of the cycle. The outstanding influence of these features may be indicated approximately by quite artificial and unreal analyses which are known as the *air standard* analyses. In these analyses it is presumed (1) that air alone is caused to pass through the typical state changes of the cycles, (2) that the temperature and pressure rises which in the actual cycles are produced by the chemical energy release during combustion shall in this hypothetical cycle be produced by a like supply of energy to the air as heat from some external source, (3) that the energy discarded by the cycle equals the energy emission during a constant-volume cooling of the air from the temperature T_e to the original temperature T_1, and (4) that the specific heat of the air may be regarded as constant and as that of air at normal atmospheric temperature.

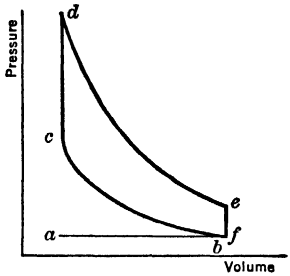

FIG. 3. Indicator Diagram of Otto Cycle (Air Standard)

A significant item associated with the *internal-combustion engine* cycle is the ratio between (1) the total volume in the cylinder at the end of intake and beginning of compression and (2) the clearance or residual volume in the cylinder when the piston is at the end of the compression stroke. This ratio is known as the *ratio of compression* and will be denoted as r_c. Referring to Fig. 3, which is representative of the events in the ideal Otto cycle,

$$\text{Compression ratio, } r_c, = \frac{V_b}{V_c}$$

A second generally significant ratio is that between the volume at the end of expansion and the volume at the beginning of expansion. This ratio is known as the *ratio of expansion* and will be denoted as r_e. Referring again to Fig. 3,

$$\text{Expansion ratio, } r_e, = \frac{V_e}{V_d}$$

It is observed that for the ideal Otto cycle the expansion ratio and the compression ratio are equal.

An air standard analysis of the Otto cycle indicates that its thermal efficiency depends only upon the compression ratio of the cycle and increases with increase in compression ratio in accordance with the relation

$$\text{Thermal efficiency, air standard Otto cycle} = 1 - \frac{1}{(r_c)^{0.4}} \qquad (1)$$

Although more exact estimates of ideal performance as well as actual engine tests show that efficiency is likewise influenced by the proportions of the fuel-air mixture, with improved efficiency at mixtures with some excess of air, the evidence of the air standard analysis is well corroborated with respect to the effect of the compression ratio.

The evidence offered by equation (1) that, for the air standard Otto cycle, the thermal efficiency is determined solely by the compression or expansion ratio, is indicated graphically by the curve *A* of air standard thermal efficiency vs. compression ratio in Fig. 4. In the figure there are also represented, in curves *B*, *C*, and *D*, the results of computations made by Goodenough and Baker[*] for the ideal (indicated) thermal efficiency of an Otto cycle employing real mixtures of gasoline and air. In their computations careful attention was given to the effect of specific heat variation and of chemical equilibrium during combustion, employing the then (1926) best available data. Curve *E* shows the actual thermal efficiencies (based on indicated horsepower) attained on test of a very high-grade, single-cylinder Otto engine in which the compression ratio could be varied at will, the results being those reported by Ricardo[†] when using a non-detonating fuel and a fuel mixture containing air 15 per cent in excess of the amount theoretically required for complete combustion of the fuel.

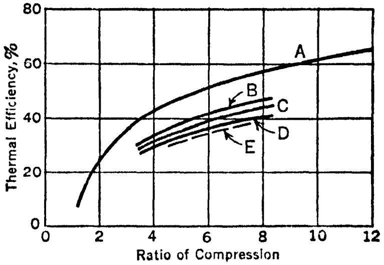

FIG. 4. Thermal Efficiencies of Otto Cycles

The results of the ideal efficiency computations (curves *B*, *C*, and *D*) and the actual efficiency results (curve *E*) distinctly corroborate the evidence offered by the air standard cycle computations in so far as those predict the material influence of compression and expansion ratio on efficiency. In addition the ideal efficiency curves indicate a material influence of the character of the fuel mixture on the ideal efficiency. Test results on actual engines operating with mixture strengths which are readily explosive further corroborate the evidence of the ideal curves, to wit, that decrease of the mixture strength acts to increase efficiency quite distinctly.

Progress in the use of distinctly weak mixtures is handicapped by the difficulty in ignition and rapid burning of the mixture and by the material reduction in the power capacity of a given size engine with reduction in mixture strength, maximum power being secured both in the ideal cycle and in the actual engine with mixtures in which the air supply is some 5 to 10 per cent less than the theoretical requirement. Progress in the direction of the higher compression ratio is handicapped by the detonation tendency of many fuels but similarly is facilitated by the development and utilization of fuels which are less detonative in character (such as gasoline-benzol blends, gasoline treated with various catalysts, alcohol, etc.). The tendency of the efficiency curves toward a gradual flattening with increase of compression ratio and a very pronounced increase of the peak pressure of the cycle without commensurate increase of the engine power will undoubtedly act to limit the ratio for which it is economically worth while to strive. With ordinary gasolines, values of the ratio in excess of about 6 cannot be used to advantage owing to detonation.

The departure of actual engine efficiency from the ideal is attributed to a number of factors, such as (1) a failure to burn portions of the fuel which are in intimate contact with the cylinder walls, (2) untimely burning of portions of the fuel during the compression stroke, this occasioned by localized contacts with hot portions of the cylinder or exhaust valve, and (3) energy conduction through the cylinder walls as heat during the combustion and expansion. The efficiency of multiple-cylinder engines is frequently decreased very materially by a poor distribution of a properly proportioned fuel mixture, that is, by the delivery of over-weak mixture to certain cylinders and over-rich mixture to others. The efficiency of two-cycle Otto engines is commonly rather less than that of a four-cycle engine by reason of a direct wastage of fuel mixture through the exhaust during the dual exhaust-induction phase of that cycle.

29. THE DIESEL CYCLE

The distinctive characteristics of the *Diesel cycle* are the induction and compression of air only to a temperature well above the ignition temperature of the fuel, whereby upon injection of an atomized fuel oil jet at the end of the compression stroke ignition will automatically occur and combustion will continue so long as fuel injection is continued and the oxygen or air supply in the cylinder does not become depleted. The resulting temperatures and pressures attained by the products during the fuel admission will depend primarily on the rate of fuel injection and combustion. In the *conventional* present-day concept of the Diesel cycle the rate is presumed to be such that the pressure which was reached at the end of compression shall be maintained during the piston travel to the end of the injection phase. Line *cd* of Fig. 5 is representative of such a condition.

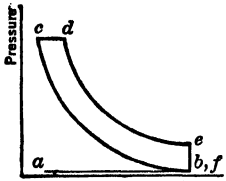

FIG. 5. Indicator Diagram of Diesel Cycle (Air Standard)

The remainder of the cycle of the figure conforms to the idealized conditions noted for the Otto cycle. In the figure, V_b/V_c is the *ratio of compression*, and V_e/V_d is the *ratio of expansion*. It is obvious that in the conventional Diesel cycle the expansion ratio is less than the compression ratio. For any given compression ratio the duration of the energy supply phase, *cd*, would be increased and the expansion ratio would be correspondingly decreased with increase in the *amount* of energy supplied to the engine per cycle. Interpreted in association with the actual engine, the amount of energy supplied per cycle is measured by the amount of fuel supplied per cycle and thus by the rate and duration of the fuel injection. Note in this connection that the ideal limiting amount of fuel which might properly be injected per cycle is established by the amount of oxygen and thus of air which had been inducted into the engine cylinder on the intake stroke of the cycle. Decreased fuel injection per cycle implies increased expansion ratio and increased air excess.

For the Conventional Diesel Cycle with constant pressure combustion the air standard analysis indicates that the cycle efficiency is influenced jointly by the compression ratio and the expansion ratio in accordance with the relation

$$\text{Thermal efficiency, air standard Diesel cycle} = 1 - \frac{1}{(r_c)^{0.4}} \frac{(r_c/r_e)^{1.4} - 1}{1.4(r_c/r_e - 1)} \qquad (2)$$

For a given compression ratio the Diesel efficiency is less than that of the Otto and departs progressively from the Otto with decreasing values of the expansion ratio r_e. This last fact is due directly to the increase of the temperature T_e (at the end of the expansion and the beginning of the energy rejection phases of the cycle) with decrease of the expansion ratio. This temperature increase is in turn due jointly to the increasing temperature T_d resulting from greater energy supply to the fluid during the longer injection phase and the concurrently lesser opportunity for temperature drop during the expansion phase. In spite of this apparent handicap the actual Diesel engine is in general able to attain thermal efficiencies higher than those obtained by the Otto, owing to the compensating advantage that the detonating character of the fuel used with the Otto engine and the very high maximum pressures encountered in that cycle limit its practicable compression ratio to about 5 or 6, whereas the Diesel engine may and commonly does employ compression ratios of 12 or over.

In the Diesel engine a very thorough atomization of the fuel oil jet is necessary as well as a jet momentum sufficient to cause the fuel particles to penetrate the mass of highly compressed air, and also there needs be a considerable turbulence in that air, all in order that the fuel and oxygen molecules may quickly become intimately associated and rapid combustion may thereby be facilitated. It has been the usual practice to assist the atomization of the fuel and the mixing by introducing with the fuel jet a jet of very highly compressed air which was furnished by an accessory compressor. With more recent advances in the art, fuel nozzles are being developed which provide adequate pulverization and dissemination of the fuel without the aid of the air jet. The two methods of introducing the fuel are known respectively as *air injection* and *airless injection* or, as the latter is frequently although rather inaptly termed, *solid injection.*

For Methods of Testing and Reporting the Performance of internal-combustion engines, reference should be made to the Test Code for Internal Combustion Engines published by the American Society of Mechanical Engineers, 29 W. 39 St., New York City.

It may be stated that the items brake horsepower, indicated horsepower, mechanical efficiency, brake mean effective pressure, indicated mean effective pressure, etc., have the

same significance and are determined in quite the same manner as described for the steam engine, Art. 25.

For the single-acting four-cycle engine Ihp $= \frac{PALN}{2 \times 33{,}000}$ per cylinder, and for the two-cycle single-acting engine the Ihp per cylinder is $\frac{PALN}{33{,}000}$.

In American practice the thermal efficiency of the internal-combustion engine is based upon the higher heating value of the fuel.

REFRIGERATION

Symbols and Abbreviations

C.P. = coefficient of performance.
c_p = specific heat at constant pressure.
H = enthalpy, Btu per pound of fluid.
J = Joule's equivalent (778 ft-lb per Btu).
k = specific heat ratio, c_p/c_v.
P = pressure, pounds per square foot, absolute.
P_1 = pressure of refrigerant in condenser or cooler.
P_2 = pressure of refrigerant in evaporator or refrigerator.
Q = energy transferred as heat, Btu per pound of fluid.
S = entropy per pound mass of fluid.
T = temperature, degrees Rankine (degrees fahrenheit absolute).
V = specific volume, cubic feet per pound.

The refrigerating machine is the practical example of the reversed heat engine, in that it acts to abstract energy as heat from a region of lower temperature and to deliver heat to a region of high temperature and does this by the supplying of energy to the machine usually as shaft work but also possibly as heat from some still higher temperature level.

The objective of the heat engine is the transformation to work of a maximum portion of the energy which is supplied from a high-temperature source, but a necessary accompaniment of the engine is the rejection of an unavailable residue of energy to that universal energy receiver, the atmosphere. The heat engine thus operates through a temperature range which extends from atmospheric temperature upward. In distinction, the refrigerating machine has for its practical objective only the securing and maintenance of a temperature which is below that of the atmosphere, but again the energy which it discards must go to the same general energy receiver, the atmosphere. Consequently the refrigerating machine operates through a temperature range which extends downward from the temperature of the atmosphere.

30. THE CARNOT REFRIGERATION CYCLE

The Reversed Carnot Cycle may be described as one abstracting energy from a lower-temperature region and returning it to a region of higher temperature by means of the work supplied. Examining this reversed Carnot cycle by the aid of the T–S diagram of Fig. 1 it is seen that, by operating the cycle in the direction indicated, heat Q_2 may be abstracted from a region at the lower temperature T_2 in the amount $T_2(S_b - S_a)$, and heat Q_1 may be delivered to a region at the higher temperature T_1 in the amount $T_1(S_c - S_d)$ or $T_1(S_b - S_a)$. For the operation of this complete cycle work will be required in the amount $Q_1 - Q_2$, or alternatively, $W/J = Q_1 - Q_2 = (T_1 - T_2)(S_b - S_a)$.

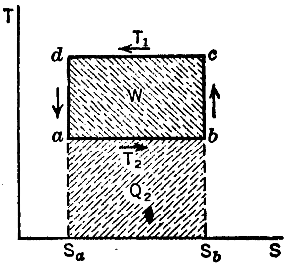

Fig. 1. Carnot Refrigeration Cycle

31. PERFORMANCE AND CAPACITY

As a natural objective in refrigeration is the removal of energy from the lower temperature region with a minimum expenditure of work, a suitable index of the performance of a

refrigeration machine is the ratio between the amount of heat removed, or the refrigerating effect, and the work required. This ratio is called the *coefficient of performance* of the machine, or

$$\text{Coefficient of performance (C.P.)} = \frac{\text{Heat removed } (Q_2)}{\text{Work required } (W/J)}$$

For the reversed Carnot cycle the coefficient thus becomes

$$\text{C.P.} = \frac{Q_2}{W/J} = \frac{T_2(S_b - S_a)}{(T_1 - T_2)(S_b - S_a)} = \frac{T_2}{T_1 - T_2}$$

This Carnot or reversible cycle coefficient is the maximum coefficient of performance conceivably obtainable with any refrigerating machine operating in any manner with any fluid between a given (constant) lower temperature T_2 and a given (constant) upper temperature T_1.

The Carnot refrigeration cycle may ideally be realized with any vapor. It is instructive to see how a fluid such as water might be used. Referring to the T–S diagram of a vapor, as presented in Fig. 2, and starting with the substance at state *d* in a saturated liquid state at the upper temperature (and pressure) of the cycle, let the liquid be expanded adiabatically and reversibly in a cylinder to state *a*. As it expands, the temperature drops, part of the liquid vaporizes, and some work output is obtained. Between states *a* and *b* additional liquid is caused to vaporize at the constant lower temperature and pressure of the cycle by the absorption of energy as heat from the cold region. Here the refrigeration is accomplished. After the partial vaporization to some suitable state *b*, work energy is supplied and the vapor and liquid mixture is compressed isentropically to a state *c* which in the figure is the saturated vapor state at the upper pressure and temperature. The vapor is now condensed at the constant upper temperature and pressure to the original state at *d*, condensation being effected by heat energy rejection in an amount equal to that absorbed from the lower-temperature region plus the *net* work of the cycle. The net work is that required for the compression less that regained by the expansion.

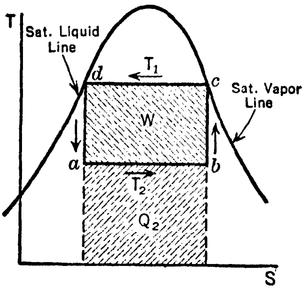

FIG. 2. Carnot Refrigeration Cycle with a Vapor

Example. A Carnot refrigeration cycle is operated between the temperatures of 50 and 100 deg. fahr. What vapor pressures would be required if the fluid were steam, and what would be the coefficient of performance? What refrigeration would be accomplished per pound of steam?

Solution. From the saturated steam tables the necessary pressure would be 0.178 and 0.95 lb per sq in abs, respectively. The coefficient of performance would equal (50 + 460)/(100 − 50) or 10.2. The heat rejected per pound of steam to the upper temperature region at 100 deg. fahr would be the enthalpy or " latent heat " of evaporation at that temperature or, from the steam tables, 1036.3 B.t.u. per lb. From the definition of coefficient of performance and the necessary energy relations of the cycle,

$$10.2 = \frac{\text{Refrigeration}}{\text{Work}} = \frac{1036.3 - \text{Work per lb}}{\text{Work per lb}}$$

Solving this equation for the work term, the net work required per pound of steam circulating equals 92.2 B.t.u. Finally therefore the refrigeration accomplished per pound of steam = $Q_1 - W/J = 1036.3 - 92.2 = 944.1$ Btu.

For evaluating the rate of available energy delivery from an engine or power plant the horsepower (or the kilowatt) is employed as the conventional unit of capacity. The analogous unit which is used for expressing the rate of heat energy intake from the cold region of a refrigerating machine, or its *refrigerating capacity*, is the *tons of refrigeration per 24 hours*. This term is frequently abbreviated, and the rate of refrigerating effect is stated simply in *tons*.

The standard commercial ton is arbitrarily defined as a removal of energy as heat from the cold region at the rate of 288,000 Btu per 24 hours or $\left(\frac{288,000}{24 \times 60}\right) = 200$ Btu per minute. The unit originates from the fact that the " latent heat of fusion " of ice is approximately 144 Btu per lb or (144 × 2000 =) 288,000 Btu per short ton, whence a refrigerating machine which is operating at a capacity of one ton is absorbing energy at a rate equal to that which would exist if one ton of ice were melting in the refrigerated region each 24 hours.

An index of refrigerating-machine performance which is employed in practice rather more than the coefficient of performance is a derived one which is associated with the ton unit of capacity, namely, *horsepower required per ton* of refrigeration per 24 hours. The relation between the performance so expressed and the coefficient of performance is readily obtained by recalling that

$$\text{Refrigerating effect, Btu per minute} = \text{tons (per 24 hours)} \times 200$$

and

$$\text{Work required, Btu per minute} = \text{Hp} \times \frac{2545}{60} = \text{Hp} \times 42.4$$

whence

$$\text{Coefficient of performance} = \frac{\text{Tons} \times 200}{\text{Hp} \times 42.4} = \frac{4.71}{\text{Hp per ton}}$$

It is practically advantageous to modify the reversed Carnot cycle, or Carnot refrigeration cycle, in some particulars and to carry out the resulting fluid cycles in a succession of apparatus through which the fluid is caused to flow progressively and in each of which one phase of the cycle is accomplished. These practical adaptations fall in general into three classifications:

(*a*) *Vapor cycles*, in which the transfer of the vapor from the lower temperature and pressure of the cycle to the upper is accomplished through the agency of work supply to a *compressor*.

(*b*) *Gas (air) cycles*, in which the transfer of the fluid from the lower temperature and pressure to the upper is likewise effected by a *compressor*.

(*c*) *Vapor cycles* in which the transfer of the vapor from the lower pressure and temperature to the upper is accomplished in an *absorption system*, primarily through the agency of heat supplied at a still higher temperature.

These several practical cycles are considered in some detail in the following articles.

32. THE VAPOR COMPRESSION SYSTEM

The practical vapor compression system of refrigeration differs in principle from the Carnot cycle in two features. The one is the segregation of the several phases of the cycle into various devices to and through which the vapor is caused to flow progressively. The other is that, owing to the failure to develop as yet a practicable engine or turbine in which to accomplish the expansion of the condensed liquid from the upper temperature and pressure of the cycle to the lower, this expansion is in practice done in an irreversible throttling process which takes place in an *expansion valve*.

The resulting cycle as it would appear with these modifications, but still idealized in some respects, is represented in the *T-S* and *H-S* diagrams of Figs. 3 and 4, respectively. A diagrammatic representation of the arrangement of the apparatus appears in Fig. 5.

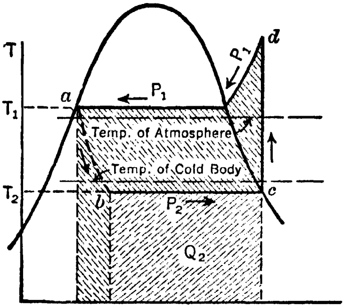

FIG. 3. Vapor Compression Cycle, *T-S* Diagram

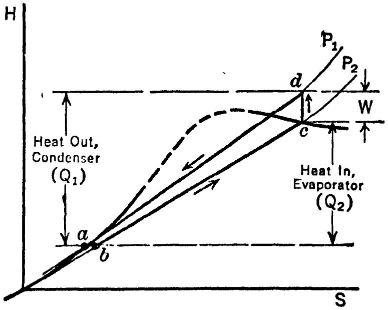

FIG. 4. Vapor Compression Cycle, *H-S* Diagram

Starting at point *a* in each figure the fluid, which is called the *refrigerant*, leaves a storage tank in which it exists as a liquid at about atmospheric temperature and at its corresponding saturation pressure P_1. Between *a* and *b* the fluid is permitted to escape under control through the expansion valve to the low-pressure region of the cycle. Owing to the throttling character of the process the enthalpy of the fluid at state *b* must equal that at state *a*, with the result that a sensible portion of the liquid must vaporize, but owing to the lower pressure of the vapor its temperature must have fallen. Specifically it must have dropped to the saturation temperature corresponding to the lower pressure.

After leaving the expansion valve the low-temperature and low-quality vapor mixture enters the *evaporator*. Here the provision is made for the absorption of energy as heat by the fluid from the region or substance which it is desired to refrigerate. The pipe coils which constitute the evaporator may be placed directly in the region that is to be cooled, in which event the system would be said to be one with *direct expansion*, or they may be placed in and act to cool some liquid with low freezing point, such as calcium chloride brine, which is circulated to the region that is to be cooled and which thus acts simply as a convective energy carrier. The latter system would be known as one with *indirect expansion*. In either event the reception of energy by the refrigerant will act to cause it to evaporate. The amount of energy received by each pound of the refrigerant and thus the degree of completeness of its evaporation will depend on the rapidity of its circulation, on the temperature difference between the fluid in the evaporator and its environs, and on other operating conditions. In the figures the fluid is shown as leaving the evaporator at state *c*, which is the saturated vapor state. It may in fact leave as a wet vapor mixture or even moderately superheated. In connection with the process of evaporation in the evaporator it is to be observed that the temperature therein must be *below* the temperature of the cold region in order that heat transition may occur in the desired direction. The pressure maintained therein must be the saturation pressure corresponding to the temperature, which pressure we shall designate as P_2.

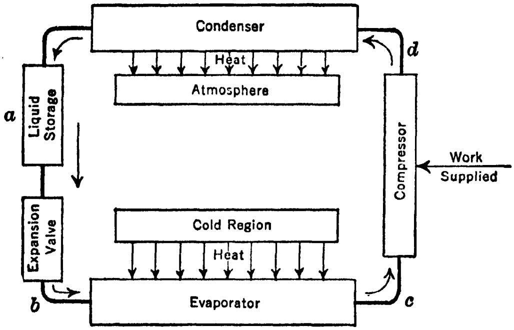

FIG. 5. Elements of Vapor-Compression Refrigeration Cycle

From the evaporator the refrigerant passes to the *compressor*. The function of the compressor is twofold. The one function is that of withdrawing the fluid from the evaporator at a rate sufficient to maintain the necessary reduced pressure and temperature in the evaporator. The other is that of compressing and delivering the fluid at a temperature which is adequately *above* that of the atmosphere or of the region or substance to which the fluid must next discard its " load " of energy. The increase of temperature of the vapor must be accompanied by increase of pressure. In this compression process, a reversible adiabatic or isentropic compression must be regarded as the best that might be obtained. The figures show such a compression. The state change represented by line *c–d* is one that will dry and superheat the refrigerant.

After leaving the compressor at state *d* the vapor enters the *condenser* in which it must first be de-superheated and then condensed. The departing energy passes as heat to *circulating water* which may be expected to be at or about atmospheric temperature. The temperature during the condensation must moderately exceed that of the water in order that the heat transition may proceed in the desired direction. The refrigerant pressure which must be delivered by the compressor is the saturation pressure P_1 corresponding to the condensing temperature. The state change of the refrigerant within the condenser is represented in the figures by line *d–a*.

A variety of fluids have been used as the refrigerant in vapor compression systems. For larger commercial installations ammonia is used almost universally at the present time. For the small self-contained household installations sulfur dioxide vapor is very popular. In marine installations on combatant ships neither of the foregoing is considered desirable on account of their active toxicity, and carbon dioxide is preferred. Various hydrocarbons such as ethyl chloride and propane are also used. Ammonia offers the advantages of moderate condenser pressures and moderate specific volume at the evaporator pressures. Sulfur dioxide offers the further advantage of even more moderate pressures but requires considerably more compressor displacement on account of fairly high specific volumes at the evaporator pressure. Carbon dioxide has the disadvantage of requiring very high pressures in both the condenser and the evaporator.*

Probably the most effective means of improving the performance of a refrigerating process, but at the same time one that is too frequently overlooked, is that of providing adequate, well-designed and well-maintained heat-transfer surfaces in the evaporator and in the condenser and an ample amount of cool circulating water to the condenser. The effect is to reduce as far as practicable the total temperature range, $T_1 - T_2$, through which the refrigerant must pass by enabling its lower temperature T_2 to be a minimum amount below the requisite cold region temperature and its upper temperature T_1 to be a minimum amount above the circulating water supply temperature.

---

* For a complete description of the various refrigerants, a discussion of their adaptability under various conditions, and tables and charts of their thermodynamic properties see Macintire, Handbook of Mechanical Refrigeration, John Wiley & Sons, 1928.

The energy relations for the several phases of the cycle, both for actual operation and for the ideal cycle, are (regarding all kinetic energy terms as negligible), per pound of vapor circulated,

for the expansion valve, $H_a = H_b$

for the evaporator, $H_b + Q_{\text{in},\,b-c} = H_c$, or

$$Q_{\text{in},\,b-c} = H_c - H_b = H_c - H_a$$

for the compressor,

$$JH_c + W_{\text{in},\,c-d} = JH_d + JQ_{\text{out},\,c-d}, \quad \text{or}$$

$$W_{\text{in},\,c-d} = J(H_d - H_c) + JQ_{\text{out},\,c-d}\,^*$$

$$= J(H_d - H_c)_S \text{ for isentropic compression}$$

for the condenser, $H_d = H_a + Q_{\text{out},\,d-a}$, or

$$Q_{\text{out},\,d-a} = H_d - H_a$$

for the complete cycle,

$$W_{\text{in}} = J[(Q_{\text{out},d-a} - Q_{\text{in},\,b-c}) + Q_{\text{out},\,c-d}] = J(H_d - H_c + Q_{\text{out},\,c-d})^*$$

Coefficient of performance

$$= \frac{H_c - H_a}{H_d - H_c + Q_{\text{out},\,c-d}}$$

$$= \frac{H_c - H_a}{(H_d - H_c)_S}, \text{ for isentropic compression}$$

In these relations, the several subscripts are to be interpreted as referring to locations with respect to the various apparatus of the plant rather than to particular states indicated by the letters on the foregoing H–S or T–S diagrams.

Example. For an indirect-expansion ice-making installation operating with ammonia assume that the brine leaves the cooler (evaporator) at 14 deg fahr and that to obtain this temperature the necessary vapor temperature in the evaporator is 5 deg fahr. Also assume that the cooling water is supplied at 70 and leaves at 80 deg fahr, enabling the ammonia to condense at 86 deg fahr.

Assuming dry saturated vapor at the compressor suction, isentropic compression, and no subcooling of the liquid from the condenser, ascertain the pressures in the evaporator and the condenser, the temperature after compression, and the ideal coefficient of performance and horsepower per ton of refrigeration. Compare with the Carnot cycle performance between the vapor temperatures in the evaporator and condenser and with a Carnot cycle performance between the lowest brine temperature and the cooling water supply temperature. Indicate the reasons for the lower performance of the vapor cycle as compared with the Carnot between the same temperature limits.

Solution. From tables of the properties of ammonia (Bureau of Standards):

Evaporator (suction) pressure = saturated pressure corresponding to 5 deg fahr = **34.3 lb** per sq in. abs (= 19.6 lb gage).

Condenser (discharge) pressure = saturated pressure at 86 deg fahr = 169.2 lb per sq in. abs (= 154.5 lb gage).

For saturated vapor at 5 deg fahr, $H = 613.3$ (= H_c), and $S = 1.3253$ (= S_c).

After compression at a constant entropy of 1.3253 to 169.2 lb abs, t (from charts) = 210 deg fahr and $H = 713$ (= H_d).

For saturated liquid at 86 deg fahr, $H = 138.9$ (= H_a and H_b).

Coefficient of performance $= \dfrac{613.3 - 138.9}{713 - 613.3} = \dfrac{474.4}{99.7} = 4.76.$

Horsepower per ton of refrigerating effect per 24 hours $= \dfrac{4.71}{4.76} = 0.99.$

Carnot performance between (460 + 5 =) 465 deg R and (460 + 86 =) 546 deg R

$$= \frac{465}{546 - 465} = 5.74.$$

Carnot performance between (460 + 14 =) 474 deg R and (460 − 70 =) 530 deg R

$$= \frac{474}{530 - 474} = 8.47.$$

---

* As with any compressor, energy departure as heat *which might act to reduce the enthalpy increase* acts to reduce instead of increase the work requirement. In distinction, any heat emission occasioned by mechanical friction in moving parts obviously acts to increase the work.

The ammonia cycle coefficient is lower than the Carnot (4.76 vs. 5.74) because of (*a*) the irreversible throttling in the expansion valve and (*b*) the higher temperature at which the heat is rejected during the de-superheating of the ammonia vapor leaving the compressor.

Charts Having Absolute Pressure Plotted against Enthalpy are found most useful to show the refrigeration process. Fig. 6 shows such a chart for the refrigerant freon, upon which is drawn a characteristic cycle diagram. The throttling process is represented by the line *da*; the absorption of energy as heat in the evaporator is represented by the line *ab*; the adiabatic compression process is represented by the line *bc*; and the discarding of energy as heat to the atmosphere is represented by the line *cd*.

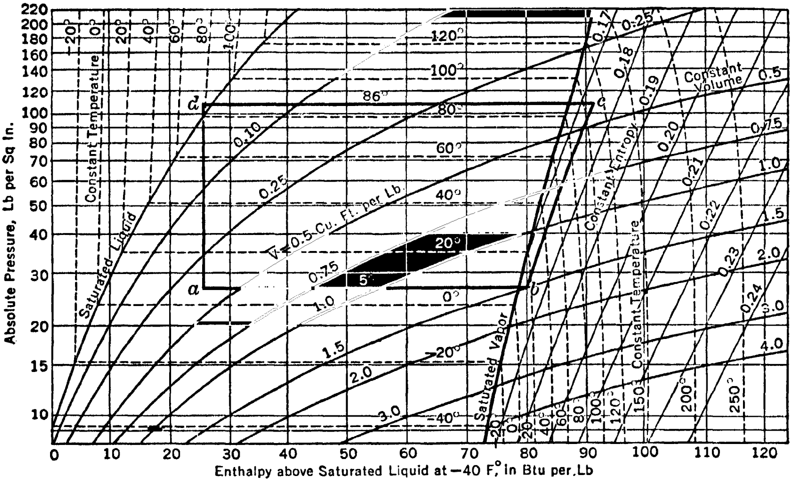

FIG. 6. *P-H* Diagram for Freon*

Table I shows the physical properties of the refrigerants in most common use.

Table I. Some Properties of Refrigerants

Refrigerant	Symbol	Molecular Weight	Boiling Point at 1 Atmos., °F	Critical Temperature, °F	Critical Pressure, lb/sq in. abs	Freezing Point, °F	Liquid Density at Boiling Point, lb/cu ft	Gas Density,* lb/cu ft	Ratio of Specific Heats, $k = c_p/c_v$

33. THE AIR COMPRESSION SYSTEM

The apparatus required for an air compression system is in principle the equivalent of that required for a vapor system, *except that* for obtaining the low air temperature it is necessary that the compressed air shall do work in its expansion, instead of being permitted simply to throttle through an expansion valve. An air engine is therefore employed for effecting the pressure and temperature drop which must occur as the air passes to the cooling coils.

---

* Redrawn, by permission, from Barnard, Ellenwood, and Hirshfeld, Heat-Power Engineering, Part III, John Wiley & Sons.

The arrangement of the elemental components of an air compression system of refrigeration is shown diagrammatically in Fig. 7 and the ideal state changes of the cycle are represented in the T, H–S, and P–V diagrams of Figs. 8 and 9, respectively.

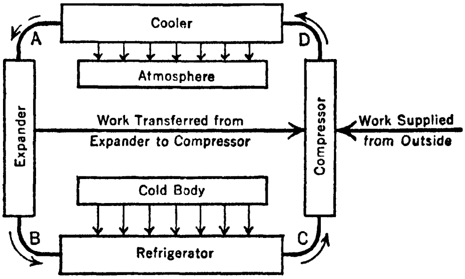

Fig. 7. Elements of Air-compression Refrigeration Cycle

Referring to the several locations and state points indicated on the figures, state *a* represents air at slightly above atmospheric temperature but under a pressure considerably above atmospheric. The air at this state enters the *expander cylinder* or engine through which it would ideally expand isentropically to a state *b*, at which state the pressure commonly would still exceed considerably the atmospheric pressure but the temperature would be 50 deg fahr or more below the temperature of the region which it is desired to refrigerate. The work output from the expander engine is available for and would actually be used for assisting in driving the compressor of the system.

Between states *b* and *c* the air passes at ideally constant pressure through the refrigerating coils and there absorbs energy by heat transition from the cold region, departing from the refrigerating coils at a temperature still moderately below that of the cold region.

After leaving the coils at state *c* the air enters the compressor cylinder and is compressed to its original pressure at *a* but to a temperature considerably above that of the atmosphere. An isentropic state change, *c* — *d*, is represented in the figures, but as usual heat emission from the air during its compression would act to reduce the work required for the compression. The work necessary for driving the compressor comes partly from an external source and partly from the expander engine.

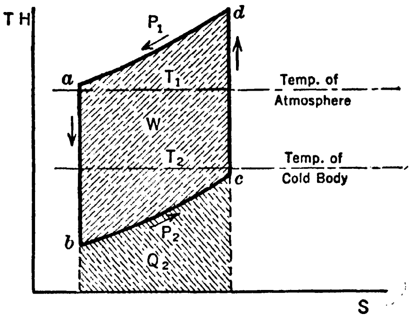

Fig. 8. T–S Diagram for Air-compression Cycle

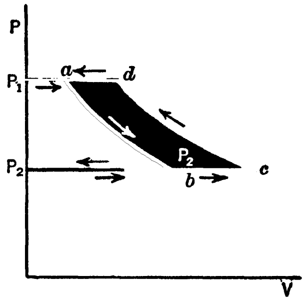

Fig. 9. P–V Diagram for Air Compression Cycle

Upon leaving the compressor at state *d* the hot air passes at ideally constant pressure through a cooler where it emits energy as heat to the circulating water and is thus recooled to the original state *a*.

Presuming the ideal conditions of constant pressure cooling and warming and isentropic expansion and compression the energy relations for the various phases of the cycle are; for the expander cylinder, per pound of air,

$$W_{\text{out}} = Jc_p(T_a - T_b)$$
$$= Jc_p\,T_b[(P_1/P_2)^{(k-1)/k} - 1]$$

for the refrigerating coils, $Q_{\text{in}} = c_p(T_c - T_b)$

for the compressor, $W_{\text{in}} = Jc_p(T_d - T_c)$

$$= Jc_p\,T_c[(P_1/P_2)^{(k-1)/k} - 1]$$

for the air cooler, $Q_{\text{out}} = c_p(T_d - T_a)$

for the complete cycle,

$$W_{\text{in, net}} = Jc_p(T_c - T_b)[(P_1/P_2)^{(k-1)/k} - 1]$$

Coefficient of performance

$$= \frac{T_c - T_b}{T_d - T_a - T_c + T_b}, \quad \text{or}$$

$$= \frac{1}{(P_1/P_2)^{(k-1)/k} - 1}, \quad \text{or}$$

$$= \text{either } \frac{T_b}{T_a - T_b} \quad \text{or} \quad \frac{T_c}{T_d - T_c}$$

It may be seen from the T–S diagram of Fig. 8 or from the last expressions above that for a useful temperature range $T_a - T_c$ the air cycle coefficient of performance must be materially lower than that of the Carnot cycle, owing to the necessary temperature depression between b and c and the temperature elevation between d and a. At a given capacity the performance may be improved by a more rapid mass-rate of circulation of air, due to the consequent possibility of reducing the temperature range in the refrigerator $(T_c - T_b)$ and in the air cooler $(T_d - T_a)$.

The air compression system once held sway in marine installations, as the *dense air* system, but now it is practically abandoned partly because of its relatively poorer coefficient of performance and partly because of operating difficulties arising from the freezing of any moisture in the air and the consequent stoppage of the expander valves, etc.

34. THE ABSORPTION SYSTEM REFRIGERATION THROUGH THE SUPPLYING OF ENERGY AS HEAT

In the refrigerating systems hitherto considered the energy required for passing the refrigerant from the lower temperature and pressure of the cycle to the upper temperature and pressure was supplied as work at the compressor. Instead of effecting this by work supply through a power-driven compressor, arrangements may also be made whereby it is accomplished through a direct supply of heat energy from a high-temperature source. Several typical forms and arrangements of apparatus have been devised and are in use for this purpose, all of which may be designated, however, as *absorption systems*. Those in practical use employ ammonia as the refrigerant and act by the alternate absorption of the cold ammonia vapor by some *adsorbent* and subsequent elimination of the ammonia at a higher temperature by the application of heat energy. The system in most common use employs water as the ammonia adsorbent.

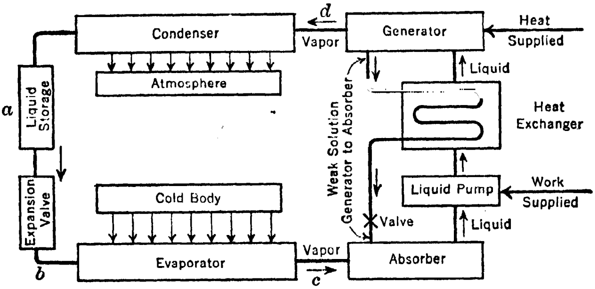

FIG. 10. Elements of Vapor-absorption Refrigeration Plant

The elements of an ammonia absorption system are shown diagrammatically in Fig. 10. The usual condenser, expansion valve, and evaporator are evident. Through these occurs the customary progressive flow of the refrigerant. The distinctive items of the system are the *absorber*, *liquid pump*, *heat exchanger*, and *generator*. These jointly replace the conventional compressor of the compression system, and through them there is a closed circuit of an ammonia-water solution. The general actions in this circuit are as follows.

The cold vapor leaving the evaporator passes to the absorber and is there avidly absorbed by a weak solution of water and ammonia known as the *weak aqua*. This absorption process has the characteristic of emitting energy, whence it is necessary that cooling water be circulated through coils in the absorber in order to maintain the temperature of the liquid sufficiently low and thus permit the building up of an adequate ammonia concentration. The weak aqua in the absorber thus becomes eventually a *strong aqua* and is then delivered by the liquid pump through the heat interchanger to the generator. In the generator heat energy is supplied, usually by a low-pressure steam coil, and the temperature of the strong aqua is thereby raised sufficiently that the ammonia which had been taken up in the absorber is eliminated from the strong aqua and is thus delivered as ammonia vapor to the condenser. The resulting weak aqua then completes the aqua circuit by returning through the heat exchanger to the absorber. The action in the exchanger is the mutual one of warming the strong aqua which is en route from the absorber to the generator by the cooling of the weak aqua which is returning from the generator to the absorber.

In certain smaller absorption systems the liquid pump, which is observed to be the only moving part required in the system, is dispensed with by employing the same element alternately as the absorber and as the generator, with a consequent intermittent action of the system. Also there is an ingenious system in use in household units in which the pump is dispensed with by introducing hydrogen gas in the evaporator and absorber, with the result that the system is under virtually the same *total* pressure throughout. Circulation is brought about by differences in the densities of the liquids in various parts of the system. The total pressure in the evaporator is the sum of the partial pressures of the hydrogen gas and the ammonia vapor, but the temperature is established only by the partial pressure of the saturated ammonia vapor.

Various other adaptations of the absorption system employ other absorbents, such as anhydrous ammonium nitrate and silica gel.

The energy relations for the condenser, expansion valve, and evaporator of an absorption system are in principle the same as those for a compression system, but in practical application they may become more complicated because there may be a carry-over of some of the adsorbent (such as water vapor in the aqua system) from the generator to and through the condenser and evaporator. For the absorber, pump, exchanger, and generator, together with the various accessory apparatus which are found in the actual plant, the energy relations become still more involved by reason of the semi-chemical character of the processes of vapor absorption by and elimination from the adsorbent.

It will have been observed that the elemental requisites for refrigeration are simply a supply of a liquid refrigerant under some pressure, an expansion valve, and the coils in which the expanded refrigerant may evaporate at the lower pressure and temperature. If an unlimited supply of the liquid refrigerant were available and if its saturation pressure at the desired refrigeration temperature should perchance be above the pressure of the atmosphere, then continued refrigeration might be secured simply by letting the refrigerant escape. It would thus appear that the greater portion of the equipment which is employed for effecting a practical, economical, and continuously operating refrigeration system is required only in order that the refrigerant may be recovered and be reliquefied at atmospheric temperature.

GAS AND VAPOR MIXTURES, HUMIDITY, AND AIR CONDITIONING

Symbols and Abbreviations

a = subscript designating the air constituent of a mixture.
f = subscript designating the saturated liquid state.
g = subscript designating the (dry) saturated vapor state.
fg = subscript designating the change of a property during change of a fluid from the saturated liquid to the saturated vapor state.
l = subscript designating a liquid constituent of a mixture.
m = subscript designating a mixture.
P = subscript designating constancy of pressure.
V = subscript designating constancy of specific volume.
v = subscript designating a vapor constituent of a mixture.
w = subscript designating the water (vapor, liquid, or both) constituent in a mixture.
x, y, z = subscripts designating the several constituents x, y, and z of a (gas) mixture.
ϕ = relative humidity.
c = specific heat, of a constituent or a mixture.

E = molecular energy, Btu per pound of a constituent or of a mixture.
H = enthalpy, Btu per pound of a constituent or of a mixture.
k = ratio of specific heats (c_p/c_v).
m = molecular weight of a constituent (or of mixture).
M = mass of a constituent (or of mixture).
P = partial pressure of a constituent (or total pressure of mixture).
Q = energy transferred by radiation or conduction (as heat).
R = gas constant of a constituent (or of a mixture).
S = entropy per pound of a constituent (or of mixture).
t = temperature, degrees fahrenheit.
T = temperature, degrees Rankine (degrees fahrenheit absolute).
$V_{x,\,y,\text{ or }z}$ = volume (not specific volume) of a constituent x, y, or z in a mixture if the constituent is segregated and put under the temperature and total pressure of the mixture, as in volumetric analysis.
V_g = specific volume of (dry) saturated vapor.
x = quality (saturated-vapor fraction) of a mixture of saturated liquid and vapor.

Various of the fluids which are encountered in engineering processes are mixtures either of gases or of a gas and vapor. Thus dry air is itself a mixture primarily of oxygen and nitrogen, and atmospheric air is a further mixture of dry air with superheated water vapor or with saturated vapor and perhaps some unvaporized liquid, as in clouds or during fog and rainfall. Several of the simpler of such types of mixtures are presented in the following.

35. GAS MIXTURES

The Actual Gas Mixture consists of a haphazard aggregation of molecules of each constituent, the molecules of any single constituent being distributed uniformly throughout the entire space and also acting or moving quite as if they occupied the space alone. As a consequence the total pressure exerted by the mixture against the walls of its container by reason of the molecular bombardment of those walls may be distributed between several *partial* pressures, each of which is individually attributable to the molecules of a corresponding individual constituent and each of which would be the pressure exerted by that constituent if it alone should fill the space or volume occupied by the mixture (V_m) at the common temperature (T_m) of it and of all the components of the mixture. The values of the partial pressures of the gases in a mixture are:

$$P_x = M_x R_x \frac{T_m}{V_m} = 1545 \frac{M_x}{m_x} \frac{T_m}{V_m}$$

$$P_y = M_y R_y \frac{T_m}{V_m} = 1545 \frac{M_y}{m_y} \frac{T_m}{V_m}$$

$$P_z = M_z R_z \frac{T_m}{V_m} = 1545 \frac{M_z}{m_z} \frac{T_m}{V_m}$$

where P_x, P_y, and P_z = the partial pressures attributable individually to constituents x, y, and z.
M_x, M_y, and M_z = the relative masses of those constituents.
R_x, R_y, and R_z = their individual gas constants.
m_x, m_y, and m_z = their molecular weights.
T_m = the mixture temperature.
V_m = the volume occupied by the mixture.

The Relation between the Partial Pressure of any one constituent (as x) and that of any other (as y) is

$$\frac{P_x}{P_y} = \frac{M_x R_x}{M_y R_y} = \frac{M_x/m_x}{M_y/m_y} \tag{1}$$

Also,

$$\frac{P_x}{P_m} = \frac{P_x}{P_x + P_y + P_z} = \frac{M_x R_x}{M_x R_x + M_y R_y + M_z R_z}$$

$$= \frac{(M_x/M_m)R_x}{(M_x/M_m)R_x + (M_y/M_m)R_y + (M_z/M_m)R_z}$$

$$= \frac{\dfrac{M_x/M_m}{m_x}}{\dfrac{M_x/M_m}{m_x} + \dfrac{M_y/M_m}{m_y} + \dfrac{M_z/M_m}{m_z}}$$

where M_m = mass of mixture, $M_x + M_y + M_z$.
P_m = total pressure, $P_x + P_y + P_z$.

The several ratios M_x/M_m, M_y/M_m, and M_z/M_m in the last relation evidently represent the mass proportions of each constituent with respect to the mass of the whole, as would be determined by or would determine the gravimetric analysis of the mixture. It frequently happens that, as in the practical analysis of furnace gases or of an internal-combustion engine exhaust, the several constituents of a gas mixture are in effect segregated progressively and their relative volumes are determined *when maintained under the original temperature but brought (individually) to the original total pressure of the mixture.* An expression of the proportional composition of a mixture in terms of the ratios of the individual volume of the constituent, when so segregated and at the temperature and total pressure of the mixture, to the actual mixture volume is known as its *volumetric* analysis.

The Volume of Each Component under such temperature and pressure conditions is

$$V_x = M_x R_x \frac{T_m}{P_m} = 1545 \frac{M_x T_m}{m_x P_m}, \text{ etc.,}$$

and the ratio between those volumes for any pair of the constituents is

$$\frac{V_x}{V_y} = \frac{M_x R_x}{M_y R_y} = \frac{M_x/m_x}{M_y/m_y} \left(\text{and } = \frac{P_x}{P_y}, \text{ by eq. 1}\right) \tag{2}$$

Also relations are readily obtainable by which to convert from gravimetric to volumetric analyses, and *vice versa*. Thus

$$\frac{V_x}{V_m} = \frac{V_x}{V_x + V_y + V_z} = \frac{M_x/m_x}{M_x/m_x + M_y/m_y + M_z/m_z} = \frac{\dfrac{M_x/M_m}{m_x}}{\dfrac{M_x/M_m}{m_x} + \dfrac{M_y/M_m}{m_y} + \dfrac{M_z/M_m}{m_z}} \tag{3}$$

and

$$\frac{M_x}{M_m} = \frac{M_x}{M_x + M_y + M_z} = \frac{V_x m_x}{V_x m_x + V_y m_y + V_z m_z} = \frac{(V_x/V_m)m_x}{(V_x/V_m)m_x + (V_y/V_m)m_y + (V_z/V_m)m_z} \tag{3a}$$

Relations are thus available by which to ascertain the partial pressure of any constituent of a gas mixture and by which to convert from gravimetric to volumetric analysis, or the reverse. It remains to be observed that any given mixture has its own effective or equivalent gas constant, molecular weight, and specific heats, which may be used in analyses of mixture processes quite as for any single gas.

R_m, the Equivalent Gas Constant for the Mixture, is obtained from

$$R_m = (M_x/M_m)R_x + (M_y/M_m)R_y + (M_z/M_m)R_z \tag{4}$$

Since, for the gases, $mR = 1545$, an equivalent molecular weight may be computed for a mixture by the relation

$$m_m = \frac{1545}{R_m} \tag{4a}$$

c_m, an Equivalent Specific Heat for the Mixture, is obtained from

$$c_m = \frac{M_x}{M_m} c_x + \frac{M_y}{M_m} c_y + \frac{M_z}{M_m} c_z \tag{5}$$

With the foregoing relations at hand it is in general possible to proceed with analyses of engineering processes with a gas mixture quite as though the mixture were a single gas, *so long as the mass proportions of the mixture do not change* during the process. In this connection it will be recalled that the practice of regarding a gas mixture as effectively equivalent to a single gas is exemplified by the treatment of the properties and energy relations of air as though it were a single gas.

36. GAS AND VAPOR MIXTURES

There are Several Distinctive Conditions of Gas-vapor Mixtures which are of general concern and which are classifiable as:

(*a*) Mixtures of gas and (low-pressure) superheated vapor, as exemplified by the air and superheated water vapor which constitutes normal atmospheric air.

(*b*) Mixtures of gas and (low-pressure) saturated vapor, as exemplified by the atmosphere at the incipiency of fog or rainfall.

(*c*) Mixtures of gas, saturated vapor, and saturated liquid, as exemplified by the atmosphere during fog or rainfall.

Considering these in order:

(**a**) The low-pressure vapors, when even very moderately superheated, and in fact even when saturated if at a sufficiently low vapor pressure, are found to conform closely to the gas characteristics. As a consequence, engineering computations involving gas-superheated vapor mixtures are commonly made as for gas mixtures, employing the foregoing gas mixture and gas relations. However, with respect to a given mixture, before one may proceed with confidence upon that basis it is necessary first to verify the fact of, or to ascertain the degree of, superheat of the vaporous constituent. To do so it is necessary to possess data concerning the temperature and total pressure of the mixture and the mass proportion of the vapor. It is further necessary to recall that the vapor pressure (or temperature) of a *saturated* vapor is established solely and unchangeably by its temperature (or pressure), as is also the density or any other property of the saturated vapor. The following example will illustrate the principles involved perhaps better than a collection of formulas, since recourse must be had to the steam tables in any case.

Example 1. A parcel of atmospheric air at a (total) pressure of 14.7 lb per sq in. (abs) and a temperature of 70 deg fahr is found (by hygrometric determination) to contain 0.009 lb of water vapor per lb of air (not mixture). Is the vapor superheated and, if so, by how many degrees? What is the partial pressure of the air? Compute the density of each constituent, the density of the mixture, the mass of vapor per pound of mixture, and the density of moisture-free air at the above temperature and pressure. What is the equivalent gas constant and molecular weight of the mixture? Compute the enthalpy per pound of mixture, relative to air and water at 32 deg fahr.

Solution. By equation (1) et seq.:

$$P_v\text{, if superheated} = 14.7\,\frac{\dfrac{0.009/1.009}{18}}{\dfrac{0.009/1.009}{18}+\dfrac{1.0/1.009}{29}} = 0.210 \text{ lb per sq in.}$$

Temperature of saturated vapor at 0.21 lb per sq in. = 54.4 deg fahr (from steam tables).
Vapor is therefore superheated by (70 − 54.4 =) 15.6 deg fahr.

$P_{\text{air}} = 14.7 - 0.21 = 14.49$ lb per sq in.

$$\text{Density, vapor} = \frac{0.21 \times 144}{86 \times (70 + 460)} = 0.00066 \quad (86 = R \text{ for superheated vapor}).$$

$$\text{Density, air} = \frac{14.49 \times 144}{53.3 \times (70 + 460)} = \underline{0.07393.}$$

$$\text{Density, mixture} = 0.07459 \text{ lb per cu ft.}$$

$$\text{Vapor per pound of mixture} = \frac{0.00066}{0.07459}\left(\text{or } \frac{0.009}{1.009}\right) = 0.00892 \text{ lb.}$$

$$\text{Density, moisture-free air} = \frac{14.7 \times 144}{53.3(70 + 460)} = 0.07493 \text{ lb per cu ft.}$$

$R_m = 0.00892 \times 86 + 0.99108 \times 53.3 = 53.6$; $m_m = 1545/53.6 = 28.8$

H_{air} per pound of mixture $= 0.99108 \times 0.241 \times (70 - 32) = 9.07$ Btu.

H_{vapor} per pound of mixture $= (M_v/M_m)H_{g,\,70°}$ (since for low-pressure vapor H depends solely on temperature) $= 0.00892 \times 1090.8 = 9.73$ Btu.

$H_{\text{mixture, per lb}} = 9.07 + 9.73 = 18.80$ Btu.

(**b**) In the consideration of mixtures consisting of a gas and a saturated vapor, or so-called *saturated* mixtures, the items of outstanding significance are that, although the strictly gaseous constituents continue to conform to the typical gas characteristics, the *saturated* vapor constituent now acts independently, that is, in conformity with the typical vapor characteristics. The application of these considerations, as well as certain additional features and properties of a saturated mixture, are developed in the following examples.

Example 2. An air-water vapor mixture at 14.7 lb per sq in. total pressure is known to be saturated (i.e., the vapor constituent is saturated vapor) at 70 deg fahr. Ascertain the partial pressures and densities of the vapor and air constituents and the density of the mixture. Compute the mass of vapor per pound of air and per pound of mixture, and the relative enthalpy per pound of mixture.

Solution.

P, saturated vapor at 70 deg fahr. by steam tables, = 0.363 lb per sq in.

P of air $= 14.7 - 0.363 = 14.337$ lb per sq in.

$$\text{Density of vapor} = 1/869\text{, by tables, or} = \frac{0.363 \times 144}{86 \times (460 + 70)} = 0.00115$$

$$\text{Density of air} = \frac{14.337 \times 144}{53.3 \times (460 + 70)} = \underline{0.07301}$$

$$\text{Density of mixture} = 0.07416$$

Vapor per pound of air = 0.00115/0.07301, or (eq 1) $\frac{0.363}{14.337} \times \frac{18}{29} = 0.0157$.

Vapor per pound of mixture = 0.00115/0.07416, or 0.0157/1.0157 = 0.0155.
$R_m = 0.0155 \times 86 + 0.9845 \times 53.3 = 53.8$.
$H_{\text{vapor, per lb of mix.}} = 0.0155 \times 1090.8 = 16.91$ Btu
$H_{\text{air, per lb of mix.}} = (1.000 - 0.0155) \times 0.241 \times (70 - 32) = 9.02$ Btu

$H_{\text{mixture, per lb}} = 25.93$ Btu

Example 3. Referring to the mixture of example 1 (0.009 lb of vapor per lb of air, not mixture), ascertain the temperature at which the mixture would become saturated upon cooling at constant (total) pressure, and compute the amount of energy removal as heat necessary to have effected the specified cooling, Btu per pound of mixture.

Solution. As the low-pressure vapor conforms to gas characteristics down to saturation, and as the same mass proportions between the vapor and air will persist so long as the cooling is not sufficient to have produced any condensation of the vapor, the vapor pressure at saturation is the same as in example 1 or 0.210 lb per sq in. The temperature at which the vapor (and mixture) will become saturated is therefore its saturation temperature corresponding to that pressure, or 54.4 deg fahr.

$H_{\text{air, per lb of mix.}} = 0.99108 \times 0.241 \times (54.4 - 32) = 5.35$ Btu
$H_{\text{vapor, per lb of mix.}} = 0.00892 \times 1083.7 = 9.67$ Btu

$H_{\text{mixture, per lb}} = 15.02$ Btu

Energy abstracted for constant pressure cooling = ΔH = 18.80 − 15.02 = 3.78 Btu per lb of mixture.

R is the same as in example 1.

In connection with the last example it is to be noted that the temperature at which a (unsaturated) mixture becomes saturated upon cooling at constant pressure is known as the *dew point* of the original mixture.

(c) Mixtures of a gas, saturated vapor, and saturated liquid may be encountered when a saturated mixture is cooled or compressed, or when a volatile liquid is introduced into a space containing a gas but in a greater amount than can exist in the space as saturated vapor at the existing temperature. Again the gas constituent conforms to the gas characteristics, but the properties of the saturated liquid and vapor are independently interrelated in accordance with the saturation characteristics of the vapor. The following example illustrated one phase of these considerations.

Example 4. The mixture of examples 1 and 3 is further cooled at a total pressure of 14.7 lb per sq in. to a temperature of 40 deg fahr. Ascertain the partial pressures and densities of the remaining vapor and of the air; the masses of saturated vapor and of the fog or rain which must have condensed out, pound per pound of air and per pound of mixture; the quality of the vapor-fog mixture; the enthalpy of the mixture; and the heat-energy removal necessary to have cooled from the dew point to 40 deg fahr.

Solution.

P, saturated vapor at 40 deg fahr, by steam tables, = 0.1217 per sq in.
P of air = 14.7 − 0.1217 = 14.578 lb per sq in.
Density of vapor (by tables) = 1/2445 = 0.00041.

$$\text{Density of air} = \frac{14.578 \times 144}{53.34 \times (460 + 40)} = 0.07878.$$

Vapor per pound of air = 0.00041/0.07878 = 0.0052 lb.
Fog per pound of air = 0.009 − 0.0052 = 0.0038 lb.
Fog per pound of mixture = 0.0038/1.009 = 0.00376 lb.
Vapor per pound of mixture = 0.0052/1.009 = 0.00515 lb.
Quality of vapor-fog component = 0.0052/0.009 = 0.577 = 57.7%.
$H_{\text{vapor, per lb of mix.}} = (0.0052/1.009) \times 1077.1 = 5.55$ Btu
$H_{\text{fog, per lb of mix.}} = (0.0038/1.009) \times 8.05 = 0.03$ Btu
$H_{\text{air, per lb of mix.}} = (1.0/1.009) \times 0.241 \times (40 - 32) = 1.91$ Btu

H, per pound of mixture........................... = 7.49 Btu
Energy abstracted, = ΔH = 15.02 − 7.49 = 7.53 Btu per lb of mixture.

37. HUMIDITY AND HYGROMETRY

In many circumstances, as in scientific ventilation and air conditioning, it becomes most essential that air of closely prescribed temperature and moisture content shall be provided. This moisture content may be designated in several ways, but the index commonly employed by the engineer is that of the *relative humidity* of the mixture. This is defined as the *ratio between the density of the actual (superheated) vapor in the mixture* *and the density of saturated vapor at the temperature of the mixture.* As for both circumstances the density of the (low-pressure) vapor is satisfactorily computable by the gas relation, density $= P/RT$, it follows that the relative humidity is also expressed by the ratio between the actual partial pressure of the vapor in the mixture and its saturation pressure corresponding to the mixture temperature. Thus, denoting relative humidity by the symbol ϕ

$$\phi = \frac{\text{Actual vapor density}}{\text{Density, sat. vapor at mixture temperature}}$$

or

$$= \frac{\text{Actual vapor pressure}}{\text{Sat. pressure at mixture temperature}}$$

To illustrate, the mixture of example 1 would be said to have a relative humidity of (0.00066/0.00115 or 0.210/0.363 =) 0.575, or 57.5 per cent. In the same parlance, the saturated mixture of example 2 would be said to have a relative humidity of 100 per cent. Likewise, in accordance with example 3, the mixture of example 1 would attain a 100 per cent relative humidity upon cooling to its dew point (at 54.4 deg fahr). Its humidity might alternatively have been brought to 100 per cent if supplied with (0.0155 − 0.00892) 0.0066 lb of moisture (per pound of mixture) while maintained at 70 deg fahr and atmospheric pressure.

Devices Which Determine the Humidity of gas-vapor mixtures are known as *hygrometers* or *psychrometers*. The type which is most used by the engineer consists simply of two thermometers, with the bulb of one *dry* and the bulb of the other covered by a wick which is kept *wet* with the same liquid as exists in the vapor phase in the mixture (as the water in atmospheric air). An active current of the mixture under test is caused to pass across the wet bulb, effecting a continuous vaporization from the bulb and consequent cooling and temperature depression, due to the energy absorption required for producing the vaporization.

The immediate environs of the wet bulb are thus a region to which there pass steadily the air and superheated vapor in the air mixture under test, where the water which passes up the wick is evaporated, and from which there departs a mixture of air and *saturated* vapor. By writing the steady-flow energy equation for this region it is possible to develop an expression for direct evaluation of the mass of the vapor per pound of air (not mixture) in the air mixture as supplied. From these data the relative humidity is readily computable by the methods of example 1 and the above.

In developing the equation the following symbols are employed:

t_d = dry bulb (actual mixture) temperature, degrees fahrenheit.
t_w = temperature registered by wet bulb, degrees fahrenheit.
$M_{v,1}$ = mass of (superheated) vapor per pound of air (not mixture) in the approaching mixture at t_d.
$M_{v,2}$ = mass of (saturated) vapor per pound of air (not mixture) in the *mixture* leaving the immediate surface of the wet-bulb wick, at t_w.
$M_{v,2} - M_{v,1}$ = mass of liquid passing up wick, at t_w and vaporizing, pound per pound of air (not mixture).
$H_{f,1}$ = enthalpy of saturated liquid at t_d, Btu per pound.
$H_{g,1}$ = enthalpy of (superheated) vapor in the approaching mixtures at t_d, Btu per pound. At the very low vapor pressures encountered this effectively equals the enthalpy of saturated vapor (H_g) *at the same temperature*, t_d. (See example 1.)
$H_{fg,1}$ = enthalpy of vaporization at t_d.
$H_{f,2}$ = enthalpy of liquid passing up wick to wet bulb, at t_w, Btu per pound.
$H_{g,2}$ = enthalpy of saturated vapor leaving wet bulb, at t_w.
$H_{fg,2}$ = enthalpy of vaporization at t_w.
$H_{a,1}$ = enthalpy of air (not mixture) approaching at t_d Btu per pound.
$H_{a,2}$ = enthalpy of air (not mixture) leaving at t_w Btu per pound.
c_p = specific heat of air at constant pressure = 0.241.
Q_r = energy to wet bulb as heat by radiation, etc., from its warmer environs, Btu per pound of air (not mixture).

Writing the steady-flow energy equation for the wet bulb by equating the sum of the energies coming to the bulb via the water which passes up the wick, via the approaching mixture and by radiation, to the sum of the energies leaving via the departing air and saturated vapor, all energies being in Btu per pound of air (not mixture),

$$(M_{v,2} - M_{v,1}) \times H_{f,2}] + [1.0 \times H_{a,1} + M_{v,1} \times H_{g,1}] + Q_r = [1.0 \times H_{a,2} + M_{v,2} \times H_{g,2}]$$

or, collecting terms in $M_{v,1}$,

$$M_{v,1}(H_{g,1} - H_{f,2}) = M_{v,2}(H_{g,2} - H_{f,2}) - (H_{a,1} - H_{a,2}) - Q_r$$

But $H_{g,1} - H_{f,2} = H_{f,1} + H_{fg,1} - H_{f,2} = H_{f,g\,1} + (t_d - t_w)$

$H_{g,2} - H_{f,2} = H_{fg,2}$

and $H_{a,1} - H_{a,2} = c_p(t_d - t_w) = 0.241(t_d - t_w)$

whence,

$$M_{v,1} = \frac{M_{v,2}\,H_{fg,2} - 0.241(t_d - t_w) - Q_r}{H_{fg,1} + (t_d - t_w\ )} \tag{6}$$

In this relation the value of $M_{v,2}$ is directly computable from equation 1 (Art. 35), that is, $M_{v,2} =$ (for air and water vapor) $18\,P_{v,2}/29\,(P_{\text{mix.}} - P_{v,2})$, where $P_{v,2}$ is the saturation pressure of the vapor at t_w. (See also example 2.)

Measurement of Q_r is quite impracticable in actual use of the wet and dry bulb hydrometer, but tests indicate that with a conventional wick-covered mercury thermometer the radiation correction may be compensated with reasonable accuracy if the observed wet-bulb temperature be reduced by about 0.016 (1.6 per cent) of the observed wet-bulb depression $(t_d - t_w)$.

The application of equation 6 is shown by the following example, which contains data such as would be secured in the use of a wet and dry bulb hydrometer with the mixture of example 1.

Example 5. Observed psychrometric data taken with a wet and dry bulb hydrometer in air at a barometric pressure of 14.7 lb per sq in. were

$$t_d = 70 \text{ deg fahr};\ t_w = 60.65 \text{ deg fahr}$$

Compute the mass of vapor per pound of air (not mixture) and the relative humidity of the mixture as supplied.

Solution.

Corrected wet-bulb temperature = 60.65 − 0.016(70 − 60.65) = 60.50 deg fahr.

Saturated vapor pressure at 60.50 deg fahr = 0.2608 lb per sq in.

$M_{v,2} = 18 \times 0.2608/29 \times (14.7 - 0.2608) = 0.01121.$

$H_{fg,1}$ (at 70 deg fahr) = 1052.7; $H_{fg,2}$ (at 60.50 deg fahr) = 1057.9.

$$M_{v,1} = \frac{0.01121 \times 1057.9 - (0.241 \times 9.50)}{1052.7 + 9.50} = \frac{9.58}{1062.2} = 0.0090.$$

$$\frac{P_{v,1}}{14.7 - P_{v,1}} = \text{(by equation 1) } \frac{0.009/18}{1/29} = \frac{1}{69};\ P_{v,1} = 14.7/70 = 0.210.$$

Relative humidity = 0.210/0.363 = 57.8 per cent.

Psychrometric Charts for Air-water Vapor Mixtures at or about a total pressure of 14.7 lb per sq in., as well as tables giving the mass of saturated vapor per pound of air at various temperatures but at the standard atmospheric pressure, are provided in the various mechanical engineering handbooks and give in graphical and tabular form the results of computations such as the foregoing. Their utility is in general limited, however, to the above total pressure. A psychrometric chart in common use is that devised by H. W. Carrier and shown on p. 7-92 as Fig. 1.

The Ferrel Psychrometric Formula,* with empirical constants that hold for temperatures between −40 and 140 deg fahr, is:

$$\frac{p' - p}{t_d - t_w} = 0.000367\,p_m\left(\frac{t_w + 1539}{1571}\right)$$

where p = the actual partial pressure of the water vapor in the mixture, in inches of mercury absolute.

p' = the saturation pressure at the wet-bulb temperature, in inches of mercury absolute.

t_d = the dry-bulb temperature, in degrees fahrenheit.

t_w = the wet-bulb temperature, in degrees fahrenheit.

p_m = the total pressure of the mixture (commonly the barometric pressure), in inches of mercury absolute.

This relation is the wet-bulb energy equation with certain constants supplied. With the dry-bulb and wet-bulb temperatures and the total mixture pressure experimentally determined, the actual partial pressure of the water vapor in the mixture may be found from this formula.

The saturation pressure of water vapor for temperatures at 32 deg fahr and above may be found from steam tables or charts. For convenience, Table I is included, in which the *saturation pressures of water vapor in contact with ice* at temperatures from −20 to 31 deg fahr are given. The values in this table are from the Weather Bureau Bulletin 235.

---

* U. S. Dept. of Agriculture, Weather Bureau Bull. 235.

With the partial pressure, p, of the water vapor in the mixture known, the *dew point* can then be found, since the dew point of the mixture is the saturation temperature

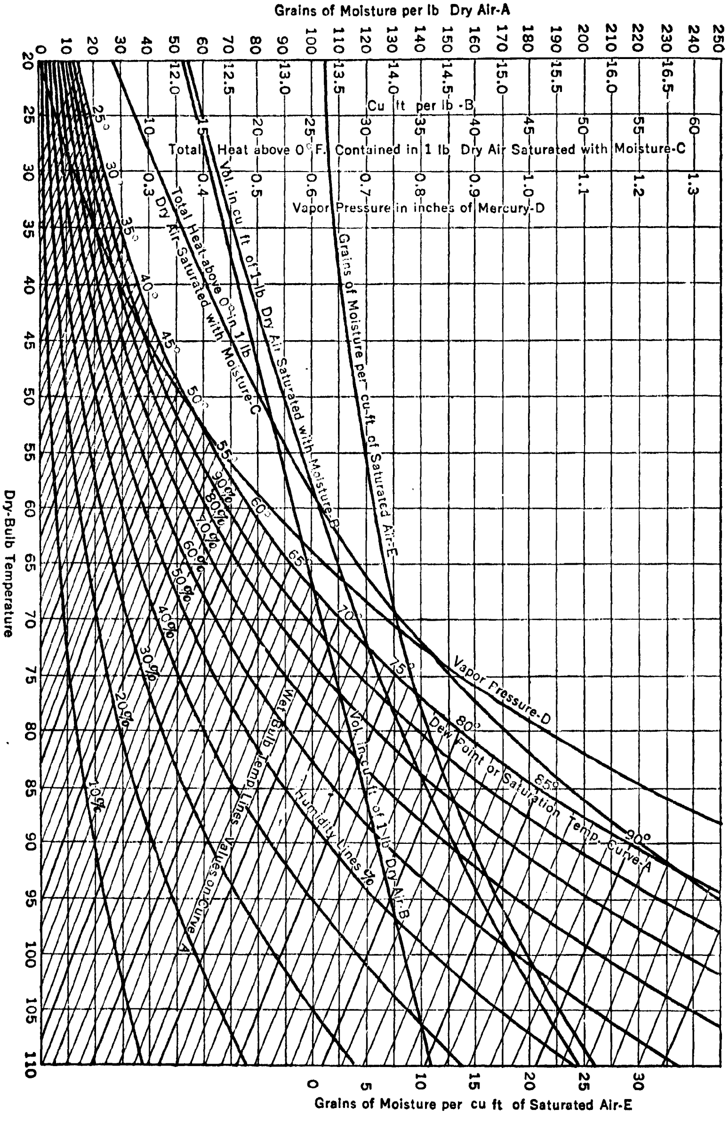

Fig. 1. Psychrometric Chart

corresponding to this vapor pressure. If the mixture were cooled at constant pressure the dew point would be that temperature at which condensation of the water vapor would start. The dew point is shown as t_3 in Fig. 2. The relationship between dry-bulb temperature, wet-bulb temperature, and dew point is also shown in the same figure for the mixture in which the water vapor is superheated.

Table I. Pressures of Saturated Water Vapor in Contact with Ice

t Deg. Fahr	*p* In. Hg	*t* Deg Fahr	*p* In. Hg	*t* Deg Fahr	*p* In. Hg	*t* Deg Fahr	*p* In. Hg
−20	0.0126	−7	0.0260	6	0.0515	19	0.0979

−12	0.0199	+1	0.0403	14	0.0772	27	0.143
−11	0.0210	2	0.0423	15	0.0810	28	0.150
−10	0.0222	3	0.0444	16	0.0850	29	0.157
− 9	0.0234	4	0.0467	17	0.0891	30	0.164
− 8	0.0247	5	0.0491	18	0.0933	31	0.172

The density of the atmosphere * is given by the equation:

$$d_m = \frac{B - 0.38\,p_v}{0.754\,T_d} \tag{7}$$

In this equation, the vapor pressure, p_v, may be computed with adequate accuracy by the following modification of Apjohn's equation:

$$p_v = 0.49\,p_w - \frac{B}{30}\,\frac{(t_d - t_w)}{90} \tag{8}$$

where d_m = density of atmosphere, a mixture of air and water vapor, pounds per cubic foot.
B = barometric pressure, inches of mercury at 32 deg fahr.
p_v = actual vapor pressure, inches of mercury at 32 deg fahr.
p_w = pressure of saturated water vapor at the wet bulb temperature, in pounds per square inch (as found from steam tables).
t_d (T_d) = dry-bulb temperature, degrees fahrenheit (absolute).
t_w = wet-bulb temperature, degrees fahrenheit.

The density is to be computed to only three significant digits (e.g., 0.0764).

The vapor pressure needs to be computed to only two significant digits (e.g., 0.63 in. of mercury).

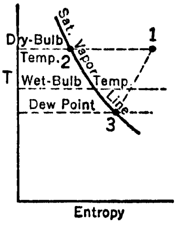

Fig. 2. T–S Diagram Illustrating Dew Point

Temperatures must be measured to the nearest single degree fahrenheit; barometric pressure to 0.01 in. of mercury.

Computation of density to four significant digits demands measurements of temperature to closer than 0.1 deg fahr.

The items of greatest fundamental interest in connection with hygrometry are (*a*) partial pressure of the vapor in the atmosphere, (*b*) relative humidity, and (*c*) dew point. Summarizing, these may be determined as follows: (*a*) The *partial pressure* of the vapor in the atmosphere may be found from (1) the theoretical formula (equations 1 and 6) as illustrated in example 5; (2) Ferrel's equation by solving for p; (3) steam tables, if dry-bulb temperature and humidity are known, by use of $p = \phi p_g$, where p is the partial pressure of the vapor, ϕ is the relative humidity, and p_g is the saturation pressure at the dry-bulb temperature; (4) Carrier or similar psychrometric charts by direct reading with dry-bulb and wet-bulb temperatures known; (5) equation 8. (*b*) *Relative humidity* may be found from (1) the theoretical formula as illustrated in example 5; (2) Ferrel's equation, in which $\phi = p$/saturation pressure at dry-bulb temperature; (3) Carrier or similar psychrometric charts by direct reading, with dry-bulb and wet-bulb temperatures known; (4) tables giving values of humidity for various dry-bulb and wet-bulb temperatures. (*c*) The *dew point* may be found from (1) Carrier or similar psychrometric chart by direct reading with dry-bulb and wet-bulb temperatures known; (2) steam tables, the temperature of saturation at the partial pressure of the vapor; (3) dew-point instrument, which measures dew-point temperature directly.

---

* Based upon considerations discussed in three articles by Professor C. H. Berry of Harvard University, published in *Combustion*, vol. 6, August, 1934, p. 15; September, 1934, p. 24; October, 1934, p. 21.

38. AIR CONDITIONING

Air Conditioning consists chiefly of the simultaneous control of temperature, humidity, motion, and purity of air to meet the requirements of human comfort. Some of the principal factors that affect human comfort and welfare as influenced by air environment are the (1) dry-bulb temperature, (2) humidity, (3) motion, (4) distribution, (5) dust content, (6) bacteria content, and (7) odors. Other factors which may influence comfort, but the effects of which are not so well established at the present time, are (8) light, (9) ozone content, (10) ionic content, and (11) pressure.

Human Occupancy of a confined space produces at least six important alterations in the properties of the air: (1) the oxygen content is decreased slightly; (2) the carbon dioxide content is increased slightly; (3) products of decomposition, usually accompanied by odors, are given off; (4) the air temperature is raised; (5) the humidity is increased by evaporation of moisture from the skin and lungs; and (6) the number of positive and negative ions in a unit volume of the air is decreased.

Effective Temperature may be defined as an arbitrary index of the degree of warmth or cold felt by the human body in response to temperature, humidity, and air movement. The numerical value of the effective temperature index for any given air condition is fixed by the temperature of saturated air which, at a velocity or turbulence of 15 to 25 ft per min, induces a sensation of warmth or cold like that of the given condition. Fig. 3 shows the effective temperature-humidity relation at various values of humidity and dry-bulb temperature when the air movement is between 15 and 25 ft per min. The intersection of the dry-bulb and the wet-bulb temperature lines will give the relative humidity and also the effective temperature. This figure shows the comfort zone as established by experiment, upon which are shown the average comfort lines for winter and summer. The fact that the summer average is greater than the winter average is probably due partly to adaptation to seasonal weather and partly to differences in clothing worn in the two seasons.

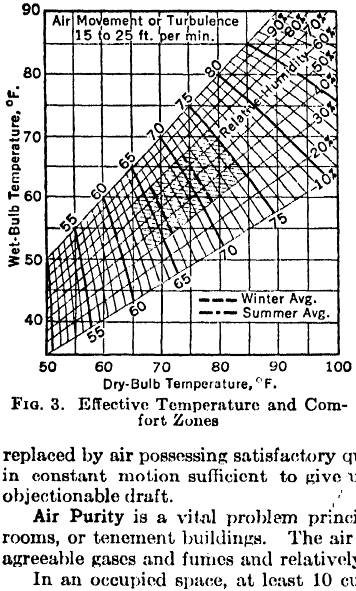

Fig. 3. Effective Temperature and Comfort Zones

It is now recognized that the importance of air motion in air conditioning ranks second only to temperature. In an occupied space, air having all the other essential qualities but lacking motion feels stagnant, stuffy, and depressing, because the vitiated air next to the body is not replaced by air possessing satisfactory qualities. The air in an occupied space should be in constant motion sufficient to give uniformity in temperature and humidity without objectionable draft.

Air Purity is a vital problem principally in manufacturing establishments, crowded rooms, or tenement buildings. The air should be free from all toxic, unhealthful, or disagreeable gases and fumes and relatively free from odors and dust.

In an occupied space, at least 10 cu ft of fresh air per minute per person should be provided from an outside source to remove body heat, body odors, and products of respiration. In rooms where the occupants smoke, an additional 6 to 7 cu ft of fresh air per minute per person should be provided. This volume of air change is inadequate to provide proper air motion. It is customary to provide the minimum quantity of fresh air required for the removal of heat and odors and to recirculate the additional volume required for proper air motion.

Control of Relative Humidity is very important if comfortable conditions are to be maintained. Cold, outside air in winter usually will have a very low relative humidity after it has been heated. Such air should be humidified. On the other hand, air in the summer months may have a too great relative humidity. The standard established by the American Society of Heating and Ventilating Engineers states: The relative humidity shall be not less than 30 per cent, nor more than 60 per cent, in any case. The effective temperature shall range between 64 and 69 deg when heating or humidification is required and between 69 and 73 deg when cooling or dehumidification is required.

Air-conditioning Equipment has evolved from the air washer which has been used in large buildings for many years. In the air washer, air is forced through a chamber containing a water spray and then over baffle plates which eliminate free moisture and wet particles of solid matter. Although the air washer was initially used for the removal of dust from the air, its principal use in air conditioning is to change the water-vapor content of the air. Under typical winter conditions, merely heating the air will result in a water-vapor content too low to satisfy comfort requirements. Under usual summer conditions, mere cooling to the desired final temperature will result in too high a water-vapor content. The most satisfactory method which has been devised for effecting a desired water-vapor content at a desired dry-bulb temperature, and one which is used in the large majority of cases, is that which is known as the dew-point method. In the dew-point method of temperature and humidity control, air is brought to a saturated condition at the temperature at which it contains the desired quantity of moisture. This temperature is the dew point of the desired final condition of the air. The air may then be merely heated from this dew point to bring it to the desired dry-bulb temperature and relative humidity. The required dew-point condition can be reached only by the removal or addition of water.

The moisture content may be reduced by sufficiently cooling the air to cause condensation of excess vapor or by physical-chemical means.

An increase in moisture content may be accomplished by a combination of heating and addition of water. This heating and water addition may be done simultaneously or separately, providing that the mixture be brought to a saturated condition at the desired dew-point temperature. Heating and humidification may be accomplished simultaneously by means of a warm water spray. In another process, the air is first preheated, without the addition of moisture, until its wet-bulb temperature is equal to the dew point of the desired final air. Then, without the addition or removal of heat, the air is *saturated* in a water spray. This will bring it to the required, saturated, dew-point condition. Finally, by heating from this dew-point temperature, the air-vapor mixture will be brought to the desired final condition of dry-bulb temperature and relative humidity. Example 6 illustrates the process just described.

Example 6. The outside air has a dry-bulb temperature of 40 deg and a relative humidity of 65 per cent. It is desired to condition the air to dry-bulb temperature of 74 deg and relative humidity of 45 per cent, which will give an effective temperature of about 69 deg.

The air is (1) heated before it enters the washer until the wet-bulb temperature is equal to the dew point of the final air, then (2) saturated in the spray to the temperature equal to the dew point of the final condition, then (3) heated to the dry-bulb temperature required. This brings it to the final desired relative humidity.

A tabulation of the air condition in the various stages will illustrate the process.

Table II

	Initial Air Condition	After Heater	After Spray	Final Air Condition
Dry-bulb temperature, degrees fahrenheit	40.0	72.0	51.3	74.0
Relative humidity	0.65	0.205	1.00	0.45
Wet-bulb temperature, degrees fahrenheit	35.6	51.3	51.3	60.5
Dew point, degrees fahrenheit	29.6	29.6	51.3	51.3
Vapor pressure, pounds per square inch	0.0791	0.0791	0.1869	0.1869

The preheat temperature and the temperature of the water spray need not be definitely as described as long as the air from the spray is saturated and at the temperature of 51.3 deg. If the water is warmer than 51.3 deg, not so much preheating is required. Example 7 illustrates the dehumidification of air under summer conditions.

Example 7. The outside air has a dry-bulb temperature of 95 deg and a relative humidity of 65 per cent. It is desired that the final condition of example 6 be attained.

Table III

	Initial Condition	After Cooler	Final Condition
Dry-bulb temperature, degrees fahrenheit	95.0	51.3	74.0
Relative humidity	0.65	1.00	0.45
Wet-bulb temperature, degrees fahrenheit	84.0	51.3	60.5
Dew point, degrees fahrenheit	81.4	51.3	51.3
Vapor pressure, pounds per square inch	0.5297	0.1869	0.1869

In this case the cooler must decrease the temperature of the saturated mixture to the desired dew point of 51.3 deg.

ELECTRICITY AND MAGNETISM

Scope

In this section are presented the principles of electricity and magnetism together with formulas basic to the solution of electric and magnetic circuits.

1. SYSTEMS OF UNITS

Three Systems of Units are in use, in terms of which electric and magnetic quantities are expressed. These systems are known as the cgs electrostatic system, the cgs electromagnetic system, and the practical system (see Section 3). The various units in the practical system have been given short names which are in common use, e.g., ampere, volt, coulomb, etc. For the sake of brevity the corresponding units of the electrostatic system will be designated by these same names with the prefix " stat," and the corresponding units in the cgs electromagnetic system will be designated by these same names with the prefix " ab," the latter prefix arising from the term " absolute " sometimes applied to this system.

The use of the electrostatic and electromagnetic systems of units arises from the manner in which certain of the fundamental quantitative relations, or " laws," were originally formulated. The practical system is related to the electromagnetic system by even multiples of ten times the units in the latter, e.g., 1 volt = 10^8 abvolts, 1 ampere = 10^{-1} abampere, 1 ohm = 10^9 abohms.

Quantitative Relations between electric quantities given here are independent of the system of units employed provided all the quantities involved are expressed in the same system of units. For some of the magnetic quantities, certain additional practical units have been introduced which are not related to the cgs electromagnetic units by multiples of 10; consequently, to avoid confusion it is best to reduce all quantities to electromagnetic units before applying any of the formulas given.

Standard symbols for quantities are given in Section 1, Table 4. When vector relations are involved the symbol is in bold face type.

ELECTRON THEORY

2. ELECTRICITY AND MATTER

Electrical Entities. Contemporary physics identifies electricity with matter. For example, an atom of the element hydrogen is thought of as consisting of a single nuclear quantity or charge of electricity called a *proton* about which rotates a second charge of electricity called a *negative electron.* These two charges are equal in magnitude and opposite in sign. Each represents what is believed to be the smallest quantity of electricity which can exist discretely. They are in effect atoms of electricity. Almost the entire mass of the atom resides in the proton. The electron * has a mass of approximately $^1/_{1800}$ of the mass of the proton. The orbital electron may revolve in elliptical or circular paths. The radii and eccentricities of the possible paths of the electron in the hydrogen atom can be computed. While hydrogen is the simplest of the elements, all elements are believed to consist of nuclei made up of tightly packed protons and electrons, surrounded by rotating orbital electrons. The intra-atomic spaces between the nucleus and the orbital electrons are believed to be enormous relative to the size of the electron or proton. Every atom containing an equal number of electrons and protons is said to be a neutral atom.

Although the proton and the negative electron are the most common of the electrical entities, and their properties have been most thoroughly studied, two others which have been observed are important. The *positive electron* or *positron* consists of a positive charge, equal in magnitude to the charge carried by the negative electron, associated with a mass equal to the mass of the electron. The positive electron has no place in the atom model described above. The *neutron* is an entity having a mass approximately equal to that of the proton but having no electric charge. It is not known whether or not a neutron consist of an intimately bound proton and electron. The accuracy with which its mass has been determined is not great enough to disprove or to strengthen this hypothesis.

---

* The term electron used alone means negative electron. When positive electron is meant the word positive will always be used.

A fifth entity, intimately associated with the four already mentioned but somewhat different in concept, is the *photon*. A photon is a quantum of electromagnetic radiation (q.v.) having a definite frequency and a definite energy content. It was supposed, on the basis of the Bohr-Sommerfeld theory, which gave rise to the atom model described above, that a photon (light, x-rays, etc.) was radiated or absorbed when and only when an electron jumped from one orbit to another. This is now believed to be untrue.

The study of electricity has to do with the properties of these entities, in particular the proton and negative electron.

Mass, Energy, and Frequency Relations. Modern quantum physics identifies mass with energy. Thus the law of conservation of energy has been revised to require that the total mass plus energy of the universe be conserved. Quantum physics also to a certain degree identifies electric particles with electromagnetic waves. Under some circumstances entities which have properties normally ascribed only to particles, exhibit characteristics normally observed only in waves. In such cases the energy of the particle and the frequency of the wave are proportional.

The above principles are stated in the following experimental laws:

(*a*) Whenever energy is transformed into mass or mass is transformed into energy

$$E = mc^2 \tag{1}$$

in which E is the energy transformed, m is the mass transformed, and c is the velocity of light in vacuo. ($c = 3 \times 10^{10}$ cm per sec approximately.)

(*b*) A photon of electromagnetic radiation always has associated with it an energy proportional to its frequency.

$$E = h\nu \tag{2}$$

in which E is the energy of the photon, ν is its frequency, and h is a constant factor known as Planck's constant. ($h = 6.55 \times 10^{-27}$ erg-second.)

In nuclear disintegration, in emission of particles or waves by bombardment, and in transmutation of elements the above principles find application. For example, if a photon of radiation strikes a nucleus it may cause the emission of a positron and an electron. In this case

$$\frac{h\nu}{c^2} = \text{Mass of positron} + \text{Mass of electron} + \frac{1}{c^2}(\text{Energy of positron} + \text{Energy of electron}) \tag{3}$$

3. PROPERTIES OF ELECTRICAL ENTITIES

The Negative Electron. The results of experiment justify the following assumptions regarding the electron:

(*a*) No charge of electricity can be produced which is not an integral multiple of the charge carried by a simple electron. The value of this charge is

$$e = 4.774 \times 10^{-10} \text{ cgs electrostatic unit} \tag{4}$$

(*b*) The mass of an electron may be defined as the force required to give it unit acceleration.* Experiments indicate that the mass of an electron, as thus defined, is

$$m = 8.999 \times 10^{-28} \text{ gram} \tag{5}$$

The " effective " mass of the electron increases with increase in velocity (see equation 8).

Unless otherwise stated, wherever the expression " mass of an electron " is used in this article, it is to be understood that this effective mass is meant.

(*c*) An electron having a charge e and moving with velocity v produces the same magnetic field as an elementary length ds of a conduction current of strength i, where $ev = ids$ (see Art. 11).

(*d*) Every neutral atom of matter contains at least one electron which is held in position by forces analogous to elastic forces, that is, an electron may oscillate within the atom, or may be displaced by an impressed electrostatic field. The electrons are always of the same nature irrespective of the substance in which they exist.

---

* That is, $f = ma$, where f is the force, a is the acceleration, and $m = \frac{f}{a}$ is the mass, computed at low electron velocities (less than one-tenth the velocity of light).

(*e*) An electron may be forced from the atom by the influence (mutual repulsion) of a "free" electron moving at a high velocity in its immediate vicinity. This action is usually spoken of as a bombardment, or collision, although it is not necessary to assume that the free electron hits the atom.

(*f*) When a neutral atom loses an electron, this atom manifests the properties of a positively charged body and is called a positive ion.

(*g*) When a neutral atom gains an electron, this atom manifests the properties of a negatively charged body and is called a negative ion.

(*h*) In every substance there exists, in addition to the electrons within the atoms, a certain number of "free" electrons, i.e., electrons which can move freely in the interatomic spaces; these free electrons may also pass from one substance to another. Under certain conditions, e.g., in a gas at ordinary pressures, a free electron may attach to itself one or more atoms or molecules.

The Positive Particles. Experiment also justifies the following assumptions regarding the positively charged particles:

(*a*) The smallest positive charge that it has been found possible to produce is numerically equal to that of an electron, viz., 4.774×10^{-10} cgs electrostatic unit.

(*b*) This smallest possible positive charge when associated with a particle having a mass of the same order of magnitude as that of a hydrogen atom is called a proton.

(*c*) This smallest possible positive charge when associated with a particle having a mass of the same order of magnitude as that of the negative electron is called a positive electron.

(*d*) Other positively charged particles may consist of atoms from which one or more electrons have been expelled. Their masses therefore depend upon the number of protons in the nuclei of the atoms. A "free" positively charged particle may also attach to itself one or more neutral atoms or molecules.

(*e*) The term "ion" is usually reserved to designate any charged body having a mass of the order of magnitude of that of a molecule or atom. In this sense a positive or negative electron is not an ion, but the proton is an ion. If, however, the electron becomes attached to an atom or molecule, then this combination forms an ion. In the discharge of electricity through gases at low pressure, the negative electron, although it is not attached to an atom or molecule, is sometimes called an ion.

The Photon. Experiment justifies the following assumptions regarding the photon:

(*a*) The photon is a discrete quantity or *quantum* of electromagnetic radiation (see p. 8–03).

(*b*) The photon is electrically neutral, not being attracted or repelled by electric charges.

(*c*) Photons are capable of producing ionization. A photon may be absorbed by an atom, an electron being emitted in the process. It is thought that occasionally a photon may vanish and give rise to a pair of oppositely charged electrons. When this happens the charge of the universe remains unchanged and the energy of the photon is converted into the mass of the two electrons.

(*d*) Deflection of photons by magnetic fields has not been observed.

(*e*) The energy and frequency of a photon always satisfy the relation $E = h\nu$.

The Neutron. Experiment justifies the following assumptions regarding the neutron:

(*a*) The neutron is electrically neutral, not being deflected from its path by electric charges or magnetic fields.

(*b*) The mass of the neutron is nearly (or perhaps exactly) the same as that of the proton. The best measured value is 1.0051 ± 0.005.

(*c*) Transmutation can be effected by neutrons. For example, a neutron plus a nitrogen nucleus yields a boron nucleus plus a helium nucleus.

(*d*) Neutrons are capable of producing ionization through the intermediary of recoiling nuclei.

Determination of the Constants. A few fundamental principles properly combined yield a powerful set of working tools for the investigation of the properties and the constants of the entities described above. These principles are:

(*a*) If a charged particle falls through a difference of potential, it acquires a kinetic energy equal to the loss of potential energy.

$$\tfrac{1}{2} mv^2 = eV \tag{6}$$

(*b*) If a charged particle is acted upon simultaneously by electric and magnetic fields which are mutually perpendicular, its path is a circle, the radius of curvature of which is

$$\rho = \frac{mv}{He} \tag{7}$$

(*c*) Supersaturated water vapor condenses quickly on charged particles formed in the presence of the supersaturated vapor.

(*d*) Matter inserted in the path of a moving particle may absorb energy and thus reduce the velocity of the particle. When a photon encounters a barrier of matter it also may lose energy; this changes the frequency of the photon but does not change its velocity.

The cloud chamber of C. T. R. Wilson, which makes use of principle (*c*) above, enables the observer to photograph the paths of particles or waves through a gas. The character of the paths under various conditions allows the calculation of many of the fundamental constants to be made.

Mass of the Electron. Experiment shows that the mass as defined by $m = f/a$ (see footnote, p. 8–03) varies with the velocity of the electron, changing appreciably as the velocity of the electron becomes greater than about one-tenth that of light. The formula which represents the experimental facts is

$$m = \frac{m_0}{\sqrt{1 - \left(\frac{v}{c}\right)^2}} \tag{8}$$

where m_0 ($= 8.999 \times 10^{-28}$ gram) is the " rest " or minimum mass of the electron, v is the velocity of the electron, and c is the velocity of light (3×10^{10} cm per sec). There are two theories as to the constitution of the mass m.

1. The earlier theory assumes that the mass is made up of two parts: one a purely mechanical or Newtonian mass invariant with velocity; and a second part, electromagnetic in origin, which is associated with the charge of the electron and which represents the energy of the magnetic field caused by the moving electron. This second part is a function of the velocity of the electron.

2. A second theory dispenses entirely with the concept of mechanical mass and attributes the inertial properties of the electron wholly to the energy associated with the electron.

Relativity, on theoretical grounds, requires that the mass of the electron ($m = f/a$) should change as indicated in equation 8.

4. EMISSION PHENOMENA

Thermionic Emission of Electrons. When a metal is heated to a high temperature in a high vacuum it gives off electrons freely. The amount of the electron emission is subject to the temperature of the metal or cathode and to the electric field at its surface, as due, for example, to a neighboring anode.

The theory assumes that in accordance with the kinetic theory of matter the electrons within the metal are in a constant state of motion, and that of those nearest the surface a certain proportion escape, a few at high, the greater number at lower, velocities in accordance with Maxwell's distribution law. When an electron leaves the surface the metal becomes positively charged, thus putting a retarding force on the electron and tending to make it return. The distance traversed by the electron is greater the greater its initial velocity, and in the presence of a neighboring neutral charged surface it may not return at all. The higher the temperature of the heated metal or cathode the greater the velocities of the electron leaving it, and the greater the volume of electron discharge.

An electron can escape from a metal when, and only when, its kinetic energy is greater than the work which must be done in escaping; that is, when

$$\tfrac{1}{2} mv^2 = w_0 \tag{9}$$

where m is the mass of the electron, v is the component of its velocity normal to the emitting surface, and w_0 is the electron affinity or internal work of electron evaporation of the emitting substance.

With a given cathode temperature there is a maximum electron current beyond which an increase in anode voltage is ineffective. Under these conditions all the electrons emitted from the cathode are drawn to the anode. This condition is known as *voltage saturation.*

This electron current follows the law

$$i = Ne = AT^{\lambda}\epsilon^{-(w_0/KT)} \tag{10}$$

where i is the saturation current per square centimeter of emitting surface, N is the number of electrons emitted per second per square centimeter, e is the charge per electron, A a constant of the material, T the absolute temperature in degrees Centigrade, λ a number not much different from unity, ϵ the base of the Napierian system of logarithms, and K the Boltzmann constant. As far as the individual electron is concerned, this is a statistical law. The value of the current given in equation 10 is independent of the potential of the anode.

With a given anode voltage there is a maximum electron current beyond which an increase in cathode temperature is ineffective. This is due to the condition known as *space charge.* When the cathode is first heated, electrons are emitted with varying velocities. If the anode voltage is zero the first few of these electrons experience no external force, except a slight attraction toward the cathode. These first few electrons ultimately land on the anode or on the walls of the container. The succeeding electrons experience a repulsion due to the electrons, previously emitted but still near the cathode, in the space between the anode and cathode; and if the energies of the newly emitted electrons are small, their motion will be retarded or even reversed. There is thus built up an electric field of force tending to decelerate an electron emerging from the cathode and to make it return to the cathode. If there is no removal of electrons from the space surrounding the cathode this electric field increases in strength until a condition of equilibrium is reached, that is, until as many electrons are entering the cathode as are leaving it. The charge due to the presence of these electrons constitutes the space charge. From the above it is evident that for a given anode voltage an increase in cathode temperature beyond a certain value will serve only to increase the space charge without increasing the current to the anode. This condition is known as *temperature saturation.*

Electron Tubes. A glass bulb, either evacuated or gas filled, and containing two or more electrodes is called an *electron tube.* Electrons (and positive ions) are produced in such tubes by the thermionic emission, photoelectric emission (q.v.), or by bombardment, and are caused to move by the action of an electric field. This electron flow is made to serve various purposes depending upon its magnitude, velocity, and method of control. The various tubes are classified according to number of electrodes, purpose, or particular electronic characteristic utilized.

The two-electrode tube (hot cathode and cold anode in highly evacuated bulb) conducts in only one direction and is an excellent rectifying device for small alternating currents. If a third electrode in mesh or grid form be placed between the cathode and anode, relatively very small potentials on the grid will cause wide variations in the potential gradient at the cathode surface and hence large changes in the number of electrons reaching the anode. Three-electrode tubes are used as amplifying devices, as modulators, demodulators, oscillators, electrostatic voltmeters, relays, etc. Their principal applications are in the field of communication such as telephone, radio, phonograph, talking motion pictures, and transmission of pictures by wire and television, but their applications in other fields are innumerable. Tubes having two and even three control electrodes in addition to the cathode and anode are being extensively employed.

Other important types of electron tube are the x-ray tube, the cathode-ray tube, the gaseous rectifier tube, and the photoelectric cell.

Cathode Rays and Canal Rays. At the occurrence of an electric discharge in an electron tube and at a certain value of the pressure of the gas contained in the tube, it is noticed that a greenish phosphorescence occurs on the walls of the tube. By placing solid bodies in the tube it appears that the phosphorescence is due to something proceeding in straight lines perpendicularly from the surface of the cathode. The name *cathode rays* has been given to this agent which produces the phosphorescence. These rays are deflected by both electric and magnetic fields and communicate a negative electric charge to an insulated conductor. They consist of a stream of rapidly moving electrons. The amount of the deflection of the rays, under the action of magnetic and electrostatic fields, can be calculated or observed.

Cathode-ray tubes with hot cathodes (incandescent filament) have been constructed in which potential differences of a million or more volts are impressed between anode and cathode. A window of extremely thin aluminum foil permits a substantial proportion of the electron stream to emerge into the open air. The behavior of chemical substances and of living tissue under the bombardment of these rays is being studied. Cathode-ray tubes are used as oscillographs and as receiving tubes for television.

If the cathode of a tube producing cathode rays is perforated, faint luminous streaks are seen to proceed through these perforations in a direction opposite to that of the cathode rays. The name *kanalstrahlen* or *canal rays* has been given to this phenomenon. These rays are also deflected by both electric and magnetic fields but to a lesser extent and in relatively the opposite direction from the deflection of cathode rays, and they communicate a positive charge to an insulated conductor.

In terms of the electron theory these rays are positively charged ions. Calculations from actual measurements, making this assumption, show that the charge carried by each of these ions is numerically equal but opposite to that of an electron, and that the mass of each ion is never less than the mass of a hydrogen atom, but may be greater, depending

upon the nature of the gas and the pressure in the tube. That is, the cathode particle is an electron traveling in one direction, and the canal-ray particle is what is left of the atom which has lost an electron, traveling in the opposite direction.

Electromagnetic Waves. Under certain conditions, disturbances which are propagated through space arise in the electric and magnetic fields associated with the points in space. Such disturbances are described mathematically by the equations

$$H = F_1(x - vt) \tag{11}$$

$$E = F_2(x - vt) \tag{11a}$$

in which E and H are the electric and magnetic fields (q.v.), x is the distance from some datum to the point in question along the direction of propagation, v is the velocity of propagation, and t is the time. These disturbances are called *electromagnetic waves.*

The physical concept of an electromagnetic wave is aided if one visualizes a medium (this medium is called the ether) in which the wave exists as a transverse vibration. Many of the experimentally observed properties of electromagnetic waves can be explained on the basis of the assumption of an ether through which the waves are propagated. An electromagnetic wave which is a simple harmonic vibration is termed a monochromatic wave. A monochromatic wave has a definite *frequency* which is the reciprocal of the number of periods per second. The character of a given wave is dependent upon its frequency. The various classes of waves extend over a considerable band of frequencies. In order of increasing frequency these classes are:

(*a*) Long radio waves.
(*b*) Radio broadcast waves.
(*c*) Short radio waves.
(*d*) Ultra-short radio waves.
(*e*) A band not yet completely investigated.
(*f*) Heat waves.
(*g*) Infra-red rays.
(*h*) Visible light.
(*i*) Ultra-violet rays.
(*j*) X-rays.
(*k*) Gamma rays from radioactive substances.
(*l*) Cosmic rays.

The mechanism of producing the radiations in groups (*a*) to (*d*) from about 10^4 to about 3×10^{10} cycles per second is that of accelerating electrons in electric circuits. The mechanism of producing the radiations in groups (*f*) to (*l*) from about 10^{13} to more than 10^{22} cycles per second is that associated with the increase of temperature of a substance, the sudden stopping of high-velocity electrons, or the forced or spontaneous disruption of atoms or atomic nuclei. It is with these extremely high-frequency radiations that the quantum theory is associated.

Photoelectric Effect. Experiment shows that when light of sufficient energy falls upon a substance electrons are liberated from the surface. The number of electrons released per unit time is directly proportional to the intensity of the incident light. The maximum energy of electrons released is independent of the intensity of the incident light but directly proportional to the frequency of the light. The energy equation representing this effect is

$$h\nu = {}^1/_2\, mv^2 + P \tag{12}$$

in which h is Planck's constant, ν is the frequency of the incident radiation, ${}^1/_2\, mv^2$ is the kinetic energy of the liberated electron, and P is the energy required to free the electron from the parent body. P is called the *work function* of the given surface. If equation 12 is written

$$ {}^1/_2\, mv^2 = h(\nu - \nu_0) \tag{13}$$

then ν_0 is the threshold frequency of the substance.

The work function for the alkali metals is lower than that for other substances. Special films having extremely low work functions have been produced by the use of potassium, rubidium, and other elements. It is possible to construct photoelectric surfaces having selective frequency characteristics such that color sensitivity is produced.

Photoelectric cells consisting of a photoelectric surface and an anode in an evacuated glass tube are used commercially for automatic control, product testing, television, etc.

X-rays. When cathode rays strike a target of metal, x-rays are radiated from the metal surface. The wave-length spectra of such x-rays depend primarily on the velocity of the impinging electrons and the material of the target. In general, the higher the voltage between anode and cathode, and the denser the metal of the target, the shorter will be the wave-length of the x-radiation.

The x-ray output of a tube operating at constant potential difference between anode and cathode consists of a continuous spectrum superposed with a number of characteristic lines.

The cathode stream has been shown to consist of electrons traveling at high velocities. Thomson and Stokes have shown, by means of the electromagnetic theory of Maxwell, that the deceleration of these electrons at the anode may produce a pulse of electromagnetic radiation. They have shown further that the radiated energy traversing a unit area at a point P, distant from the region of deceleration of one of the electrons, is for electron velocities small compared to the velocity of light

$$S_p = \frac{ac^2\beta}{4\,\pi r^2c^2}\sin^2\theta \tag{14}$$

in which a is the electron deceleration.
e is the charge of the electron.
β is ratio of velocity of electron before deceleration to velocity of light in vacuo.
r is distance from P (at which energy flux is S_p) to the source of radiation.
c is velocity of light in vacuo.
θ is angle measured from line of travel of electron before deceleration to line joining source of radiation to the point P.

A further development of this electromagnetic pulse theory, by expressing the pulse as a Fourier integral, predicts the spectrum of the radiation to be of the form:

$$I_\lambda d\lambda = K\sin^2\left(\frac{\pi l}{\lambda}\right)d\lambda \tag{15}$$

in which I_λ is the x-ray intensity between the wave-lengths λ and $(\lambda + d\lambda)$.
l is the pulse thickness, i.e., the product of its velocity c and the time for deceleration of the electron producing the pulse.
K is a constant.

This expression indicates a continuous radiation with all frequencies from zero to infinity. Duane found that the continuous x-ray spectrum was limited by a maximum frequency $\nu_{\max}$ in such a way that

$$h\nu_{\max} = eV \tag{16}$$

in which e is the electronic charge and V is the maximum x-ray tube voltage—which agrees with the quantum theory. The electromagnetic theory offers no suggestion concerning the cause of the characteristic line spectra mentioned above.

X-rays are of immense value in diagnosis and therapeutics in medicine, in the examination and inspection of engineering materials for structure and flaws, and in the study of the constitution of matter. The molecules of matter act as diffraction gratings of an x-ray. The resulting interference patterns yield important evidence with regard to the arrangement and spacing of the atoms composing the substance.

Absorption, Scattering, Reflection, and Refraction. The following principles observed in the study of x-rays apply with slight modifications to the other electromagnetic radiations.

When monochromatic x-rays traverse matter, the intensity (I) of the beam after traversing a distance x in a given material is associated with the initial intensity (I_0) by:

$$I_x = I_0\epsilon^{-\mu x} \tag{17}$$

where ϵ is the base of the natural system of logarithms and μ is the linear absorption coefficient, defined by the relation above shown.

Other absorption coefficients defined for convenience are:

The mass absorption coefficient $\mu_m = \dfrac{\mu}{\rho}$ where ρ is the density of the absorbing material.

The atomic absorption coefficient $\mu_a = \dfrac{\mu}{n}$ where n is the number of atoms per cubic centimeter of the volume occupied by the absorbing material.

If the heterogeneous radiation from an x-ray tube traverses matter the absorption coefficient varies with the thickness of the absorbing material. Its value is found to depend chiefly upon the x-ray tube voltage and upon the atomic number of the absorbing material, assumed to be an element.

Two effects are noted when x-rays traverse matter. Electrons are ejected from the absorbing material at high velocities (see photoelectric effect). The radiation is scattered, reducing the intensity along the lines of incidence of the primary beam. Thus μ may be conveniently divided into two parts, τ and σ. The coefficient τ represents the transformation of the energy of the original beam of x-rays into high-speed electrons; σ is the coefficient describing the scattered radiation. Experiment shows that not all the scattered radiation has the same wave-length as the primary beam. The number of photoelectrons ejected by x-rays, at such speeds that the energy of the photoelectron is nearly equal to the energy $h\nu$ of an incident photon, has been shown to be equal, within the limits of experimental error, to the number of photons (" truly absorbed ") represented by accurate measurements of τ.

Measurement of x-ray wave-lengths can be made by taking advantage of the regularity of atomic structure in crystals. W. L. and W. H. Bragg showed that x-rays of wave-length λ incident upon the face of a crystal at a glancing angle θ would, if the crystal planes were separated by a distance d, be reinforced upon reflection, if:

$$n\lambda = 2\,d \sin\theta \quad (n = \text{integer}) \tag{18}$$

This is known as Bragg's law.

By calculations based on an assumed crystal structure, experimental data of density, Avogadro's number and the molecular weight, the value of d may be obtained for some more simply constructed crystals. Then Bragg's law may be used to measure wave-lengths of an x-ray beam.

Ionization of Gases. Under ordinary circumstances at atmospheric pressure, gases are very poor conductors of electricity. By irradiation with x-rays or radioactive substances, by brush discharge, corona, or contact with hot flame, and by other known means, it is possible to make a gas a comparatively good conductor. The process is known as *ionization*. It appears that agents such as those mentioned have the power of breaking down a portion of the gas molecules into free electrons and positively charged particles.

According to the quantum theory, radiation is absorbed by an atom in discrete amounts. The absorption of these quanta makes an electron jump from its then orbit to one of greater radius. If sufficient energy is absorbed the electron leaves the atom altogether and becomes, at least temporarily, a free electron. This leaves the remainder of the atom positively charged. This positively charged particle is known as a positive ion. The electrons and positive ions thus released respond to the force exerted by an electric field and in moving give rise to an electric current. The gas thus becomes conducting. In the absence of such an electric field the electrons and positive ions tend to recombine, and when the radiation producing ionization is removed, this recombination eventually renders the gas non-conducting. At sufficiently high gas pressures the free electrons and positive ions tend to attract neutral molecules to which they attach themselves. At low pressures, however, the mean free paths of the molecules are so great that the charged particle rarely comes within attracting distance of the molecule.

It is assumed that all substances contain at all times some free ions. In a gas under the action of an electric field these ions may attain sufficient velocity to detach electrons from neutral molecules by " collision." The electric field in this instance becomes an ionizing agent. As the ionization increases the gas becomes more and more conducting until the rate of recombination of ions balances the rate of ionization.

Theory of Corona. When the voltage between two conductors becomes sufficiently great, the electric field, which is greatest at the surface, ionizes the air at the surfaces of the conductor. The increase in the conductivity of the air or other gas surrounding the conductor is equivalent to an increase in the effective diameter of the conductor to the value at which the decreasing electric field is balanced by the dielectric strength of the air. The phenomenon is known as *corona*. When the corona is formed, there is visible a faint violet light near the conductor. If the voltage is raised, a *brush discharge* occurs in which bluish streaks like the bristles of a brush are visible near the surface of the conductor. If the voltage is still further increased, a disruptive spark discharge takes place between conductors.

In transmission lines, corona is accompanied by power losses, frequently of serious proportions. It can be controlled by the use of larger-diameter conductors and by operating with voltages low enough to prevent its formation.

DIRECT-CURRENT CIRCUITS

5. ELECTRIC CHARGE, CURRENT, AND ELECTROMOTIVE FORCE

Electric Charge and Electric Current. The unit of electric charge (or quantity of electricity) is called a *coulomb* in the practical system of units. In terms of the charge carried by an electron it requires 6.28×10^{18} electrons to equal a coulomb. An electric charge in motion constitutes an electric current. The rate at which a quantity of electricity flows past a given point in a circuit determines the value of the current. In the practical system of units, the unit of current is called an *ampere* and is the flow of one coulomb per second. (See Section 3 for relationship between practical and other units and for international standards for practical units.)

Electromotive Force. The agent which tends to produce or to maintain an electric current in a circuit is called an *electromotive force* (often abbreviated emf). The names in common use are *difference of potential* and *voltage*, the latter being derived from the practical unit of electromotive force, the *volt* (see Section 3). Electromotive force is not a force in the mechanical sense. Quantitatively it is the electrical energy developed per unit charge

$$E = W/Q \qquad (1)$$

where E is the electromotive force in volts, Q is the charge in coulombs, and W is energy or work in joules. (One joule = 1 watt-second = 10^7 ergs.) The energy W is that required to move the charge Q between two points the difference of potential of which is E. For a more fundamental definition of emf see Section 3.

Sources of Emf. The primary sources of emf are:

1. *Electromagnetic Induction* (see p. 8–27, Art. 12).

2. *Contact of Two Dissimilar Bodies.* Under this head, apart from primary cells and storage batteries, may be included the following sources of emf:

(*a*) *Volta effect* (contact emf). When two dissimilar substances are brought in contact an emf is developed between them. This is explained by the electron theory on the basis of the fact that certain substances have less tendency to give up electrons than other substances. Zinc releases electrons more easily than copper; therefore, if zinc is brought into contact with copper, some of the electrons leave the zinc and enter the copper making the copper negative and the zinc positive. The emf's thus produced are usually very small. According to the electron theory frictional electricity is due to the same cause. However, where the conductivities of the substances are low, friction is required to bring the surfaces into sufficiently intimate contact for the transference of electrons.

(b) *Thermoelectric effects.* If a closed circuit is made of two different metals and the two junctions are held at the same temperature, no current will flow because although emf's are developed at both junctions (see Volta effect, above) they are equal and opposite. If, however, one junction is held at a higher temperature than the other a current will flow as long as the difference of temperature is maintained. This is known as the *Seebeck effect.* According to the electron theory the relative release of electrons is a function of the temperature of the metal. Such junctions are used in thermometry and also for current measurements. The *Peltier effect* is the inverse of the Seebeck effect. If a current is sent through the junction of two dissimilar metals, heat is absorbed by the junction when the current flows in one direction and is emitted by the junction when the current is reversed. The sign of the Peltier effect is connected with the direction of the thermoelectric current which would be produced at a given junction. A current which cools a junction (Peltier effect) flows in the same direction as the thermoelectric current when that junction is heated, and conversely. The *Thomson effect* is apparently an extension of the Peltier effect. In certain metals heat is carried in the direction of the current flow when the current flows from hot to cold regions. When the current flows from cold to hot regions, the hotter parts are cooled. In other metals these effects are reversed.

(c) *Pyroelectric effect.* When certain crystals such as quartz and tourmaline are heated an emf is developed between faces. If the crystal be broken into fragments or even ground to powder, each particle will exhibit this same electrical effect.

(*d*) *Piezoelectric effect.* When certain crystals such as quartz and rochelle salt are subjected to mechanical pressure, electric charges proportional to the pressure appear on certain parts of the crystal. If a crystal of rochelle salt (cut so that two of its faces are perpendicular to its optical axis) is compressed between two electrically connected metal plates applied to the two opposite crystal faces, and a metal band is placed around the middle of the crystal between the end plates, an emf of considerable magnitude will be developed between the band and end plates, upon small changes of pressure between end plates. Compression produces a positive charge on one plate and a negative charge on the other plate. Tension causes the charges to reverse. The pressure due to sound waves may under proper conditions produce emf's of several volts. The piezoelectric effect is reversible. A variable emf applied between the plates and band will cause the crystal to expand and contract mechanically in synchronism with the varying applied emf. This effect has been experimentally applied in loud-speaking telephone receivers. Certain crystals, notably quartz, vibrate at natural periods, dependent upon the thickness of the crystal and its elastic constants, if an emf is applied which has the same frequency as the natural frequency of the crystal. The energy supplied by the electrical oscillator may cause very violent vibrations of the crystal. The constancy of frequency of properly constructed quartz vibrators is so great that they are universally employed to control master oscillators for radio. The natural frequency of vibrations of such crystals lies between about ten thousand and several hundred thousand vibrations per second.

Direction of an Emf. The direction of the emf in any portion of a circuit is taken as the direction in which a positive charge would be forced around a circuit containing only this one source of emf. A closed circuit may contain several sources of emf; in this case the resultant emf acting around the circuit is the algebraic sum of all these emf's, those acting around the circuit in one direction being taken as positive and those acting around the circuit in the opposite direction being taken as negative. Those which act in the opposite direction to the resultant emf are called " back " or " counter " emf's.

A convenient symbol for a source of constant emf is shown in Fig. 1; the long light line represents the positive terminal and the short heavy line the negative terminal. Fig. 2 shows two emf's acting around a circuit in the same direction, and Fig. 3 shows two acting around the circuit in opposite directions. In the first instance the resultant emf is $E_1 + E_2$ and the two emf's are said to be " in series aiding," whereas in the second the resultant emf acting in the right-handed direction around the circuit is $E_1 - E_2$ and the two emf's are said to be " in series opposing." When E_2 is less than E_1 then E_2 is a back or counter emf.

Difference of Electric Potential. Consider a portion of a path A between any two points 1 and 2 in an electric circuit (Fig. 3). The total work done on a unit charge, by the emf's external to this portion of the path when a unit charge moves from 1 to 2, is called the " drop of electric potential " from 1 to 2. The term " difference " of electric potential is also commonly used to designate this quantity; the term " drop " is preferable since it signifies the direction of the difference. Electric potential drop is of the same nature as emf and is expressed in the same units. It is frequently abbreviated " p.d."

FIG. 1

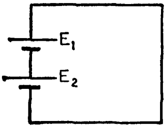

FIG. 2

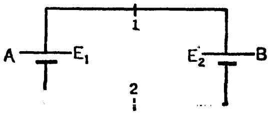

FIG. 3

Potential drop may be due either (1) to a back emf, analogous to the back pressure of a pump, or (2) to an opposing force analogous to that due to the resistance of a pipe to the flow of water. The symbol for potential drop is V when it is desired to distinguish it from electromotive force.

Positive and Negative Terminals. That terminal of a device which is at the higher potential is called the positive terminal, the other being called the negative terminal. The drop of potential is always from the positive to the negative terminal, irrespective of the direction of flow of electricity through the device.

Conductors and Insulators. (See also p. 8-62, Conduction of Electricity in Solids and Fluids.) All substances may for practical purposes be divided into two classes: conductors, and insulators or dielectrics. With conductors a continuously applied emf is accompanied by a continuous flow of electric current. With dielectrics upon first applying an emf there is a transient flow of current until the back emf produced by the establishment of a positive charge at one terminal and a negative charge at the other terminal exactly balances the applied emf, after which current ceases to flow. Strictly speaking, every substance conducts electricity to some extent; that is, a constantly applied emf is always accompanied by a constant flow of current. In those substances which are classed as dielectrics this constant flow is negligibly small. A perfect dielectric may be defined as a substance through which it is impossible to maintain a continuous flow of electricity; no such conductor exists, but very poor conductors are approximately such. The electron theory of conduction assumes that any substance contains, in addition to the electrons and protons which form its atoms and molecules, a certain number of free electrons which like the molecules are in violent agitation. These free electrons or ultimate particles of negative electricity tend to drift towards the point of highest potential when an emf is applied to the substance. This drift constitutes the electric current. According to the theory, good conductors have great numbers of these free electrons, and poor conductors and dielectrics have comparatively very few. In dielectrics the momentary flow of electricity is believed to be due to the displacement of *bound electrons* in the atoms without their actual removal from the atom to which they are bound. The greater the applied emf the greater the displacement of the electron within the atom until a point is reached at which the electron is torn from the atom and the dielectric " breaks down," becoming a partial conductor. This breakdown tends to destroy the solid dielectrics.

Metals are the best conductors and are almost universally employed for electric circuits. For the properties of metals as conductors see Section 11. Carbon and most moist substances are fair conductors; dry non-metallic bodies such as air and other gases (at normal pressure), porcelain, glass, rubber, and dry paper are very good insulators.

A wire covered with an insulating substance or supported on insulating substances is said to be " insulated," even though its ends are connected to a source of emf. For the properties of insulating materials see Section 12.

If decomposition takes place when a current of electricity is passed through liquids which are chemical compounds, the liquid is called an *electrolyte*. Certain solid chemical compounds and fused salts behave as electrolytes. For a discussion of electrolysis and electrolytes see Section 10.

Continuous, Direct, Pulsating, Alternating, and Transient Current. A *continuous* electric current is defined as a current which does not vary with time. A *direct* current is a current which is always in the same direction but may vary or pulsate in value. The term *direct current* is ordinarily used to designate either a continuous current or a current which varies or pulsates only by an inappreciable amount, such as the current from a battery or direct-current generator (q.v.). A *pulsating* current is a direct current which pulsates by an appreciable amount, such as the current from a rectifier (q.v.). An *alternating* current is a current which reverses in direction, being first positive and then negative, but alternates between constant maximum positive and negative values (see p. 8–45, Arts. 19 and 20). A *transient* current (see p. 8–57, Art. 24) is a current which flows when a circuit is closed, opened or altered, that is, before a steady state of direct or alternating current has been reached or when such a state is in any way altered. Transients may be " oscillatory " or " non-oscillatory." An oscillatory current is a current which reverses in direction, oscillating between positive and negative values which either decrease or increase with time. A non-oscillatory current either begins at zero and rises to a steady value, or begins at some finite value and decreases to zero, in either event without oscillation.

For continuous currents

$$I = \frac{Q}{T} \tag{2}$$

where I is the current in amperes, Q is the charge of electricity passing a given cross-section of the circuit, and T is the time in seconds. When the flow of current is not continuous its value at any instant is given by

$$i = \frac{dq}{dt} \tag{3}$$

where i is the *instantaneous* value of the current in amperes and $\frac{dq}{dt}$ is the instantaneous rate of flow of charge through a given cross-section of circuit in coulombs per second.

6. OHM'S LAW, RESISTANCE AND CONDUCTANCE

Ohm's Law. If a steady difference of potential V (in volts) is impressed across a conductor which (*a*) is held at constant temperature and in which (*b*) there is no internal emf,

$$V = rI \tag{4}$$

where I is the steady current in amperes which will flow through the conductor and r is the factor of proportionality called the *resistance* of the conductor. The drop in potential V is therefore equivalent to the drop in potential rI, this latter being called the *resistance drop.* Equation 4 may also be written

$$I = gV \tag{5}$$

where I and V are the same as before and g is termed the *conductance* of the conductor. Obviously *under the conditions stated*

$$g = \frac{1}{r} \tag{6}$$

The practical unit of resistance is the *ohm,* and the practical unit of conductance is the *mho.* For standards and conversion factors see Section III and tables in Section I.

Equations 4 and 5 are forms of what is called Ohm's law. If there is one or more counter emf's between the terminals across which V is impressed the relationship is given by

$$V = rI + E \tag{7}$$

where V, r, and I are the same as in equation 4 and E is the algebraic sum of *counter emf's* within the circuit. In this computation all counter emf's have positive signs while all emf's in the direction of the current receive negative signs; hence such an emf is a negative counter emf. Equation 7 is sometimes referred to as the *modified* Ohm's law.

Terminal and Impressed Voltage. The application of this equation is shown by considering a simple circuit containing a generator and a motor or other receiving device,

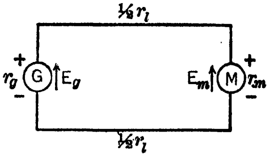

FIG. 4

Fig. 4. Let I be the current in this circuit, r_g the internal resistance of the generator, r_m the internal resistance of the motor, r_l the total resistance of the "line" or connecting wires, E_g the emf developed by the generator, E_m the back emf developed by the motor, V_g the terminal voltage of the generator, and V_m the terminal voltage of the motor. Through the generator the current flows from the − to the + terminal, the emf is from the − to the + terminal, and the drop of potential is from the + to the − terminal. Hence

$$V_g = E_g - r_g I \tag{7a}$$

i.e., the terminal voltage is less than the generator emf by an amount equal to the resistance drop in the armature circuit. Through the motor the current flows from the + to the − terminal, the emf is from the − to the + terminal, and the drop of potential is from the + to the − terminal. Hence

$$V_m = E_m + r_m I \tag{7b}$$

i.e , the terminal voltage is greater than the back emf of the motor by an amount equal to the resistance drop through the motor.

The terminal voltage of the motor is less than that of the generator by an amount equal to the resistance drop in the line, i.e.,

$$V_m = V_g - r_l I \tag{7c}$$

The expression *impressed* emf is also used to designate the rise of potential from the negative to the positive terminal of any receiving device, for example, a motor, bank of lamps, etc., regardless of whether or not the device contains a source of emf.

Resistance and Conductance. It should be carefully noted that the definitions of resistance and conductance expressed by equations 4 and 5 hold only when there is no emf in the portion of the circuit under consideration; this condition is realized only when the current remains constant in value (i.e., a continuous current) and the conductor is of uniform material and at constant temperature throughout. Also, the definition is meaningless unless the same current flows through each cross-section of the conductor and the drop of potential is the same between all points in the two end surfaces; i.e., the end surfaces must be equipotential surfaces. For cylindrical conductors whose ends are equipotential surfaces and for any homogeneous conductor or wire of constant cross-section in which the diameter of cross-section is small in comparison with the length of the conductor, and through which the current is continuous and uniformly distributed

$$r = \rho \frac{l}{A} \quad \text{and} \quad g = \gamma \frac{A}{l} \tag{8}$$

where r is the resistance in ohms, l is the length of the conductor in centimeters, A is the cross-sectional area in square centimeters, and ρ is called the *resistivity* in ohms per centimeter cube or, more briefly, ohm centimeters. Similarly g is the conductance in mhos and γ is the *conductivity* in mhos per centimeter cube or mho centimeters. Note that the word "cube" used in the resistivity-conductivity units refers to a cube of unit dimensions and is *not* an exponent. The ρ may be defined as the resistance in ohms of a cube of the material under consideration having a length of 1 cm and a cross-section of 1 sq cm. Similarly γ may be defined as the conductance in mhos of a cube of the material under consideration having a length of 1 cm and a cross-section of 1 sq cm. It is evident from equations 6 and 8 that

$$\rho = \frac{1}{\gamma} \tag{9}$$

ρ and γ depend upon the material and temperature of the conductor and upon the choice of units (see next paragraph), but are independent of the shape and size of the conductor. Hence ρ is sometimes called the *specific resistance* and γ the *specific conductance* of a substance.

Equation 8 cannot be directly applied to irregularly shaped conductors, but the following equation may be applied to elementary volumes of irregular conductors and the total resistance found by processes of summation or integration:

$$r = \rho \frac{dl}{dA} \quad \text{and} \quad g = \gamma \frac{dA}{dl} \tag{10}$$

where dl is the length and dA is the cross-sectional area of an elementary cylinder or prism of the volume of the conductor.

Temperature Coefficient of Resistance. Practically all substances show a variation of resistance with change in temperature. All metals and most alloys used in electrical engineering increase in resistance with increase in temperature; the resistance of non-metallic conductors such as carbon and electrolytes, also of most dielectrics, decreases with increase in temperature. In general, the relation between the resistance r_t of a given mass of a substance at any temperature t may be expressed in terms of its resistance r_0 at zero degrees by the following power series:

$$r_t = r_0 (1 + at + bt^2 + ct^3 + \text{etc.}) \tag{11}$$

where r_t and r_0 are in ohms, t is in degrees centigrade, and a, b, c, etc., are constants. With metallic conductors such as copper and aluminum the following expression is sufficiently accurate for most practical purposes:

$$r_t = r_0 (1 + \alpha_0 t) \tag{12}$$

where r_t and r_0 are as above and α_0 is called the *zero degree temperature coefficient of resistance.* α_0 is the change in ohms per ohm per degree in the neighborhood of zero centigrade. For dielectrics the linear relationship expressed by equation 12 is not sufficiently accurate. When resistance increases with temperature α is positive; when resistance decreases with temperature α is negative. (For properties of resistance materials see Section 11.)

7. DIRECT-CURRENT NETWORKS

Resistances and Conductances in Series. When several conductors are connected end to end so that the same current flows through each of them (Fig. 5), they are said to be connected *in series*. Let I_{12} be the current in each conductor in the direction from 1 to 2; let r', r'', r''', etc., be the resistances of the various conductors and E_{12}', E_{12}'', E_{12}''', etc., the emf's in the circuit between 1 and 2 in the direction from 1 to 2. Then the potential drop from 1 to 2 is

$$V_{12} = r'I_{12} - E_{12}' + r''I_{12} - E_{12}'' + r'''I_{12} - E_{12}''' + \text{etc.}$$

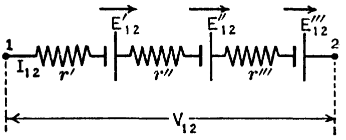

Fig. 5

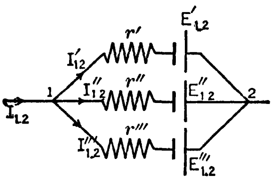

Fig. 6

Therefore, the resistances between the points 1 and 2 are equivalent to a single resistance

$$r = r' + r'' + r''' + \text{etc.,} \tag{13}$$

and the emf's between the points 1 and 2 are equivalent to a single emf:

$$E_{12} = E_{12}' + E_{12}'' + E_{12}''' + \text{etc.} \tag{13a}$$

The equivalent conductance of several conductances g', g'', g''', etc., in series when there are no emf's in the path, is g where

$$\frac{1}{g} = \frac{1}{g'} + \frac{1}{g''} + \frac{1}{g'''} + \text{etc.} \tag{13b}$$

Resistances and Conductances in Parallel. When several conductors are connected to two common junction points so that the same potential drop is established through each (Fig. 6), they are said to be *in parallel*. Let the currents, emf's, and resistances be as designated in the figure. Then since $\Sigma I = 0$ (Kirchhoff's Law)

$$I_{12} = I_{12}' + I_{12}'' + I_{12}''' + \text{etc.}$$

and from equation 7*a*

$$V_{12} = r'I_{12}' - E_{12}' = r''I_{12}'' - E_{12}'' = r'''I_{12}''' - E_{12}''' = \text{etc.}$$

from which relations the currents in the individual branches may be calculated.

When there are no emf's in the various branches, the combined resistance of the several branches from 1 to 2 is r where

$$\frac{1}{r} = \frac{1}{r'} + \frac{1}{r''} + \frac{1}{r'''} + \text{etc.} \tag{14}$$

and the combined conductance is

$$g = g' + g'' + g''' + \text{etc.} \tag{14a}$$

where g', g'', g''', etc., are the individual conductances.

In the special case of two conductors in parallel, and no emf in either, the combined resistance is

$$r = \frac{r_1 r_2}{r_1 + r_2} \tag{14b}$$

Series-parallel Circuits. When a circuit is made up of several conductors some of which are in series and some in parallel, it is called a *series-parallel circuit.* The total resistance or conductance of such a circuit can be calculated from the constants of the several branches by applying successively the formulas for series and for parallel circuits.

Kirchhoff's Network Laws. The relations given above for conductors in series and in parallel are special cases of two general laws, namely:

1. The algebraic sum of the currents coming to any junction in a network of conductors is always zero.
2. The algebraic sum of the potential drops around any closed loop in a network of conductors is always zero.

These two statements are known as Kirchhoff's laws. By making use of them one can always predetermine (*a*) the current in each branch of a network when the resistance of each branch and the emf in each branch are known, or (*b*) the emf in each branch when the current in each branch and the resistance of each branch are known.

It should be carefully borne in mind in applying these laws that a current leaving a point is equivalent to a negative current entering that point, and that an emf in any chosen direction is equivalent to a rise of potential in that direction. In working out any problem concerning a network of circuits it is convenient to make a diagram of the network and to place on each branch in this diagram a number or symbol to represent the value of the current (the directions of the current are arbitrarily assumed) and wherever there is an emf to place a number or symbol to represent its value and an arrow or subscripts to indicate its direction. Then at any junction point those currents represented by arrows pointing toward the point are to be considered positive and those represented by arrows pointing away from the point are to be considered negative; and for any closed mesh those currents and emf's represented by arrows pointing around the mesh in the clockwise direction are to be considered positive and those pointing around the mesh in the counter-clockwise direction are to be considered negative. With this understanding, these laws may be written

$$\Sigma I = 0 \text{ at every point} \tag{15}$$

$$\Sigma E - \Sigma rI = 0 \text{ for every closed mesh} \tag{16}$$

where I, r, and E represent the current, the resistance, and the emf respectively in each branch of the mesh, and the symbol Σ indicates the algebraic sum of the quantities following it.

These equations enable one to write down a set of simultaneous equations for the given network, but it will be found in the case of networks having more than one mesh, that at least one of the current equations may be derived directly from the other current equations, and that at least one of the potential equations may be derived from the other potential equations. That is, the number of independent equations of each form will be at least one less than the number which it is possible to write down. It should also be noted that it is frequently unnecessary to write down formally all the possible independent equations; many of the simpler problems can be solved by writing down two independent expressions for the potential drop between each pair at points and equating them.

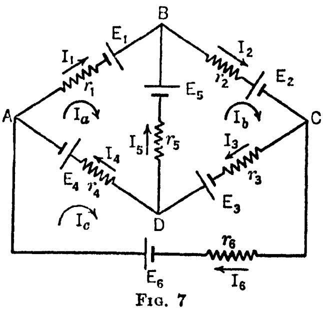

FIG. 7

Solution of Networks. In solving networks of conductors there are several alternative methods all of which are equivalent as far as results are concerned. Directions for solution by one method are here given. In Fig. 7 let the resistances and emf's be given. It is desired to find the currents in the five branches. There are four junction points, A, B, C, and D. Since the currents and their directions are unknown some assumption of direction must be made. Assume directions of currents in all branches and indicate by arrows and symbols I_1, I_2, I_3, I_4, I_5, and I_6. This is shown in the figure. Apply the first law to junctions A, B, and C as follows, remembering that a current approaching a junction is positive and a current leaving a junction is negative.

Since $\Sigma I = 0$

At junction A $$I_4 + I_6 - I_1 = 0 \tag{17a}$$

At junction B $$I_1 + I_5 - I_2 = 0 \tag{17b}$$

At junction C $$I_2 - I_3 - I_6 = 0 \tag{17c}$$

If the first law is applied to the currents at the junction D, there will result an equation derivable from equations 17. The second law is next applied to the closed loops formed by branches. The potential drops will be summed *clockwise* about the loops. The following conventions will be adopted:

1. All potential drops will be positive, and all potential rises will be negative.
2. In summing potential drops around a mesh, a given emf will be considered positive when we proceed from its positive to its negative pole, *regardless of the direction of the current through it.*
3. In summing potential drops around a mesh, a given emf will be considered negative when we proceed from its negative to its positive pole, *regardless of the direction of the current through it.*
4. In summing potential drops around a mesh, the difference of potential across a given resistance will be considered positive if the assumed direction of the current is clockwise with respect to that mesh.
5. In summing potential drops around a mesh, the difference of potential across a given resistance will be considered negative if the assumed direction of the current is counter-clockwise with respect to that mesh.

Applying the above conventions to Fig. 7 the equations representing the second law may be written

Mesh $ABDA$ $$r_1I_1 - E_1 + E_5 - r_5I_5 + r_4I_4 + E_4 = 0 \tag{18a}$$

Mesh $BCDB$ $$r_2I_2 + E_2 + r_3I_3 - E_3 + r_5I_5 - E_5 = 0 \tag{18b}$$

Mesh $ADCA$ $$-E_4 - r_4I_4 + E_3 - r_3I_3 + r_6I_6 - E_6 = 0 \tag{18c}$$

Any further mesh equations are derivable from equations 18. The six equations 17 and 18 permit the solution for currents in all branches. When these equations are solved a positive sign in front of a current indicates that the assumed direction of the current was correct. When a negative sign appears in front of a current, that current actually flows in a direction *opposite* to the direction assumed.

It is frequently convenient to use fictitious currents called *mesh currents* since the first law is automatically taken care of when writing the second law equations by means of mesh currents. Referring again to Fig. 7, the circular arrows represent the mesh currents. The second law equations may then be written

Mesh a $$r_1I_a + r_5(I_a - I_b) + r_4(I_a - I_c) = E_1 - E_5 - E_4 \tag{19a}$$

Mesh b $$r_2I_b + r_3(I_b - I_c) + r_5(I_b - I_a) = E_3 + E_5 - E_2 \tag{19b}$$

Mesh c $$r_6I_c + r_4(I_c - I_a) + r_3(I_c - I_b) = E_6 + E_4 - E_3 \tag{19c}$$

These three equations may be solved for I_a, I_b and I_c. The branch currents can then be found from

$$\left.\begin{aligned} I_1 &= I_a \\ I_2 &= I_b \\ I_3 &= I_b - I_c \\ I_4 &= I_a - I_c \\ I_5 &= I_b - I_a \\ I_6 &= I_c \end{aligned}\right\} \tag{20}$$

The law of the *superposition of currents and voltages* simplifies the calculation of certain types of distributing networks. If electric energy is being supplied over a network to a number of individual loads: (1) the current at any point in the network is equal to the algebraic sum of the currents which would flow if the individual load currents were considered in succession instead of simultaneously, and (2) the voltage drop from the source to any point in the network is equal to the algebraic sum of the drops to that point, each drop being calculated on the basis of individual load currents, taken successively instead of simultaneously.

8. ENERGY AND POWER

Electric Energy and Power. From the definition of emf and potential drop it follows that the total work done by the external agents in forcing Q units of electricity from any point 1 in a circuit to any point 2 is $W = VQ$. (See equation 1.) From the definition of electric current the quantity of electricity carried from 1 to 2 when the current I is established from 1 to 2 is $Q = It$, where t is the time during which the current exists. Hence when a current I is established through any device for a time t by an impressed voltage V, the energy input to this device is

$$W = VIt \tag{21}$$

and the power input, i.e., energy input per unit time, is

$$P = VI \tag{22}$$

When V and I are expressed in volts and amperes respectively the power input is in watts; if t is in seconds, the energy input is in joules or watt-seconds. When V and I are in statvolts and statamperes respectively, or in abvolts and abamperes respectively, the power input is in ergs per second; if t is in seconds the energy input is in ergs.

Applying the above relations to the simple circuit shown in Art. 6, Fig. 4, containing a generator and a motor (armature circuit only is considered), the power input to the motor armature is

$$P_i = E_mI + r_mI^2 \tag{22a}$$

the power output of the generator armature is

$$P_o = E_gI - r_gI^2 \tag{22b}$$

and the power lost in the line is

$$P_l = r_lI^2$$

The term r_gI^2 represents the power lost in heating the armature circuit of the generator due to its resistance, and the term r_mI^2 represents the power dissipated as heat in the armature circuit of the motor. The net electric input to the generator armature is E_gI, and the gross mechanical output of the motor armature is E_mI. The gross mechanical input to the generator is greater than E_gI and the net mechanical output of the motor is less than E_mI by an amount equal to the friction and " core loss " in the respective machines.

Joule's Law. That portion of the power input to any device which is equal to the product of the resistance of the conductors forming the winding of the device and the square of the current through this winding is always converted into heat. That is, when a current I flows through a resistance r, heat is always " dissipated " in this resistance, and the rate of dissipation is

$$P_h = rI^2\,. \tag{23a}$$

This experimental fact is known as " Joule's law." This law applies directly only to continuous or non-varying currents. The relation $P_h = rI^2$ is, however, used as the basis for defining the " effective " resistance of a conductor to an alternating current (q.v.).

Effective Resistance and Conductance. In Art. 6, equation 4, resistance was defined as the factor of proportionality in Ohm's law. On this basis it was shown that resistance is a variable factor dependent upon material, temperature, size, and shape of conductor and upon current distribution. Furthermore, equation 4 applies only where there is no internal emf in the circuit. The most general definition of the resistance r of a substance between any two equipotential surfaces intersecting the path of a current I is

$$r = \frac{P_h}{I^2} \tag{23b}$$

where P_h is the power dissipated as heat between the two equipotential surfaces and I is the effective value of the total current from one surface to the other. With a varying current this dissipation of heat may occur in four different ways, viz.: (1) as heat due to the conduction current through the substance, (2) as heat due to dielectric hysteresis accompanying the displacement current through the substance (when the substance is an insulator), (3) as heat due to magnetic hysteresis accompanying the varying magnetic flux produced by the current, and (4) as heat due to eddy currents induced in neighboring conductors.

In a continuous current the last three effects do not occur, and the heat is that due to the conduction current only. The resistance offered by a substance to a continuous current is called the " true," " ohmic," " continuous-current," or " direct-current " resistance, as distinguished from the " effective " resistance offered by the substance to a varying current. The effective resistance, even when there are no losses due to dielectric or magnetic hysteresis, is in general greater than the ohmic resistance, owing to the skin effect.

Similarly, the general definition of conductance is

$$g = \frac{P_h}{V^2} \tag{23c}$$

where P_h has the same meaning as above and V is the effective value of the potential difference between the two equipotential surfaces. When the voltage is non-varying the conductance is called the " true," " ohmic," " continuous-current," or " direct-current " conductance as distinguished from the " effective " conductance to a varying current.

It should be noted that the ohmic resistance and conductance are reciprocals of each other, but that this is not true for the effective resistance and conductance.

ELECTROKINETICS AND THE MAGNETIC CIRCUIT

9. MAGNETS AND MAGNETISM

Magnets and Magnetic Substances. A magnet may be defined as any body which possesses the property of attracting pieces of iron or steel * and which when freely suspended takes up a definite position with respect to the geographical meridian. A magnetic substance is any body which acquires this property when it is placed near a magnet or near a conductor carrying an electric current. A body which is given this property is said to be " magnetized." A magnetic needle is a magnetized needle of iron or steel; the north-seeking end of such a needle is called its north pole, and the south-seeking end its south pole. When such a needle is freely † suspended near a magnet or a conductor carrying an electric current a couple is bound to be exerted upon it which causes it to take up a definite direction. The needle is said to " point " in the direction of a line drawn through it from its south to its north pole.

See Section 11 for the magnetic properties of substances used in electrical engineering.

Magnetic Effects. The following classification due to S. R. Williams covers the various types of phenomena associated with magnetism.

1. Magneto-magnetics is covered by the paragraph immediately following in this section.
2. Magneto-mechanics includes mechanical strains due to magnetic stresses and magnetic strains due to mechanical stresses.
3. Magneto-acoustics covers the production of sound by magnetization and the influence of mechanical vibrations on magnetism.
4. Magneto-electrics involves the relationship between magnetic and electric circuits, the principal phenomena of which are covered in following paragraphs.
5. Magneto-thermics covers the influence of heat on magnetism, and vice versa.
6. Magneto-optics covers the influence of magnetism on light, and vice versa.
7. Cosmical magnetism.

Magnetic Field of Force. Any region in which a magnetic substance (e.g., a piece of soft iron), when placed therein, becomes magnetized is said to be a *magnetic field.* A magnetic field exists in and around every magnetized substance and around every electric current. The direction of the magnetic field at any point P is arbitrarily chosen as the direction in which a small magnetic needle point would point when placed at P without disturbing appreciably the existing conditions.

Ferromagnetism. Much of the contemporary theory of ferromagnetism is based on spectrum analysis and interpreted by the Bohr-Sommerfeld atomic model and its modifications. Specifically the elementary magnetic particle is the so-called " spinning " electron. The model of the atom used to account for the elementary magnetic effect requires that the electron spin about an axis passing through its center, as distinguished from the rotation in circular or elliptical orbits around the atomic nucleus. In this manner each orbital electron has a magnetic momentum due to its moving electrical charge and an angular momentum due to its moving mass.

Uncompensated Spins. It is assumed that all such orbital electrons spin, but that in general, at any particular energy level or shell within the atom, all electrons may be divided into two equal groups—those that spin in one direction and those that spin in the opposite direction, thus producing a *null* magnetic effect. This effect is known as compensated electron spins. In certain elements however it is consistent with the theory to believe that uncompensated electron spins occur in one or more shells. In other words, there are, for example, more electrons spinning in one direction than in the other, in a given shell. These excess or uncompensated electron spins are an important factor in the phenomena of ferromagnetism.

---

* With a force in excess of the gravitational force, which is extremely small.

† A needle is said to be freely suspended when no controlling force is exerted upon it through its suspension tending to make it take up any definite position.

Exchange. Fundamentally ferromagnetism consists of the reorientation of the magnetic moments of the uncompensated electron spins due to the magnetizing force of an externally applied magnetic field. While this accounts for the major ferromagnetic properties of the ferromagnetic elements such as iron, cobalt and nickel, it fails to account for the absence of such ferromagnetic properties in other elements also known to have uncompensated electron spins. This apparent discrepancy is removed when the so-called " exchange forces " are considered. For an element to exhibit ferromagnetic properties it is required that in addition to the existence of uncompensated electron spins, these spins must be parallel in contiguous atoms. Were this not the case the magnetic moments of individual atoms would be random in direction and hence the resultant magnetic moment of an appreciable region within the substance would be nil. It has been found that there must be a certain ratio existing between the diameter of an atom and the diameter of an electron shell that has uncompensated spins, in order to permit the alignment of magnetic moments in contiguous atoms. This ratio is necessary because the electron spins and charges influence each other, dependent upon the distance between them. This influence, which is known as the *exchange*, must have a proper value in order that the uncompensated spins can be aligned to produce ferromagnetic effects. These forces of exchange tend to keep the spins parallel in neighboring atoms while the forces of thermal agitation tend to destroy this alignment. When the temperature of the substance becomes great enough the forces of exchange are completely overcome and the substance loses its ferromagnetic properties. The temperature at which this occurs is the well-known Curie point. According to the theory, magnetic saturation depends both on the uncompensated electron spins and the exchange. Rough approximation makes the saturation point a function of the product of the number of uncompensated electron spins and the exchange.

Domain. In ferromagnetic substances the forces of exchange are sufficiently large so that the uncompensated electron spins in neighboring atoms are more stable when their magnetic moments are parallel, than under any other orientation, even when no external magnetic field is applied. However, this situation holds true only over very small regions in the given specimen of the substance. These regions, which are called " domains," have been found experimentally to have the volume equivalent to a cube approximately $^1/_{1000}$ inch on an edge. Ferromagnetic substances are completely divided into such domains, each domain being magnetized to saturation in a definite direction. Any specimen of a ferromagnetic substance is said to be unmagnetized when the directions of magnetization of the individually magnetically saturated domains are oriented at random with respect to each other. Thus, the application of an external magnetic field tends to reorient the individually magnetically saturated domains in the direction of this applied field.

Crystal Structure. X-ray analysis has shown that most materials are of crystalline structure. In the case of the ferromagnetic substances these crystals are too small to be seen individually. However, their properties have been studied by means of spectrum analysis and photomicrography. Due to this crystalline structure there is in general more than one axis of stable magnetic saturation. In the cubic crystal, characteristic of iron, there are six equally stable axes of magnetic saturation.

Magnetization Curves. On the basis of uncompensated electron spins, forces of exchange, the existence of domains and the multiple axes of equally stable magnetization, it is now possible to interpret the major ferromagnetic phenomena. When a small external field (say less than 10 oersteds) is applied to an unmagnetized speciman of a ferromagnetic substance, the saturation magnetization within each crystal changes its direction from its axis of stable magnetization to that axis of stable magnetization which is most nearly in line with the applied field. This process takes place as sudden individual reorientations within the individual crystals and the strength of the field required to produce these effects is dependent on the original deviation of these orientations from that of the applied field. These sudden jumps constitute the explanation of the well-known Barkhausen effect. The portion of the magnetization curve represented by the foregoing process is that up to but not including the knee of the curve. At the knee it is assumed that all individual crystals have directions of stable magnetization which lie nearest to the direction of the applied field. When stronger fields than this are applied (order of magnitude 10 to 100 oersteds) the domains themselves are rotated as a whole until the axes of magnetization of all crystal are coincident with direction with the applied field. Needless to say beyond this point an increased applied field produces no further increase in flux density due to the ferromagnetic phenomena.

On the basis of the foregoing theory it is possible to account for the shape of the magnetization curve and actually to calculate many of the known quantities which are used in ferromagnetic practice.

Magnetic Flux. Consider a small closed turn of wire, Fig. 1, placed in a magnetic field with its plane perpendicular to the direction of the field. Experience shows that when such a turn of wire is removed from the field in any manner whatever (the coil remaining short-circuited on itself or forming part of a closed circuit), or when the magnetic field is caused to disappear in any manner whatever, a momentary emf is set up or *induced* in this coil, which in turn causes a momentary electric current to flow through the coil. This emf exists only while the coil is moving across the field or while the field through the coil is varying.

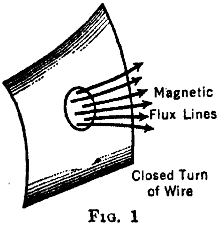

FIG. 1

The time integral of the induced emf when the coil is removed entirely from the magnetic field is taken as the measure of the magnetic flux existing through the coil when in its original position. That is, calling e the emf induced in the coil at any instant by its motion through the field, and t the time during which the emf exists in the coil, then the magnetic flux ϕ through the coil when in its original position is

$$\phi = \int_0^t e\,dt \tag{1}$$

When e is in volts and t is in seconds, ϕ is in volt-seconds. When e is in abvolts and t is in seconds, the unit for ϕ is called the *maxwell* or a *line*. See Section 3. This quantity ϕ is readily measured by means of a ballistic galvanometer.

Magnetic Flux Density. Experience shows that the magnetic flux through any closed loop, such as the turn of wire described above, depends upon the area inclosed by this loop. The magnetic flux per unit area through any surface perpendicular to the direction of the field is defined as the *magnitude* of the *magnetic flux density* at this surface, and is usually represented by the symbol B. By the magnitude of the flux density at any point is meant the magnitude of the flux density at any infinitely small surface drawn perpendicular to the field at this point. The *direction* of the *magnetic flux density* at any point is the same as that in which a magnetic needle would point if placed at this point; i.e., the direction of the flux density and the direction of the magnetic field are the same. The vector having the above-defined magnitude and direction is called the flux density and is usually designated by the symbol $\boldsymbol{B}$. When the flux density has the same value B at every point of a surface of area A and is perpendicular to this surface, then the total flux through this surface is

$$\phi = BA \text{ maxwells} \tag{2}$$

The total magnetic flux across any surface S may in general be expressed mathematically by the surface integral

$$\phi = \int (B \cos \alpha) ds \text{ maxwells} \tag{3}$$

where ds represents any elementary area of this surface and ($B \cos \alpha$) the component of the flux density perpendicular to ds. The unit of magnetic flux density in the cgs electromagnetic system is called the *gauss*; no name has been given to the corresponding practical unit.

Magnetic Flux Lines. Magnetic flux can be represented by lines drawn in the field in such a direction that their direction coincides at each point with the direction of the field at that point, and of such a number that their density at each point (number per unit area perpendicular to their direction) is equal to the magnetic flux density at that point. Such lines are called "magnetic flux lines." Experience shows that lines thus drawn in a magnetic field always form closed loops, i.e., a magnetic flux line has no ends. As a consequence of this fact the total magnetic flux coming up to any surface in a magnetic field is always equal to the total flux leaving that surface.

10. ELECTROMAGNETISM

Magnetic Fields Due to Electric Currents. Experience shows that every filament or stream line of electric current is always accompanied by a magnetic field the flux lines of which link the stream line of current. That is, the flux lines thread the loops formed by the stream lines and the stream lines thread the loops formed by the flux lines; see Fig. 2.

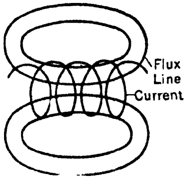

FIG. 2

Right-handed Screw Law. The direction of the current flowing around any electric circuit and the direction in which the flux lines due to that current thread this circuit are related to each other in the same manner as the direction of motion of a point on the edge of the head of a right-handed screw placed at the center of the circuit and the direction of advance of the screw. Or, if one faces the electric circuit looking in the direction of the flux lines threading it, the current producing these lines is in the clockwise direction around the circuit. The relative direction of the current and its magnetic flux may be briefly described by saying that the current is in the right-handed screw direction with respect to the flux which it produces.

Induced Emf. The measure of magnetic flux is based on the experimental fact that, whenever the magnetic field threading an electric circuit changes, an emf is induced in that circuit. When the circuit is formed by a single turn of wire this induced emf is, from the definition above, equal to the rate of change of this flux with respect to time, i.e., $e = \frac{d\phi}{dt}$. When the circuit is in the form of a coil each turn of which links the flux, the emf induced in each turn is equal to $\frac{d\phi}{dt}$, where ϕ is the flux which links that particular turn. When each turn links the same number of flux lines, then the total induced emf in a coil of N turns is

$$e = N\frac{d\phi}{dt} \text{ abvolts} \tag{4}$$

where ϕ is in maxwells.

When the change in flux is due to a motion of a circuit or part of a circuit through a magnetic field the induced emf in any conductor is also equal to the number of flux lines which cut across this conductor per unit time.

Magnetic Linkages. The condition that each turn of a coil be linked by the same flux ϕ seldom exists; some of the flux lines usually link only part of the turns. In general, the total emf is

$$e = \frac{d}{dt}(\phi_1 + \phi_2 + \ . \ . \ . + \phi_n) \text{ abvolts} \tag{4a}$$

where ϕ_1, ϕ_2, etc., represent the fluxes linking the various turns. The sum $(\phi_1 + \phi_2 + \ldots + \phi_n)$ may be called the total number of *magnetic linkages* or *flux linkages*, and may be conveniently represented by the symbol λ, viz.,

$$\lambda = \phi_1 + \phi_2 + \ . \ . \ . + \phi_n \text{ maxwells} \tag{4b}$$

and the total induced emf may then be written

$$e = \frac{d\lambda}{dt} \text{ abvolts} \tag{4c}$$

When all the N turns link the same flux, ϕ, then $\lambda = N\phi$.

Direction of Induced Emf. The direction of the induced emf around a circuit is found to be in the left-handed screw direction with respect to the increase of flux; viz., if one faces the circuit looking in the direction of the increase of flux, the induced emf is in the counter-clockwise direction. The current which would be set up by this emf, however, would produce a flux linking the circuit in the right-handed screw direction. Hence a change in the magnetic flux through an electric current always sets up an emf which tends to produce a current around this circuit in such a direction as to set up an opposing flux. This fact may be expressed mathematically by writing a minus sign before $\frac{d\phi}{dt}$ in equation 4, i.e., by putting

$$e = -N\frac{d\phi}{dt} \tag{4d}$$

The value of $\left(-N\frac{d\phi}{dt}\right)$ is then the emf induced in the circuit in the right-handed screw direction with respect to the increase of flux. Or stated in other words $\left(-N\frac{d\phi}{dt}\right)$ represents the rise of electric potential and $N\frac{d\phi}{dt}$ represents the drop of potential around the circuit in the right-handed screw direction with respect to the increase of flux.

11. MAGNETIZING FORCE AND THE MAGNETIC CIRCUIT

Simple Magnetic Circuit. In certain simple magnetic circuits the treatment is mathematically analogous to that of simple electric circuits. An expression similar to Ohm's law (see Art. 6) is employed. Consider a closed magnetic circuit such as a uniformly wound torus, Fig. 3.

For this circuit we may write

$$\mathfrak{F} = \mathcal{R}\phi \tag{5}$$

where $\mathfrak{F}$ is called the *magnetomotive force* (abbreviated mmf) and is analogous to electromotive force; $\mathcal{R}$ is a factor of proportionality called the *reluctance* and is analogous to resistance; and ϕ, the flux, is analogous to electric current. It must be remembered in considering this analogy that an unvarying flux is thought of as static condition, whereas electric current is defined as the motion of electric charge. Therefore, there is no true *physical* analogy. Equation 5 is sometimes called Ohm's law for magnetic circuits.

Magnetomotive Force. The mmf $\mathfrak{F}$, of equation 5, may also be expressed

$$\mathfrak{F} = 4\pi NI\,^{*} \tag{6}$$

where $\mathfrak{F}$ is in *gilberts*, N is the total number of turns of the coil, and I is the current in abamperes flowing through the coil. The current-turns NI are frequently spoken of as the *ampere-turns* when I is given in amperes. Obviously $\mathfrak{F}$ is in direct proportion to the ampere-turns. In general, mmf may be expressed

$$\mathfrak{F} = 4\pi\Sigma NI \tag{6a}$$

where ΣNI represent the algebraic summation of all current-turns linking the magnetic circuit. The mmf is taken as positive when the current links the flux lines in the right-handed screw direction, and negative when the current links the flux lines in the left-handed screw direction.

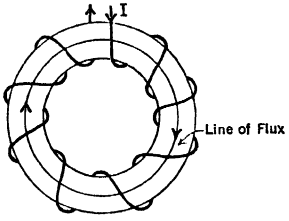

FIG. 3

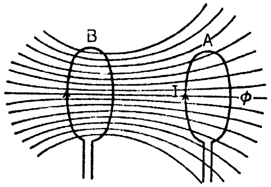

FIG. 4

Work Done by a Varying Magnetic Flux. Consider a coil A (Fig. 4) of N turns of wire, and let each of these N turns be linked by a flux ϕ due to some external agent, e.g., another coil B in which an electric current is flowing. Let the flux ϕ through A due to B be increasing at any instant at the rate $\frac{d\phi}{dt}$ in the left-handed screw direction with respect to the current I in A at this instant. Then there is induced in A at this instant an emf in the direction of I equal to $e = N\cdot\frac{d\phi}{dt}$, and therefore the electric power developed in A at this instant is $ei = NI\frac{d\phi}{dt}$. This power is transmitted to the coil A as a result of the varying flux through it; hence the power

$$p = NI\frac{d\phi}{dt} \tag{7}$$

may be looked upon as the magnetic power input, this power being converted within the coil into electric power.

Magnetizing Force or Magnetic Field Intensity. Experience shows that the magnetic flux density produced at any point by a given mmf depends (*a*) upon the position of the point with respect to the source of the mmf and (*b*) upon the nature of the substances through which this mmf produces the magnetic flux. These facts lead to the conception of the flux density at any point in a magnetic field as being due to a " magnetizing force " H at that point, this magnetizing force H depending solely upon the mmf producing the field and the distribution of the flux lines, as distinguished from the flux density B which depends not only upon these two items but also upon the nature of the medium at the point in question.

The magnetizing force (also called the " magnetic field intensity ") at successive points along any closed path in a magnetic field may be defined by the relation that its line integral around such a path is equal to the total mmf acting around this path, viz.,

$$4\pi\Sigma NI = \int(H\cos\theta)dl \tag{8}$$

---

[*] The factor 4π arises from the manner in which the conceptions of the magnetic field were originally developed.

where dl represents any elementary length of this path (see Fig. 5); ($H \cos \theta$) the value of the component of the magnetizing force at dl in the direction of dl; and ΣNI the total number of current turns linked by the path. Experience shows that such a definition leads to a simple means of expressing in a quantitative manner the interrelations of a number of experimental facts. Magnetizing force may also be expressed as the force in dynes which would act on a " unit magnetic pole."

When the path coincides in direction with the magnetizing force at each point, equation 8 may be written

$$4\pi \Sigma NI = \int H dl \tag{8a}$$

Direction of the Magnetizing Force. Experience shows that *except* for points inside a permanent magnet the magnetizing force H and the flux density B are always in the same direction. For points inside a permanent magnet the direction of the magnetic field intensity H, due solely to the magnet itself, is opposite to the direction of the flux lines, i.e., a permanent magnet produces a "demagnetizing force " on itself.

Lines of Magnetizing Force. The magnetizing force at any point in a magnetic field may be represented by lines drawn in the field in a direction such as to coincide with the direction of the magnetizing force at each point, and of such a number per unit area perpendicular to their direction that their density at each point gives the value of the magnetizing force at that point. Such lines are called *lines of magnetizing force* or *lines of magnetic field intensity*. In general the lines of magnetizing force and the magnetic flux lines coincide in direction (except within the substance of permanent magnets), but their densities are different. Only in non-magnetic substances do the flux lines and lines of magnetizing force coincide in both number and direction. The simple expression " lines of force " is frequently used to designate either the flux lines or the lines of magnetic intensity, but it is evident that such loose use of this term is likely to lead to confusion when speaking of the magnetic field within a magnetic substance.

Magnetizing force is of the nature of mmf per unit length. The cgs electromagnetic unit of magnetizing force is called a *gilbert per centimeter* or an *oersted*. When the mmf is expressed in ampere-turns, the magnetizing force is expressed in ampere-turns per centimeter or per inch.

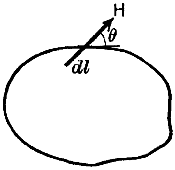

Fig. 5

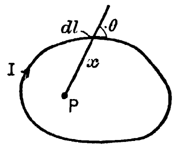

Fig. 6

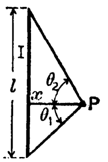

Fig. 7

When the medium surrounding the stream lines of an electric current is of a uniform magnetic nature throughout, the magnetizing force at any point may be calculated from the shape and distribution of the stream lines of the current, irrespective of whether the medium be non-magnetic or highly magnetic.

Magnetizing Force at Any Point Due to an Element of a Current-stream Line (Fig. 6). Consider any closed stream line of electric current and let the surrounding medium be uniform in its magnetic properties throughout the region in which the magnetic field produced by this stream line exists. It can be shown that each elementary length dl of this stream line may be considered as contributing to the magnetizing force H at any point P in this region an amount

$$dH = \frac{(I \sin \theta) dl}{x^2} \tag{9}$$

where I is the current flowing along this stream line, x the distance from P to dl, and θ the angle between x and dl. The direction of dH is perpendicular to the plane determined by x and dl. The total magnetizing force at P is then the vector sum or vector integral of dH for all the elementary lengths into which the stream line is divided.

Magnetizing Force Due to a Straight Wire (Fig. 7). Applying equation 9 to the case of a straight wire of circular cross-section carrying a current I, the magnetizing force at any point P due to a length l of this wire is

$$H = \frac{I}{x} (\sin \theta_1 + \sin \theta_2), \tag{9a}$$

where x is the perpendicular distance from P to the wire and θ_1 and θ_2 the angles designated in Fig. 7.

If the wire is very long compared with x, this becomes

$$H = \frac{2I}{x} \tag{9b}$$

This formula also holds approximately for any point outside a wire of any shaped cross-section, provided x is large compared with the maximum diameter of this section. For a point inside a long wire of circular cross-section of radius a the magnetizing force is also given by equation 9*b* when I is taken to represent that part of the current inside the circle through P concentric with the axis of the wire. When the current density is uniform over the cross-section, as is usual, the magnetizing force inside the wire is

$$H_i = \frac{2xI}{a^2} \tag{9c}$$

Magnetizing Force on the Axis of a Circular Coil of N Turns. Let I be the current, r the mean radius of the coil, and x the distance of the point from the center of the circle; then

$$H = \frac{2\pi NIr^2}{(r^2 + x^2)^{3/2}} \tag{9d}$$

Magnetizing Force Due to a Solenoid. A solenoid is a helical coil of wire, each turn having the same radius. Let N = total number of turns, I = current in abamperes, r = mean radius of the helix in centimeters, l = length of helix in centimeters. Then at any point on the axis of the helix (inside or outside) at a distance of x centimeters from its center, the magnetizing force in gilberts per centimeter is

$$H = \frac{2\pi NI}{l}\left[\frac{0.5l + x}{\sqrt{r^2 + (0.5l + x)^2}} + \frac{0.5l - x}{\sqrt{r^2 + (0.5l - x)^2}}\right] \tag{9e}$$

This formula holds only when the thickness of the winding is small compared with the mean radius r. When l is large compared with r this reduces to

$$H = \frac{4\pi NI}{l} \tag{9f}$$

For all points inside the solenoid (whether on the axis or not) at a distance from the ends large compared with r, that is, inside the central portion of a long solenoid, the field is uniform over the cross-section of the solenoid and its value is given by equation 9*f*. An exact formula for field intensity at any point inside a solenoid is given by O. Billieux in *Rev. gén. élec.*, 6, p. 827, Dec. 13, 1919.

Magnetizing Force Inside a Torus (Fig. 8). When a torus is uniformly wound with an insulated wire so that the turns of the wire are close together and cover the entire surface of the torus, the magnetic field is confined entirely within the space inclosed by these turns, and therefore, when the core on which the wire is wound is of uniform magnetic material throughout, both the lines of magnetizing force and the flux lines must be concentric circles, as shown in the figure. The magnetizing force will have the same value at every point on the circumference of any one of these circles, and, therefore, from equation 8*a* the value of H at any point P within the core is

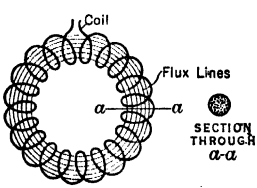

FIG. 8

$$H = \frac{4\pi NI}{l} \tag{9g}$$

where N is the total number of turns on the core, I the current in each turn, and l the length of the circumference through P. Unless the ring has a large radius compared with the radius of the cross-section of the core, H will not be uniform over this section, since l for the various points in the cross-section will differ considerably.

It should be noted that the value of H is independent of the material of the core provided only that the core be of uniform material throughout. That is, equation 9*g* applies to an iron core as well as to an air or wood core, provided the iron is uniform throughout and there is no air gap across the path of the flux lines. Even a mechanically perfect contact between two pieces of iron of the same kind, however, is sufficient to make the above formula useless.

Magnetic Permeability. Permeability is defined by the following equation:

$$\mu = \frac{B}{H} \tag{10}$$

where, in the cgs electromagnetic system, B is in gausses and H in gilberts per centimeter. The cgs electromagnetic system of units is based on the assumption of the value of unity for μ for free space. The permeability of most substances differs inappreciably from unity. Aside from iron, steel, nickel, cobalt, and synthetic magnetic alloys, all the materials used in electrical engineering have a permeability which may be considered equal to that of air. The permeability of non-magnetic substances is for all practical purposes a constant irrespective of the flux density. A physical picture of permeability may be gained from the following. A coil carrying an unvarying current produces a magnetic field in the air surrounding it. If a substance is placed, for example, inside of this coil without changing the amount or distribution of the flux inside the coil, this substance has a permeability of unity (cgs emu). If the flux inside the coil is altered in value or distribution, the permeability of the introduced substance differs from unity.

Paramagnetic, Diamagnetic, and Ferromagnetic Substances. Considering empty space truly non-magnetic all substances may be divided into three classes. *Paramagnetic* substances have a permeability relative to that of free space ($\mu_s = 1$) slightly greater than unity. For example, relative to free space the permeability of air is *greater than unity* by 3.8×10^{-7} and for aluminum by 2.3×10^{-5}. *Diamagnetic* substances have a permeability relative to that of free space slightly less than unity. For example, relative to free space the permeability of hydrogen is *less than unity* by 6.3×10^{-8}, for copper 8.8×10^{-6}, and for bismuth (the most diamagnetic of all elements) 1.8×10^{-4}. *Ferromagnetic* substances including iron, steel, nickel, cobalt, and magnetic alloys have permeabilities greatly in excess of unity. Under certain conditions the permeability of steel may exceed 2000. Furthermore, the permeabilities of ferromagnetic substances vary greatly with flux density. The permeability of such substances also depends upon previous heat treatment, the exact composition of the material, and its previous magnetic history (see Section 11).

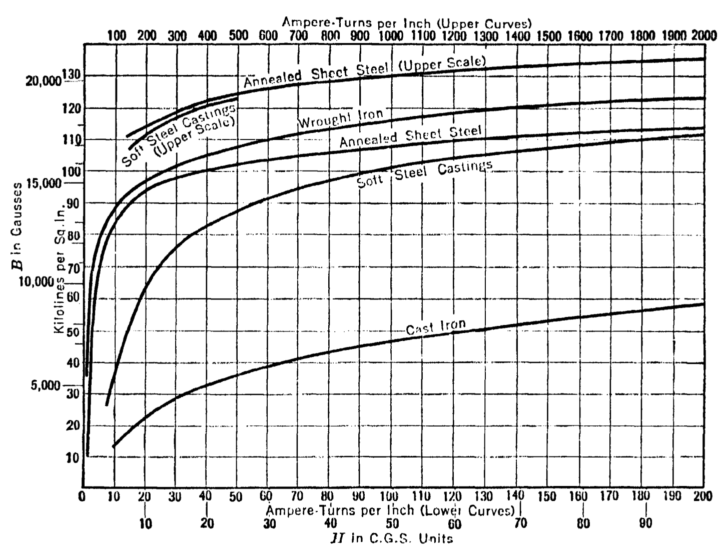

FIG. 9

Magnetization Characteristic. It is most convenient in calculations involving ferromagnetic materials to use the magnetization characteristic of the material. This characteristic shows the relationship between the flux density B and the magnetizing force H. A typical curve is shown in Fig. 9. From the relation $\mu = \frac{B}{H}$ the curve shown in Fig. 10 may be derived from Fig. 9. The shapes of the characteristics shown in Figs. 9 and 10 depend not only upon the material but also upon the exact manner of magnetization. For diamagnetic and paramagnetic substances, since the permeability is constant and equal to unity with negligible error, there is no point in plotting a magnetization characteristic since $B = H$ throughout.

North and South Poles. That portion of the surface of any magnetized body from which the flux lines pass out into the air (or any substance of lower permeability) is said to be a north magnetic pole, and that portion of the surface at which the flux lines enter the body is said to be a south magnetic pole. A *unit north pole* is a pole from which 4π flux lines emerge into the surrounding air. When a magnetic needle is placed near the surface of a magnetized body its north-seeking end points away from this surface when this surface is a north pole and toward the surface when this surface is a south pole.

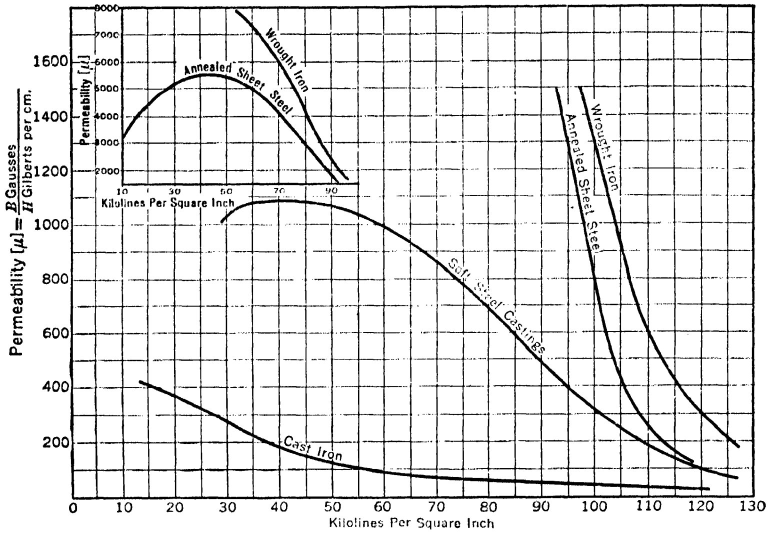

FIG. 10

Difference of Magnetic Potential. Consider any two points 1 and 2 in a magnetic field (Fig. 11), and let the path between them from 1 to 2 pass through an electric circuit producing a mmf in the direction from 1 to 2; then the expression

$$U_{12} = \int_1^2 (H \cos \theta) dl - \mathfrak{F}_{12} \qquad (11)$$

is called the *drop of magnetic potential* from 1 to 2. From the definition of magnetizing force, equation 8, it follows that around any closed circuit the drop of magnetic potential is always zero. A magnetomotive force $\mathfrak{F}_{12}$ is, therefore, equivalent to a rise of magnetic potential from 1 to 2.

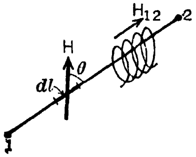

FIG. 11

When there is no source of mmf between 1 and 2 and the path coincides with a line of magnetizing force, the drop of magnetic potential is

$$U_{12} = \int_1^2 H dl \qquad (11a)$$

Magnetic potential difference is of the same nature as mmf and may, therefore, be expressed in the same units, viz., gilberts or ampere-turns.

Magnetic Equipotential Surfaces. A surface, drawn in a magnetic field in such a manner that this surface is perpendicular at each point to the magnetizing force at this point (i.e., to the line of magnetizing force through this point) is called a "magnetic equipotential surface."

Magnetic Reluctance. To establish a magnetic flux ϕ through a given portion of a substance which is not itself linked by a source of mmf, a difference of magnetic potential must always be established between the end surfaces of this substance. Let U be the magnetic potential drop established from one surface to the other; then the quotient

$$\mathcal{R} = \frac{U}{\phi} \qquad (12)$$

is defined as the magnetic reluctance of the given portion of the substance. It should be noted that the above definition is meaningless except when applied to a portion of a substance of which the end surfaces are magnetic equipotential surfaces and through every cross-section of which the same flux passes.

Factors upon Which Reluctance Depends. The magnetic reluctance of a given portion of a substance included between two equipotential surfaces and bounded laterally by a surface which no flux line passes depends upon (*a*) the magnetic permeability of the substance, (*b*) the dimensions of this portion of the substance, and (*c*) the distribution of the flux lines over each cross-section perpendicular to them. The relations are identical with those which determine the electrical resistance of a conductor, the magnetic permeability taking the place of the electric conductivity. For example, for a straight bar of constant cross-section A and length l, through which the flux lines are straight, parallel, and uniformly distributed, the reluctance is

$$\mathcal{R} = \frac{l}{\mu A} \tag{13}$$

Note particularly that this formula for reluctance is applicable only under the special conditions just stated. Formulas for other cases are much more complex; see Douglas, J. F. H., Reluctance of Irregular Magnetic Fields, *Proc.*, A.I.E.E., 34, May, 1915.

Magnetic reluctance is not a constant quantity even for a given material and given flux distribution, unless this material is non-magnetic. For all highly magnetic materials μ depends upon the magnetizing force and therefore also upon the flux density. It should also be noted that the magnetic reluctance does not represent a " resistance " in the sense of something which causes a dissipation of energy.

Magnetic Permeance. The reciprocal of magnetic reluctance is called *magnetic permeance.* The permeance of a straight bar under the conditions specified above is

$$\mathcal{P} = \frac{\mu A}{l} \tag{13a}$$

The permeability of a substance is, therefore, equal to the permeance of a unit cube of this substance when the flux through the cube is parallel to four edges of the cube and is uniformly distributed over the section at right angles to these four edges.

Magnetic permeance is analogous to electric conductance, except that it is not a factor which affects the dissipation of energy in a substance. It does, however, enter into the expression for the energy stored in a magnetic field in the same way that the electrostatic capacity of a dielectric is a determining factor in the expression for the energy stored in the electric field (see p. 8–44, Art. 18).

Kirchhoff's Laws for the Magnetic Circuit. As already noted (equation 3) the total magnetic flux coming up to any surface in a magnetic field is always zero, provided a flux leaving a surface is considered as a negative flux coming up to that surface. This fact may be represented by the formula

$$\Sigma\phi = 0 \tag{14}$$

for every surface in the field. Similarly, from the definition of magnetic potential drop, it follows that the total magnetic potential drop around any closed circuit is zero, or that the total mmf acting around any closed circuit is equal to the sum of the reluctance drops around that circuit, which may be represented by the formula

$$\Sigma\mathfrak{F} = \Sigma\mathcal{R}\phi \tag{15}$$

These two equations are identical in form with those representing Kirchhoff's laws for the electric circuit. They are, however, not so easy to use for practical calculations, for the magnetic flux is not confined to approximately geometrical lines like the currents in a network of insulated wires, but in general fills all space surrounding the coils which establish the mmf's; also, when there is iron or other magnetic material in the circuit, the permeability depends on the flux density and the previous history of the iron. (The distribution of magnetic flux in and around an iron circuit is analogous to the distribution of current in and around an uninsulated mass of copper of the same shape as the iron circuit immersed in a liquid having a conductivity about equal to that of carbon.) Only in the special case of a uniformly wound circular ring or toroid are the lines of induction confined entirely to an iron circuit; in general a certain number also exist in the air and in whatever other substances are in the vicinity of the iron circuit.

12. ELECTROMAGNETIC INDUCTION

Induction. When the current in a given electric circuit varies with time the magnetic flux accompanying this current also varies with time, and, since this flux links the current which produces it, an emf is induced in each turn of the circuit equal to the rate at which the flux through this turn is varying, and in such a direction as to oppose the change in the current. That is, an increasing electric current is always accompanied by a back emf due to the increase in the magnetic flux which accompanies this increase in current.

Again, when an electric current decreases, its accompanying flux decreases and an emf is set up in the circuit tending to oppose this decrease, i.e., tending to keep the current from decreasing. This is analogous to the effect of inertia in ordinary matter.

If the current in a given circuit is constant, but there is a variation with time of the permeances of the flux paths or of the number of turns linking a given flux path, an emf is produced in the circuit in a direction such as to tend to produce a current which would oppose the variation.

These phenomena are known as *induction.*

Coefficient of Self-induction or Inductance. In general, the coefficient L by which the rate of change of the current $\left(\frac{di}{dt}\right)$ in any circuit must be multiplied to give the self-induced emf e is called the *coefficient of self-induction* or simply the *inductance* of the electric circuit. In general, then, the self-induced emf in an electric circuit is

$$e = L\frac{di}{dt} \tag{16}$$

where L is the inductance of the electric circuit and $\frac{di}{dt}$ represents the change in the current per unit of time. Since $e = \frac{d\lambda}{dt}$ (see equation 4c) where λ is the number of magnetic linkages between the electric circuit and the flux established by the current i, the inductance may also be defined by the relation

$$L = \frac{\partial\lambda}{\partial i} \tag{16a}$$

That is, the inductance is equal to the increase in the number of linkages per unit increase in the current.

It should be noted that e in equation 16 is not the *total* induced emf, even of an isolated circuit, this being given by

$$\frac{\partial\lambda}{\partial i}\frac{di}{dt} + \frac{\partial\lambda}{\partial t} \tag{17}$$

in which the first term is the self-induced emf, and the second term is an emf induced by motion.

When the permeability of the magnetic circuit is independent of the current the inductance is also independent of the current. For example, the expression for the inductance of a coil which is not in the vicinity of any ferromagnetic substance may be written

$$L = \frac{\lambda}{i} \tag{18}$$

where λ is the total flux linkages corresponding to the current i in the coil. Since in this case λ is directly proportional to i, L is at most a function of time and is independent of the value of i. When every flux line is linked by every stream line of electric current, and the permeability of the entire magnetic circuit is independent of current,

$$L = \frac{4\pi N^2}{\mathcal{R}} \tag{18a}$$

where N is the number of turns forming the electric circuit and $\mathcal{R}$ is the reluctance of the complete magnetic circuit.

When the equation 18 holds the *total* induced emf may be written

$$e = \frac{d}{dt}(Li) \tag{19}$$

The practical unit of inductance is called the henry; for the relation between the henry and the abhenry and millihenry see Section III.

Coefficient of Mutual Induction or Inductance. In general, the coefficient M_{ab} by which the rate of change of the current $\left(\frac{di_b}{dt}\right)$ in a circuit B must be multiplied to give the electromotive force e induced by this current in another circuit A, is called the *coefficient of mutual induction* or simply the *mutual inductance* between A and B. See Fig. 4. In

general, then, the emf induced in any circuit A by a varying current i_b in any other circuit B is

$$e_a = M_{ab}\frac{di_b}{dt} \tag{20}$$

where M_{ab} is the mutual inductance between A and B. The first letter of the double subscript indicates the circuit in which the flux linkages are considered; the second, the circuit in which the current is considered.

It can be shown from the principle of the conservation of energy that the mutual inductance of a circuit A with respect to a second circuit B must be equal to the mutual inductance of B with respect to A, that is, $M_{ab} = M_{ba}$. Whence, the emf induced in B when the current in A increases by an amount di_a is

$$e_b = M_{ba}\frac{di_a}{dt}$$

Since $e_a = \frac{d\lambda_{ab}}{dt}$ where λ_{ab} is the number of linkages between the circuit A and the flux through A due to the current i_b, the mutual inductance may also be defined by the relation

$$M_{ab} = \frac{\partial\lambda_{ab}}{\partial i_b} \tag{21}$$

That is, the mutual inductance between two circuits A and B is equal to the increase in the number of magnetic linkages of the circuit A per unit increase of the current in B, and vice versa. When the permeability of the magnetic circuit is independent of the current the mutual inductance is also independent of the current and equal to the linkages of A per unit current in B, and vice versa. When every flux line linking both A and B is linked by every turn in A and every turn in B, then

$$M_{ab} = \frac{4\pi N_a N_b}{\mathcal{R}_{ab}} \tag{22}$$

where N_a and N_b are the number of turns forming the circuits A and B respectively and $\mathcal{R}_{ab}$ is the reluctance of that part of the magnetic circuit through which the flux from A to B passes when there is current in one coil only.

The units of mutual inductance are the same as those of self-inductance.

Instantaneous Potential Drop through a Coil. Consider a coil of wire which has a resistance r and an inductance L. Then when this coil contains no other source of emf than its own self-induced emf, the expression for the instantaneous potential drop through the coil is

$$v = ri + L\frac{di}{dt} \tag{23}$$

where i is the instantaneous value of the current and $\frac{di}{dt}$ the increase in this current per unit of time.

When there is another coil near the first coil, and the two coils have resistances r_1 and r_2 and self-inductances L_1 and L_2 respectively, and a mutual inductance M, then the potential drops through them are respectively

$$\left.\begin{aligned} v_1 &= r_1i_1 + L_1\frac{di_1}{dt} + M\frac{di_2}{dt} \\ v_2 &= r_2i_2 + L_2\frac{di_2}{dt} + M\frac{di_1}{dt} \end{aligned}\right\} \tag{24}$$

where i_1 and i_2 are the currents in the two coils in the same direction with respect to the magnetic circuit. These differential equations are perfectly general and can be applied to the solution of any circuit containing constant r's, L's and M's regardless of the nature of the variation of any applied emf in the circuit. The solution of transient as well as steady-state conditions are obtainable from equations 24 as will be indicated later (see Art. 24 to 26).

Skin Effect. A conductor of finite cross-section may be looked upon as made up of separate filaments each carrying its portion of the total current. When the same potential gradient is established through all of the filaments of the conductor the exterior filaments are linked by fewer flux lines than the interior filaments. If the emf producing the potential gradient through the wire is an alternating one, the induced back emf in the interior filaments will be greater than in those nearer the surface. Since the potential drop is the same across all the filaments the resistance drops in the internal filaments is less than in the external ones. This can be brought about only by the current distributing itself over the cross-section of the conductor in such a manner that the current density in the interior of the wire will be less than at the surface, i.e., the current is forced toward the surface filaments or " skin " of the wire; hence the term *skin effect* is applied to this phenomenon.

The self-induced emf depends not only upon the amount of flux set up but also upon the rapidity of its variation; hence the skin effect becomes more pronounced the greater the frequency of the impressed emf. It is also greater the larger the cross-section of the conductor, the greater its conductivity, and the greater its magnetic permeability. The skin effect also depends slightly upon the temperature since the conductivity changes with temperature.

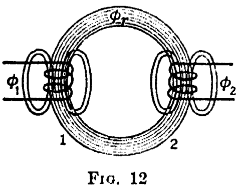

Fig. 12

Leakage Inductance. In discussing the action of a transformer which consists of two electric circuits linking the same iron core, it is necessary to deal with the resultant flux due to the currents in both electric circuits or windings; the fluxes due to the two windings separately have no meaning. Referring to Fig. 12, let ϕ_r represent that portion of the resultant flux due to the currents i_1 and i_2 in the two windings 1 and 2, and let ϕ_1 represent that part of the total flux which links 1 only and ϕ_2 that part of the total flux which links 2 only. Let λ_1 be the linkages between ϕ_1 and circuit 1, and λ_2 the linkages between ϕ_2 and circuit 2. Then

$$L_1' = \frac{\lambda_1}{i_1} \quad \text{and} \quad L_2' = \frac{\lambda_2}{i_2} \tag{25}$$

are called the *leakage inductances* of the two windings respectively; the reluctances of the paths of ϕ_1 and ϕ_2 are practically constant since the air portion of these paths forms a greater part of the reluctance in each.

Let i_1 be the current in winding 1 and i_2 the current in winding 2 linking the flux path in the opposite direction to i_1 (this is the actual relation in a transformer during most of the time), and let e_1 be the impressed emf across the terminals of the first or primary winding and e_2 the terminal emf at the terminals of the second or secondary winding when the current i_2 is flowing. Then

$$\left.\begin{aligned} e_1 &= r_1 i_1 + L_1' \frac{di_1}{dt} + N_1 \frac{d\phi_r}{dt} \\ e_2 &= N_2 \frac{d\phi_r}{dt} - r_2 i_2 - L_2' \frac{di_2}{dt} \end{aligned}\right\} \tag{26}$$

where r_1 and r_2 are the resistances of the two windings and N_1 and N_2 are the numbers of turns in the two windings respectively.

Comparing equation 26 with 24 and noting that $e_1 = v_1$ and $e_2 = - v_2$, and i_2 in 26 is taken in the opposite direction from i_2 in 24, it may be shown that

$$\left.\begin{aligned} L_1' &= L_1 - \frac{N_1}{N_2} M \\ L_2' &= L_2 - \frac{N_2}{N_1} M \end{aligned}\right\} \tag{27}$$

Whence the leakage inductance of each winding is very much less than the total self-inductance of that winding.

Energy of the Magnetic Field. Energy is required to establish a flow of electricity just as energy is required to set a column of water in motion, this " energy of motion " of electricity being analogous to the kinetic energy of a moving body. This energy of motion is most conveniently expressed in terms of the magnetic field which accompanies the flow of electricity or electric current; the mathematical expression for it may be put into various forms.

Magnetic Energy of a Single Electric Circuit, Permeability Constant. For example, consider a single electric circuit and the magnetic field which is established around this circuit when the current in it increases from zero to a value of I. When the current increases by di the linkages increase by an amount $d\lambda$ in the right-handed screw direction with respect to the current. The electric energy output of the circuit during this change is, from equation 4c, $id\lambda$, which is also equal to the magnetic energy input into the magnetic circuit which it links. Hence the total energy input into the magnetic circuit or magnetic field is

$$W = \int_0^{LI} i\,d\lambda = \int_0^{I} Li\,di \tag{28}$$

since by definition $d\lambda = L di$; see equations 4c and 16. When the permeability is constant L is also constant, whence for constant permeability

$$W = \tfrac{1}{2} LI^2 \tag{29}$$

This equation may also be written

$$W = \frac{1}{2}\lambda I = \frac{\mathfrak{F}^2}{8\pi \mathcal{R}} = \frac{1}{8\pi}\mathcal{R}\phi^2 \tag{29a}$$

where $\mathfrak{F}$ is the mmf ($= 4\pi NI$ when the coil has N turns in a concentrated winding), $\mathcal{R}$ is the reluctance of the magnetic circuit, and ϕ the total magnetic flux.

Since the impressed mmf per unit length of a magnetic flux line is equal to the magnetizing force H, and the flux per unit area perpendicular to this flux line is equal to the flux density B, the energy per unit volume of the magnetic field is

$$w = \frac{HB}{8\pi} = \frac{\mu H^2}{8\pi} = \frac{B^2}{8\pi\mu} \tag{30}$$

These various formulas should be compared with the corresponding formulas (p. 8-44) for electrostatic energy.

Magnetic Energy of Two or More Electric Circuits, Permeability Constant. It can also be readily shown that the total energy required to establish currents I_1, I_2, etc., in several electric circuits linking one or more magnetic circuits of constant reluctance is

$$\begin{aligned} W = {} & \tfrac{1}{2} L_1 I_1^2 + \tfrac{1}{2} L_2 I_2^2 + \tfrac{1}{2} L_3 I_3^2 + \dots \\ & + M_{12} I_1 I_2 + M_{13} I_1 I_3 + M_{23} I_2 I_3 + \dots \end{aligned} \tag{31}$$

where the L's and M's represent the self- and mutual inductances respectively. This may also be written

$$W = \frac{1}{2}\sum_{n=1}^{N} \phi_n I_n \tag{31a}$$

where the summation is an algebraic one and includes every complete turn of the electric circuit, I_n being the current in the nth turn and ϕ_n the magnetic flux linking this turn in the right-handed screw direction with respect to the current.

The energy per unit volume at any point in the magnetic field due to any number of electric circuits is represented by equation 30, where H and B are taken as the resultant magnetizing force and flux density respectively at this point.

When the permeability is not constant the energy transferred to unit volume of the magnetic field due to any number of currents is

$$w = \frac{1}{4\pi}\int_0^B H\,dB \tag{32}$$

provided the magnetizing force H and the flux density B are either in the same or directly opposite directions, as, for example, in a uniformly magnetized iron torus. To integrate this expression requires a knowledge of the relation between B and H. Note also that, owing to the phenomenon of magnetic hysteresis, part of the energy required to establish a magnetic field in iron or other magnetic substance is dissipated as heat and is not recoverable when the field disappears; therefore, only part of the energy represented by this formula is " stored " in the field in a recoverable form.

Hysteresis. When any completely demagnetized ferromagnetic substance is subjected to an increasing magnetizing force H, a curve such as Fig. 9 results. The dotted curve in Fig. 13 is also a representation of the phenomenon. Such a curve is variously termed a *rising characteristic*, a *virgin curve*, or a *neutral curve*; all these names are reserved for the special case of a magnetization curve of a *demagnetized* body.

If from any positive value of H, the magnetizing force is decreased the flux density will also decrease, but not along the same curve as the original rising characteristic. For decreasing values of H, B is greater than for the corresponding value on the rising characteristic. The magnetized body retains a part of its magnetization. It will be noticed that, when the magnetizing force is reduced to zero, there is still a positive value of B, which is dependent upon the maximum positive value of H on the rising characteristic, before H is decreased. The flux density which remains when H has been reduced to zero is called the *residual magnetism* and is in the nature of permanent or semi-permanent magnetism. If now the magnetizing force is reversed (e.g., by reversing the direction of the current through the magnetizing coil) a value of H will be found which will reduce B to zero. This value of H is called the *coercive force*. By proceeding through a cycle of values for the magnetizing force—from zero to a positive maximum, to zero, to a negative maximum, and back to zero—a loop of flux densities will be obtained. Such a loop is called a *hysteresis loop*, and each substance is capable of having an infinity of different hysteresis loops depending on the conditions of magnetization. During part of the magnetizing cycle the electric circuit is transferring energy to the magnetic circuit, and during the remainder of the cycle energy is retransferred from the magnetic to the electric circuit. When any ferromagnetic substance is present in the magnetic circuit more energy is transferred to the magnetic circuit than is retransferred to the electric circuit. The difference between these two amounts of energy is a loss and is dissipated as heat. Part of this loss is called the *hysteresis loss* and is presumably due to friction accompanying the change in orientation of the elementary magnets within the ferromagnetic substance. It may be shown that the hysteresis loss per cycle per cubic centimeter in any magnetic substance due to a complete cycle of changes of the flux density and the magnetizing force is equal to $\frac{1}{4\pi}$ times the area of the corresponding hysteresis loop provided this loop is determined under such conditions that there is no mechanical motion and no change in the relative distribution of the lines of force. This relation is based on the further assumption that unit distance on one scale represents one gauss and that unit distance on the other scale represents one gilbert per centimeter. The following empirical formula is useful in determining hysteresis loss.

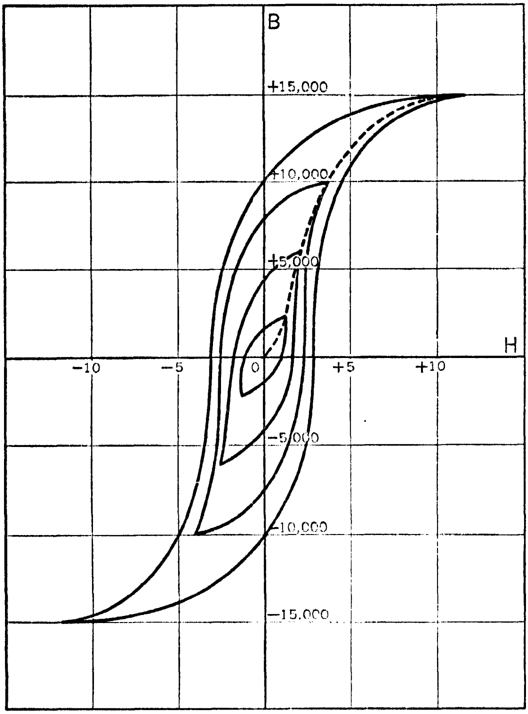

Fig. 13

$$w = \eta B_m^{1.6} \text{ ergs per cubic centimeter per cycle} \qquad (33)$$

where η is a coefficient depending upon the substance and B_m is the maximum flux density reached during a cycle.

The power loss per unit weight of magnetic material is given by

$$P_h = kfB_m^{1.6} \text{ watts per pound} \qquad (33a)$$

where f is the frequency in cycles per second and k is a constant.

Eddy Currents. Since a varying magnetic field induces an emf in every path which links the flux, such an emf will in general cause a flow of current in the magnetic materials composing the magnetic circuit. Such currents, called *eddy-currents* or *Foucault currents*, cause rI^2 losses. Eddy currents can be distinguished from ordinary induced currents by the fact that they are due solely to the lines of force which pass *through* the space occupied by the conducting mass. Ordinary induced currents are produced by lines of force which ***link*** the conductor but do not pass through the space occupied by the conducting mass. It is customary wherever possible to laminate magnetic cores in order to increase the resistance of the path of induced eddy currents. The eddy current loss in metal sheets is given by

$$P_e = \frac{\pi^2}{6 \times 10^{16}\rho}(afB_m)^2 \text{ watts per cubic centimeter} \qquad (34)$$

where ρ is the resistivity of the material, a is the thickness of each sheet, f is the frequency of the eddy-currents, and B_m is the maximum value of the flux density during a cycle. Equation 34 holds provided (a) that the lines of force are parallel to the planes of the

laminations, (*b*) that the laminations are thoroughly insulated from each other, and (*c*) that the thickness of each lamination is small in comparison with its other dimensions. The combination of hysteresis loss and eddy current loss is called *total core loss*.

13. MECHANICAL FORCES OF ELECTROMAGNETIC ORIGIN

Mechanical Forces in the Magnetic Field. Experience shows that all bodies in which an electric current exists, and all bodies in which a magnetic flux exists, exert in general mutual mechanical forces upon one another tending to produce a relative motion of these bodies such as will increase the energy of the magnetic field. Let f be the component of the force tending to move any body in the field in a given direction and let dW be the increase in the energy of the field due to displacing the body a distance dx in this direction; then

$$f = \frac{dW}{dx} \tag{35}$$

provided this displacement does not alter the existing mmf's in the field.

Similarly calling T the component of the torque tending to turn any body in the field about a given axis, and dW the increase in the magnetic energy due to the turning of the body through an angle $d\alpha$ radians about this axis, then

$$T = \frac{dW}{d\alpha} \tag{35a}$$

provided this displacement does not alter the existing mmf's in the field.

Equations 35 and 35*a* also give the actual force and torque respectively during a change in position which does cause a change in the mmf's in the field, provided dW is taken to represent the net increase in the energy of the field. This force and torque may differ greatly from the steady-state force and torque.

Force Produced by a Magnetic Field on a Coil Carrying a Current. When the magnetic flux, threading an electric circuit in the right-handed screw direction with respect to the current, increases by an amount $d\phi$, the energy output of the circuit is $dw = NId\phi$, where N is the number of turns linked by this increase in flux and I is the current in each turn. This is the energy input into the magnetic field. Whence if an increase in flux $d\phi$ is produced through the coil when it moves a distance dx, the force acting on the coil in the direction of dx is

$$f = NI\frac{d\phi}{dx}; \tag{36}$$

$d\phi$ represents the increase in the flux linking the coil in the right-handed screw direction with respect to the current in it or the number of flux lines which cut the coil as the result of its motion. Similarly, when the coil is so mounted that it can move only about a fixed axis, then the value of the torque tending to turn it about this axis is

$$T = NI\frac{d\phi}{d\alpha} \tag{36a}$$

where $d\phi$ represents the increase in the flux linking the coil in the right-handed screw direction with respect to the current in it when the coil turns through an angle α (in radians).

From these relations it follows that a coil carrying an electric current, when in a magnetic field due to any other agent (current or permanent magnet), always tends to take up that position in which it will embrace the maximum possible flux linking the coil in the right-handed screw direction with respect to the current in it. This accounts for the attraction of two parallel coils when they carry currents in the same direction, and the repulsion of two such coils when they carry currents in opposite directions. This principle is useful in determining the direction of motion of the moving element in such devices as the electric motor, galvanometer, current balance, and electrodynamometer.

Torque on the Coil When Its Plane Is Parallel to the Magnetic Field. When the coil is placed with its plane parallel to the flux lines due to some other agent (e.g., a permanent magnet or another coil carrying a current), the flux linking the coil due to this agent is zero; see Fig. 14. Let the two circles represent sections of the two sides of the coil, its plane being perpendicular to the page; and let the dot in the left-hand circle indicate that the current is up through this side of the coil and the cross in the other circle that it is down through the other side. Let B be the flux density of the field constant for each point along the flux line since the flux lines are parallel; let A be the area of the coil; and let $\phi = BA$, that

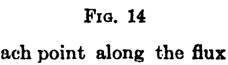

FIG. 14

is, ϕ represents the total flux which would be produced through the coil by a uniform field of flux density B at right angles to it. Then the torque on the coil when its plane is parallel to the field is

$$T = N\phi I \tag{37}$$

This relation is useful in calculating the torque on the moving element of a galvanometer, ammeter, electrodynamometer, wattmeter, etc.

Average Torque on a Coil Rotating in a Magnetic Field. Consider a coil which is rotating with an angular velocity ω about a fixed axis in a magnetic field due to some other agent (e.g., an armature coil rotating in the magnetic field produced by the current in the field coils). Let the current in this coil be constant and in the same direction with respect to the coil while the coil turns from the position in which it embraces the maximum flux ϕ in the left-handed screw direction to the position (a half revolution to a 2-pole machine) when it embraces this same maximum flux ϕ in the right-handed screw direction. The total change in the flux while the coil turns through this angle, π radians in a 2-pole machine, is 2ϕ, whence the average torque turning the coil through this half revolution is

$$T = \frac{2N}{\pi} I\phi \tag{38}$$

That is, the average torque is proportional to the product of the current and the total flux per pole. When a commutator is provided to change the direction of the current every half turn, the torque is in the same direction for a complete turn.

Force on a Wire in a Magnetic Field. Consider a wire of length l forming part of a closed circuit, Fig. 15. Let B be the value of the flux density at the wire and I the current in the direction indicated, and let the lines representing the flux be perpendicular to the wire in the direction from the eye to the page. When this wire moves a distance dx to the left the flux threading the closed loop formed by the circuit is increased by an amount $d\phi = Bldx$, whence the force acting on the wire is (from equation 36):

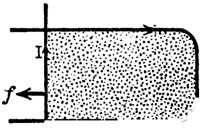

FIG. 15

$$f = BlI \tag{39}$$

Left-hand Rule. The relative directions of this force, the flux density B, and the current I may be conveniently determined by pointing the forefinger of the left hand in the direction of the flux and the middle finger in the direction of the current: then if the thumb is held perpendicular to these two fingers it will point in the direction in which the force tends to move the wire. Compare with the right-handed rule for emf.

Force between Two Current-carrying Conductors. The mutual force between any two electric circuits carrying currents i_1 and i_2, due to the magnetic field of these currents, may be readily found by combining equations 31 and 35. This gives for the component of this force in any direction the value

$$f_x = i_1 i_2 \frac{dM}{dx} \tag{40}$$

where dM is the increase in the mutual inductance between the two circuits when one circuit is displaced a distance dx with respect to the other, the distance dx being measured in the direction in which it is wished to find the component of the force. In this formula, i_1 and i_2 are both to be considered as positive when they link the mutual flux in the same direction. From this relation follows the well-known fact that two coils, or conductors, carrying currents which are in the same direction attract each other, since when one coil is moved toward the other their mutual inductance increases.

The mutual inductance of two long parallel wires when they are far apart relative to their diameters is

$$M = 2l \log_e \frac{2l}{D} \tag{41}$$

where D is their distance apart and l their length, both in centimeters. Hence, from equation 40 the force exerted by one of two parallel wires on the other is

$$f = \frac{2i_1 i_2}{D} \text{ dynes per centimeter} \tag{42}$$

and is at right angles to the wires and in the plane formed by them. This formula is also approximately true for parallel conductors of any cross-section, provided they are far apart relative to the greatest dimension of their cross-section. When this condition does not hold, e.g., in parallel bus-bars close to each other, the formula for the force is much more complex (see Dwight, H. B., Repulsion between Strap Conductors, *Elec. World*, 70. p. 522, Sept. 15, 1917).

Forces on Magnetic Bodies in a Magnetic Field. In general, the reluctance of a magnetic field to the flux set up by a given mmf depends upon the relative positions of the various magnetic bodies in the field with respect to one another and with respect to the electric circuit producing this mmf. When any magnetic body in the field is displaced the total reluctance will, in general, be changed owing chiefly to the change in the dimensions of the air portion of the circuit. From equations 29*a* and 35 it can be shown that the force acting on any magnetic body in the field is in the direction of the flux lines threading it and has the value

$$f = -\frac{1}{8\pi}\phi^2\frac{d\mathcal{R}}{dx} \tag{43}$$

(provided the mmf remains constant) where ϕ represents the total flux threading the body and $d\mathcal{R}$ represents the increase in the reluctance of the magnetic circuit corresponding to a displacement dx of the body in the direction of the flux lines. The minus sign in this formula indicates that the force is always in the direction in which a motion of the body would decrease the reluctance of the circuit. In deducing this expression it is assumed that the permeability of each body in the field is constant. It can also be shown that to a close approximation the same formula holds for actual magnetic bodies, for which the permeability is not a constant.

The above relation accounts for the attraction of one magnet for another when their unlike poles are nearer each other than their like poles, and the repulsion of two magnets when their like poles are nearer than their unlike poles. It also accounts for the attraction of iron or other paramagnetic substance by either pole of a magnet or by either " face " of an electric circuit, and the repulsion of a diamagnetic substance by either pole of a magnet or either face of an electric circuit.

ELECTROSTATICS AND THE DIELECTRIC CIRCUIT

14. ELECTROSTATIC FIELDS, POTENTIALS AND CURRENTS

Electric Fields of Force. In any portion of a substance in which the electricity is acted upon by a force tending to move it, there is said to be an *electric field of force*, or briefly an *electric field*. An electric field is also said to exist in any region of free space where a charge, if placed there, would have a force exerted upon it tending to move it.

Intensity of an Electric Field. The *intensity of an electric field* F at any point is defined as the force exerted on a unit positive charge at this point by the agent or agents producing the field, i.e., by the agent or agents tending to move the charge. The direction of the field intensity, or the direction of the field, is defined as the direction of the force acting on a positive charge at this point. A positive charge then moves or tends to move in the direction of the field, and a negative charge moves or tends to move in the opposite direction.

The unit of electric field intensity has not been given any special name, but since it is of the same nature as emf per unit distance, the intensity at any point may be conveniently expressed as so many volts, abvolts, or statvolts per centimeter or per inch. See Section III. Hence electric field intensity is frequently called the potential, or voltage, " gradient."

Lines of Electric Force. Lines of Electric Intensity. A line drawn in an electric field in such a manner that its direction at each point coincides with the direction of the field at that point is called a *line of electric force*. A line of force is usually a curved line, though in certain special cases it may be straight. Any number of such lines may be drawn in an electric field, but no two of these lines can intersect. The density of these lines, i.e., the number drawn through unit area perpendicular to their direction, may be chosen arbitrarily to represent the value of the field intensity at this area, and when so drawn are preferably called *lines of electric intensity*, as distinguished from flux and stream lines defined below. The term *lines of force*, however, is frequently used to designate any one of these three sets of lines, but this loose use of the term is likely at times to lead to much confusion. The term *line of electric force* will be used in this article to designate merely the direction of the field at any point; in any statement involving the density of these lines the proper one of the other terms will be employed.

Electric Equipotential Surfaces. A surface drawn in an electric field in such a manner that it is perpendicular at each point to the line of force through that point is called an *electric equipotential surface*. The electric intensity has no component along such a surface, and therefore no work is required to move a charge from one point to another over any path in such a surface.

Emf's and Differences of Potential. The work done by the field intensity $\boldsymbol{F}$ in moving unit positive charge around any closed path or circuit (Fig. 1) in an electric field is defined as the emf acting around this path. Emf is not a force in the mechanical sense but is work per unit charge. The relation between emf E and field intensity F, where F is the magnitude of the vector $\boldsymbol{F}$, is analogous to that between work and mechanical force, viz.:

$$E = \int_0 (F \cos \theta) dl \qquad (1)$$

where dl represents an elementary length of the path, $(F \cos \theta)$ the component of the field intensity along dl, and $\int_0$ represents the integral around this closed path. When the field intensity has the same value F at every point of a path and coincides in direction with the path at every point, the emf acting around the closed loop is

$$E = Fl \qquad (1a)$$

where l is the total length of the path.

In Fig. 1 let the path from 1 to 2 be in the direction of the line of force from 1 to 2, let E_{12} be an emf whose source is between 1 and 2 and whose direction is from 1 to 2; then the general expression for the potential drop from 1 to 2 is

$$V_{12} = \int_1^2 Fdl - E_{12} \qquad (2)$$

If the field intensity along the path from 1 to 2 is negligible, then $V_{12} = - E_{12}$; hence an emf in a given direction is equivalent to a negative drop of potential, i.e., is equivalent to an actual rise of potential. Comparing equation 2 with equation 1 it is evident that the total drop of potential around a closed circuit is always zero. This relation is conveniently expressed by the formula

$$\Sigma V = 0 \qquad (3)$$

which holds for every closed path or circuit. This is one way of stating Kirchhoff's second law. See Art. 7, equation 16.

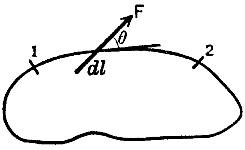

Fig. 1

Voltage Gradient. Since from equation 2 the magnitude of the field intensity F is equal in volts to the drop in voltage per unit length in the direction of $\boldsymbol{F}$, the electric field intensity is also frequently called the voltage gradient.

Flow of Electricity. Whenever an electric field is set up in a substance by any means whatever a displacement of the electricity in that substance always takes place, the nature of the displacement depending upon the nature of the substance. The positive electricity within the substance is displaced or orientated in the direction of the field intensity and the negative electricity in the opposite direction, until an opposing force is set up which just balances the forces due to the impressed field. In metallic conduction, the flow of electrons in a direction opposite to the field constitutes the electric current. In electrolytes there is a migration of positive ions in the direction of the field, and of electrons opposite to the direction of the field. It is believed that, in good insulators, actual migration is negligible but that molecules of the substance are deformed and reorientated in such a manner as to produce a momentary motion of positive electricity in the direction of the field, and of negative electricity opposite to the direction of the field. (See Art. 27 and Art. 28.)

The displacement of the electricity within a substance cannot be measured directly, but only in terms of some effect produced thereby. Two effects which always result when electricity is displaced are: (1) a magnetic field is established around the path along which the displacement takes place (but disappears when the electricity comes to rest); and (2) heat is developed in the path of the displacement. The magnetic field produced by a displacement or flow of electricity is usually taken as the measure of the rate of flow, i.e., of the quantity of electricity displaced per unit time through a surface perpendicular to the direction of the displacement. This rate of flow is called the *intensity* of the electric current, or simply the electric current.

A flow of positive electricity in one direction is equivalent magnetically to a flow of an equal amount of negative electricity in the opposite direction; hence the total flow along the given path is the sum of the positive electricity displaced per unit time in one direction past a point in this path plus the negative electricity displaced per unit time past this point in the opposite direction. The *direction* of the electric current is taken as the direction in which the positive electricity is displaced, and it is, therefore, the same as the direction of the field intensity.

Current Due to Varying Electric Field. When the electric field in any substance is varying, the total magnetic effect produced is found to depend not only upon the rate of displacement of the electricity within the substance, but also upon the rate of change of the electric field. In fact, a magnetic field is produced around a path in free space along which the intensity of the electric field is varying. In dealing with varying electric fields it is found convenient to consider the variation of the field intensity as equivalent to an actual flow of electricity, and to take as the total equivalent electric current the flow of electricity which would produce the same magnetic field as that actually observed; the actual flow of electricity is in general less than this equivalent current, but the difference is negligible except in substances which are good insulators.

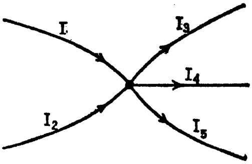

Fig. 2

Continuity of an Electric Current. When a varying electric field is considered as equivalent to an electric current, it is found that the total equivalent current coming up to any point or surface in any network of circuits, no matter how complicated, is always equal to the total current leaving that point or surface, irrespective of the nature of the substances through which the currents are constant or are varying. For example, in Fig. 2,

$$i_1 + i_2 = i_3 + i_4 + i_5 \tag{4}$$

Or calling the currents coming up to any point positive, and the currents leaving that point negative, the algebraic sum of all the currents at any point in a network of circuits is always zero. This fundamental principle is conveniently expressed by the formula

$$\Sigma i = 0 \tag{4a}$$

which holds at every junction point both for variable and for continuous currents. This is a generalized form of Kirchhoff's first law. See Art. 7, equation 15.

Stream Lines of Electric Current. Current Density. As a consequence of the continuity of an electric current, the total current in any substance of any size or shape may be looked upon as made up of a number of small streams of electricity flowing side by side, the strength (quantity of electricity per second) of each stream being constant throughout its length. If the cross-section of each stream at any point is so chosen that each stream represents unit current (unit quantity per second), then the number of these streams crossing unit area of a surface perpendicular to their direction will be equal to the current per unit area of this surface, or to the current density at this surface. Each such stream may be represented graphically by a line coinciding with its axis; such lines are called *stream lines*. When the stream lines are drawn as described their direction at any point gives the direction of the current at this point, and the number of these lines per unit area perpendicular to their direction is equal to the current density at this point.

For an insulated wire the stream lines are parallel to the axis of the wire, except in the immediate vicinity of its ends; in a long wire this non-uniformity at the ends is negligible. All the stream lines in an ordinary wire may also, in practice, be considered as coinciding, and the wire may, therefore, be treated as a geometrical line as regards external effects. However, for a short rod or strip (such as an ammeter shunt) connected in the circuit by wires attached to its ends, the stream lines are not in general parallel but diverge from one terminal and converge toward the other.

Conduction Current and Displacement Current. Experience shows that, when an electric field is established in any substance, the total equivalent electric current set up depends (1) upon the value of the field intensity, (2) upon the rate of change of the field intensity, and (3) upon the nature of the substance in which the field is established. The current density σ at any point at any instant may in general be expressed by the relation:

$$\sigma = \gamma F + \frac{1}{4\pi}\frac{d}{dt}(kF) \tag{5}$$

where F is the field intensity, γ and k are coefficients depending upon the chemical nature and physical condition of the substances at the point in question, and $\frac{d}{dt}$ means the rate of change with respect to time. The factor 4π arises from the historical definition of the quantity k; see below. The total current may then be considered as the sum of the two components having respectively the densities

$$\sigma_1 = \gamma F \quad \text{and} \quad \sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF) \tag{6}$$

The first of these components (σ_1) is called the conduction current; the second $\sigma_{(2)}$ is commonly called the displacement current. The term displacement current, however, is something of a misnomer, for both components of the total current are probably due, in part at least, to a displacement of electricity. The conduction current is the only appreciable component in substances usually classed as conductors, and the displacement current is appreciable only in substances ordinarily classed as dielectrics. The conduction current in a dielectric is usually small, though measurable; it is frequently called the leakage current. When the electric field in a dielectric is rapidly varying, the displacement current may be many times greater than the conduction or leakage current through the dielectric.

Conductivity and Resistivity. The quotient of the density σ_1 of the conduction current by the field intensity F, i.e., the coefficient γ in the expression $\sigma_1 = \gamma F$ is called the conductivity or specific conductance of the substance at the point in question. Since in an ordinary conductor the displacement current is inappreciable, the conductivity of an ordinary conductor is also equal to the density of the total current divided by the field intensity; i.e., for a conductor

$$\sigma = \gamma F \tag{7}$$

where σ represents the density of the total current. Experience shows that for a given conductor at constant temperature (and also at constant pressure, in a gas) this coefficient γ is a constant irrespective of the strength, distribution, or time variation of the current. The value of γ for a dielectric, however, is not in general a constant but depends upon the time variation of the field intensity.

The above relation between σ and F may also be written

$$F = \rho\sigma \tag{7a}$$

where ρ is the reciprocal of the conductivity γ. The constant ρ is called the *resistivity* or specific resistance of the substance. Values of γ and ρ for various conductors and insulating materials are given in Section XI. For the units of conductivity and resistivity, see Section III.

15. DIELECTRIC FLUX

Dielectric Flux and Dielectric Flux Density. As noted above, the displacement current through a dielectric at any point depends upon the rate of change of the electric field intensity and upon the nature of the dielectric. The density of this displacement current at any point may be expressed by the relation

$$\sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF) \tag{8}$$

where F is the field intensity and k a coefficient depending upon the nature of the dielectric. The coefficient k in this expression is the so-called *dielectric coefficient* or *dielectric constant.*

The quantity kF, whose rate of change is equal to 4π times the density of the displacement current, is called the *dielectric flux density* and may be represented by the symbol D. Then

$$D = kF \tag{9}$$

The direction of the dielectric flux density is arbitrarily chosen to be the same as that of the electric field intensity F. Through any surface of area A at each point of which the dielectric flux density has a constant value D and is perpendicular to that surface, there is said to exist a *dielectric flux* equal to DA. The total dielectric flux through a surface may be represented by the symbol ψ.

In general, the total dielectric flux through any surface is

$$\psi = \int D \cos\alpha \, ds \tag{10}$$

where ds represents any elementary area of this surface, $D \cos \alpha$ the component of flux density normal to the surfaces at ds, and $\int$ the sum of all the products $D \cos \alpha \, ds$ for that surface. The total displacement current through this surface is then

$$i = \frac{1}{4\pi}\frac{d\psi}{dt} \tag{11}$$

Lines of Dielectric Flux. The electric flux through any surface may be represented by lines drawn in the same direction as the lines of electric intensity, but of such a density that their number per unit area perpendicular to their direction at any point is equal to the dielectric flux density at this point. The number of these lines cutting any surface is then equal to the total dielectric flux through this surface. The ratio of the number of flux lines through any surface to the number of lines of electric intensity through that surface is equal to the dielectric coefficient of the substance in which the field exists.

Electric Charge and Dielectric Flux. Within any substance of uniform structure throughout, the dielectric flux lines are continuous lines; i.e., the number of these lines coming up to one side of a surface within such a substance is equal to the number of these lines leaving the other side of that surface. Experience shows that it is impossible to produce an appreciable dielectric flux in those substances ordinarily classed as conductors; hence dielectric flux lines cannot pass through a good conductor, but terminate at its surface. Every dielectric is a conductor to at least a slight extent, and on account of this fact not all the dielectric flux lines coming up through one dielectric to the surface of contact between this dielectric and another pass through the second dielectric, but some of them terminate at this surface.

Experience shows that, to establish an electric field in the dielectric around a conductor, electricity must be conducted through the conductor to the surface of contact between the conductor and the dielectric. For example, consider a good conductor in contact with a perfect dielectric (Fig. 3); a momentary conduction current must flow through the conductor along the stream lines of the conduction current, represented by the dotted lines. While the field is being established (and therefore varying), a displacement current is set up in the dielectric requiring an equal conduction current in the conductor, and consequently $\frac{1}{4\pi}$ times the rate of change of the dielectric flux (ψ) established in the dielectric must be equal to the conduction current (i) flowing up to this surface through the conductor, i.e.,

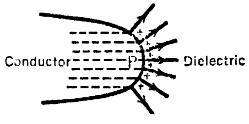

FIG. 3

$$\frac{1}{4\pi}\frac{d\psi}{dt} = i$$

or

$$\psi = 4\pi \int i\,dt = 4\pi Q, \tag{12}$$

where Q is the quantity of electricity conducted through the conductor to this surface.

This relation is a general one, viz., the total dielectric flux from any area A in the surface of a conductor is equal to 4π times the total charge on this area. Hence every flux line originates at a positively charged conducting surface and terminates at a negatively charged conducting surface, 4π of these lines connecting each unit positive to each unit negative charge.

The quantity of electricity conducted through a conductor when a momentary current is established through it can be measured readily by means of a ballistic galvanometer, and consequently the dielectric flux (equal to $4\pi Q$) may readily be determined.

Dielectric flux may be expressed in the same units as electric charge, viz., coulombs, statcoulombs, or abcoulombs; see Section III.

Surface Density of Charge. When there is no current in a conductor there can be no electric field within it (see equation 7); and therefore the surface of a conductor in which no current is flowing is always an equipotential surface. Hence the lines of electrostatic intensity, in the surrounding dielectric, and therefore the dielectric flux lines also, must leave or enter this surface in a direction perpendicular to it. The dielectric flux density in the dielectric just outside a conducting surface in which there is no electric current is perpendicular to this surface and has the magnitude

$$D = 4\pi\sigma_c \tag{13}$$

where σ_c is the charge per unit area of the surface at this point, or the ***surface density*** of the charge.

Dielectric Flux Density Due to a Number of Charged Conductors. It can be shown that, when any number of charged conductors are surrounded by a uniform dielectric, the dielectric flux density at any point in the field may be expressed by considering each elementary surface having a charge q as producing at any point P at a distance r from q a flux density equal to q/r^2, in the direction of the line from q to P when q is positive and in the direction of the line from P to q when q is negative. The total flux density at P due to all the charges is then the vector summation

$$D = \sum \frac{q}{r^2} r_1 \tag{14}$$

in which r_1 is a unit vector in the direction from q to P.

16. ELECTROSTATIC CAPACITANCE, CONDENSERS, AND INDUCTION

Electrostatic Capacitance and Condensers. To establish a given dielectric flux ψ through a given dielectric a certain difference of electric potential is always required. Consider any portion of an electric field (Fig. 4) between the two equipotential surfaces S and S_1 bounded laterally by a surface tangent at each point to the flux line through that point. Let V be the drop of potential from S to S_1, and let ψ be the dielectric flux through this region. When there is no source of emf between S and S_1 the quotient

$$C = \frac{\psi}{4\pi V} \tag{15}$$

is defined as the electrostatic capacitance of this portion of the field.

When the equipotential surfaces S and S_1 are the surfaces of two conductors, the two conductors and the dielectric between them are said to form an *electric condenser*. When all the flux lines from one conductor end on the second conductor (e.g., when they are given equal and opposite charges by connecting them respectively to the two terminals of a source of emf), then the flux from one to the other is equal to $4\pi Q$ where Q is the numerical value of the total charge on either conductor. The capacitance of the condenser may then be written

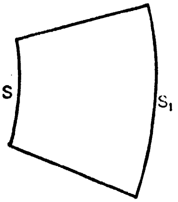

Fig. 4

$$C = \frac{Q}{V} \tag{15a}$$

When there are several charged conductors in the field, the total flux from one conductor does not in general end on another single conductor, but some of the flux lines from conductor 1 may run to 2, some to 3, etc. Let ψ_{12} be that portion of the flux from any conductor 1 which ends on any other conductor 2, and let V_{12} be the drop of potential from 1 to 2; then the capacitance between conductor 1 and conductor 2 is

$$C_{12} = \frac{\psi_{12}}{4\pi V_{12}}. \tag{15b}$$

Or, calling Q_{12} that portion of the charge on 1 which is balanced by an equal and opposite charge on 2, the capacitance between 1 and 2 is

$$C_{12} = \frac{Q_{12}}{V_{12}} \tag{15c}$$

The unit of capacitance in the practical system of units is the farad, but as this is a very large unit, a unit equal to one-millionth of a farad, called the microfarad, is usually employed. The cgs electrostatic unit is called the statfarad, and the cgs electromagnetic unit the abfarad. See Section III.

Potential Coefficients, Electrostatic Induction Coefficients. Consider any number of conductors 0, 1, 2, 3, etc., either (1) at a great distance from all other conductors or (2) completely surrounded by a hollow conducting shell, the inside surface of which is to be considered as one of the conductors, say 0, of the system. The electrostatic condition of such a system of conductors is uninfluenced by any electrostatic effects produced outside the system; it may therefore be called an *electrostatically independent system.*

Any conductor of an electrostatically independent system may be chosen as a conductor of reference; let this reference conductor be designated as conductor 0. Let v_{10}, v_{20}, v_{30}, etc., represent the potential drop from 1 to 0, from 2 to 0, from 3 to 0, etc., and let q_0, q_1, q_2, q_3, etc., represent the charges on 0, 1, 2, 3, etc. Then, if the relative positions of the various conductors and insulators in the field remain unaltered and the specific inductance capacitances of the various insulating materials between the conductors are constant (not necessarily the same for each insulating material, however), the following relations hold for all values of the charges on and potential drops between conductors irrespective of how the conductors may be connected (provided the connecting wires are of small cross-section compared with the dimensions of the conductors):

$$\left.\begin{aligned} v_{10} &= A_{11}q_1 + A_{12}q_2 + A_{13}q_3 + \text{etc.},\\ v_{20} &= A_{12}q_1 + A_{22}q_2 + A_{23}q_3 + \text{etc.},\\ v_{30} &= A_{13}q_1 + A_{23}q_2 + A_{33}q_3 + \text{etc.},\\ q_0 &= -(q_1 + q_2 + q_3 + \text{etc.}). \end{aligned}\right\} \tag{15d}$$

where all the A's are constants depending upon the distances apart of the conductors and the nature of the insulating medium between them. The coefficients A in these equations may be called the *potential coefficients* of the system of conductors.

The above equations may also be written:

$$\left.\begin{aligned} q_1 &= B_{11}v_{10} + B_{12}v_{20} + B_{13}v_{30} + \text{etc.}, \\ q_2 &= B_{12}v_{10} + B_{22}v_{20} + B_{23}v_{30} + \text{etc.}, \\ q_3 &= B_{13}v_{10} + B_{23}v_{20} + B_{33}v_{30} + \text{etc.}, \\ q_0 &= -\,(q_1 + q_2 + q_3 + \text{etc.}), \end{aligned}\right\} \tag{15e}$$

where the B's are also constants and may be expressed directly in terms of the potential coefficients A by solving the equations for q_1, q_2, q_3, etc., The constants B are called the electrostatic induction coefficients, and like the constants A are independent of how the conductors may be charged and of how they may be interconnected. The B's may be expressed directly in terms of the normal and grounded capacitances of the various conductors.

By the *normal capacitance* between any two conductors is meant the capacitance of the condenser formed by these two conductors when all the other conductors are connected to one another and to the conductor of reference, the two conductors of course being insulated therefrom. The normal capacitance between any two conductors of a system, say 1 and 2, is then, from equation 15*c*

$$C_{12} = \frac{B_{11}B_{12} - B_{12}^2}{B_{11} + B_{22} + 2B_{12}} \tag{15f}$$

When the arrangement of the conductors is perfectly symmetrical (as in a three-conductor cable), $B_{11} = B_{22}$ and the normal capacitance between 1 and 2 is

$$C_{12} = {}^1/_2\,(B_{11} - B_{12}) \tag{15g}$$

By the *grounded capacitance* of any conductor of a system is meant the capacitance of the condenser formed by this conductor as one plate, and all the other conductors, including the conductor of reference, connected together as the other plate. The grounded capacitance of conductor 1, say, is then, from equation 15*g*,

$$C_{1g} = B_{11} \tag{15h}$$

That is, the electrostatic coefficient of self-induction of any given conductor is the same as the grounded capacitance of this conductor.

Electrical Images. The distribution of charge upon conductors may often be found most simply by a method devised by Lord Kelvin. Let it be supposed that a charge $+q$ is placed in the neighborhood of an infinite conducting plane. There will be produced on the plane a charge density σ, which together with the charge $+q$ will produce a given distribution of electric field intensity throughout the region. This field intensity can be shown to be equal to the field intensity which would be produced, in the absence of the conducting plane, by the charge $+q$ and a second charge $-q$ placed at a position such that $+q$ and $-q$ are symmetrical about the plane. The charge $-q$ is called the *electrical image* of the charge $+q$, the name being suggested by the optical analogy.

The capacitance of an actual condenser formed by a wire and the earth (assuming the earth to be an infinite conducting plane parallel to the wire) is the same as the capacitance to neutral of the fictitious condenser formed by the wire and its image.

Factors upon Which Capacitance Depends. The capacitance of a given portion of a dielectric depends upon (*a*) the dielectric coefficient k, (*b*) the length of the dielectric flux lines through the dielectric, (*c*) the cross-section of the dielectric at right angles to the flux lines, and (*d*) the distribution of the flux lines over this cross-section (compare with electric conductance). In general, the capacitance of any portion of a dielectric bounded laterally by flux lines and at the ends by equipotential surfaces (Fig. 4) can be expressed by the formula

$$C = \frac{k\psi}{4\pi \int D\,dl} \tag{16a}$$

where k is the dielectric coefficient, ψ the total dielectric flux through the given portion of dielectric, dl any elementary length along one of the flux lines, and D the component of the dielectric flux density in the direction of dl at this point, the integral being taken along the flux line from one end surface to the other. When the end surfaces are conductors charged with $+Q$ and $-Q$ units respectively, then

$$C = \frac{kq}{\int D\,dl} \tag{16b}$$

By the application of this formula the capacitance of various practical forms of condensers may be calculated. It should be noted that the capacitance of a condenser depends upon the distribution of the dielectric flux (k being assumed constant), but not upon the absolute value of the flux; i.e., for a given dielectric and given distribution of flux the capacitance is a constant. In general, when any conductor or dielectric of a different specific inductive capacitance is placed in the electric field set up by the charged plates of a condenser, the distribution of the flux, and therefore the capacitance of the condenser, are altered.

Relation between Conductance and Capacitance. Comparing $r = \frac{\rho \int \sigma\, dl}{I}$ and equation 16*a*, it is apparent that, when the dielectric flux lines and the current stream lines have the same distribution in any given region, the ratio of the conductance of this region to the capacitance of this region is $4\pi\gamma/k$, where k is the dielectric coefficient and γ the conductivity of the material in this region. Hence the formulas for the capacitance and conductance of the dielectric between the plates of any shape or size of condenser differ only by a constant coefficient. That is, if C is the capacitance of any condenser, then

$$g = \frac{4\pi\gamma}{k} \cdot C \tag{17}$$

is the conductance of the dielectric between its plates.

Charge and Discharge of a Condenser. To charge a condenser a difference of electric potential must be established between its plates. This may be done, as noted above, by connecting the two plates of the condenser respectively to the two terminals of any source of emf; see Fig. 5. If the dielectric has a very high resistance and the source of emf has a constant value E, the current set up in this circuit will continue only until a difference of potential equal to E has been established across the two plates of the condenser, or until a charge equal to CE has been transferred from the *negative* to the *positive* plate of the condenser. The establishment of the electric flux through the dielectric of the condenser may be looked upon as setting up in the dielectric itself an opposing force analogous to the opposing force set up in a spring when it is compressed. When the opposing force just balances the impressed force a steady state is attained, just as the compressing of a spring ceases when the force producing the compression is just balanced by the opposing force due to the elasticity of the spring.

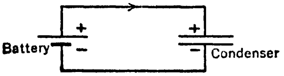

FIG. 5

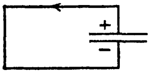

FIG. 6

When a condenser has thus been charged, the wires connecting it to the source of emf may be removed and the condenser remains charged for a length of time depending upon the resistance of the dielectric separating the plates; the higher this resistance the longer the time that the condenser remains charged. If the plates are moved apart they still retain their charges, one plate a positive charge and the other a negative charge, but the distribution of these charges on the plates will in general become altered. Experience shows that a mechanical force is required to separate the charged plates irrespective of whether or not they are connected to the source of emf.

When the two charged plates are short-circuited by a wire, as shown in Fig. 6, a momentary current is established through the wire, and the electric field between the plates and the charges disappear. The quantity of electricity discharged through the wires is equal to the quantity of charge originally on either plate. A charged condenser, therefore, acts like a source of emf, the direction of this emf around the circuit containing the condenser being in the direction through the condenser from its negative to its positive plate. A condenser when it is being charged may also be looked upon as producing a back emf, that is, an emf opposing the emf which charges it. When a condenser is considered from this point of view only the conducting portion of the circuit is to be considered in applying Kirchhoff's laws. When the condenser has an appreciable leakage its resistance must be considered to be in parallel with its emf.

Charging Current and Leakage Current. The displacement current through the dielectric of a condenser is frequently called the *charging* current. The conduction current through the dielectric is called the *leakage* current. Let C be the capacitance of the condenser, g the conductance of the dielectric, and v the voltage across the condenser; then the total current through the condenser is

$$i = gv + C\frac{dv}{dt} \tag{18}$$

where $\frac{dv}{dt}$ represents the rate of charge of v with time. The component gv of this current is the leakage current, and the component $C\frac{dv}{dt}$ is the charging current.

Capacitances in Series. When several capacitances* are connected end to end so that the same dielectric flux passes through each of them, they are said to be *in series.* The total capacitance of any number of individual capacitances C_1, C_2, C_3, etc., connected in series is C where

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \dots \tag{19}$$

Capacitances in Parallel. When several capacitances are connected between the same pair of equipotential surfaces so that the same potential drop is established through each, they are said to be *in parallel.* When there are no emf's in any of the circuits between the two equipotential surfaces the total equivalent capacitance of any number of capacitances C_1, C_2, C_3, etc., connected in parallel is

$$C = C_1 + C_2 + C_3 + \dots \tag{20}$$

Specific Inductive Capacitance and Dielectric Coefficient. From equation 16*a* it is evident that, when the capacitance of a given condenser is measured (1) with a dielectric A between the plates and (2) with some other dielectric B between these plates, then the ratio of the two capacitances is the same as the ratio of the dielectric coefficients of the two dielectrics. The *specific inductive capacitance* of any dielectric is defined as the ratio of the capacitance of a condenser having this substance as its dielectric to the capacitance of the same condenser when air forms the dielectric between the plates. The specific inductive capacitance is, therefore, independent of the system of units employed.

The cgs electrostatic system of units is based on the arbitrary choice of unity as the dielectric coefficient of free space; hence, in this system the specific inductive capacitance and the dielectric coefficient are numerically equal. In the cgs electromagnetic system of units the dielectric coefficient of free space is not unity but $\frac{1}{9 \times 10^{20}}$ (i.e., the reciprocal of the square of the velocity of light). In the practical system of units, when the centimeter is taken as the unit of length, the dielectric coefficient of free space is $\frac{1}{9 \times 10^{11}}$. Hence, calling K the specific inductive capacitance of any dielectric referred to free space as unity, and k its dielectric coefficient, then in the

cgs electrostatic system $k = K$

cgs electromagnetic system $k = \frac{K}{9 \times 10^{20}}$

Practical system (cm as unit of length) $k = \frac{K}{9 \times 10^{11}}$

Values of the specific inductive capacitance of various insulating materials are given in Section 12.

17. DIELECTRIC LOSSES

Electric Absorption and Residual Charge. The value of the dielectric coefficient k of a given dielectric is not strictly a constant unless the dielectric is perfectly homogeneous. For such non-homogeneous substances as glass, mica, rubber, paper, and cloth, the dielectric coefficient is found to depend upon the time of electrification, i.e., upon the length of time that the voltage is applied, its value increasing with the time of electrification. This phenomenon is sometimes described as *electric absorption,* the idea being that the charge from the plates of the condenser soaks into the dielectric, for an increase in the dielectric coefficient for a given impressed voltage means a greater quantity of electricity conducted to the plates. This idea is also in accord with the experimental fact that when such a condenser is discharged by short-circuiting it with a wire, Fig. 6, the wire then being removed, a *residual* charge appears on the plates after a lapse of a few seconds.

Dielectric Hysteresis. A phenomenon closely associated with electric absorption is the fact that when the electric field in a heterogeneous dielectric is caused to vary rapidly an amount of heat is dissipated in the dielectric greatly in excess of that which can be accounted for in terms of its leakage resistance as determined by continuous-current measurements. This may be due in part to an actual increase in the resistance of the dielectric with the speed of variation of the field, or it may be due to a phenomenon analogous to magnetic hysteresis, i.e., to a lag of the dielectric flux density behind the electric field intensity. Whatever may be the cause of this extra loss of power for rapidly varying fields, it is generally described as the loss due to " dielectric hysteresis." The heat developed is in many cases quite appreciable.

---

* Either condensers, or dielectrics of different kinds, sizes, or shapes, in contact along equipotential surfaces.

Dielectric Strength. When an electric field is established by a charge on a conductor, and the intensity of this field is increased, corona forms in the dielectric at the surface of conductors, and if this field is further increased a point is reached at which the dielectric breaks down. Under some conditions (corona) the breakdown is not permanent but results in the acquisition of a much higher conductivity by the dielectric only while the voltage gradient is maintained above the critical value, the dielectric regaining its insulating property when the field is reduced below this critical value.

18. ELECTROSTATIC ENERGY AND MECHANICAL FORCES

Electrostatic Energy. From the general relation expressed by equation 18, it is evident that when the potential difference between the plates of a condenser is increased from 0 to V the energy input is

$$W = \int_0^t gv^2\,dt + \int_0^V Cv\,dv \tag{21}$$

The energy represented by the first term on the right-hand side of this equation is dissipated as heat in the dielectric, but the energy represented by the second term, which, when C is constant, may be written

$$W = {}^1/_2\,CV^2 \tag{22}$$

does not represent a dissipation of heat; this is a fact of experience. Moreover, when the condenser is discharged, by short-circuiting its plates with a wire, this same amount of energy ${}^1/_2\,CV^2$ is transferred to the wire. Hence, the energy represented by ${}^1/_2\,CV^2$ is said to be stored in the condenser, or preferably in the dielectric of the condenser, for the electric force F exists only in the dielectric. This stored energy is called the " electrostatic " energy. It is analogous to the energy stored in a spring when the spring is compressed or stretched. Equation 22 may also be written

$$W = \frac{1}{2}\frac{Q^2}{C} = \frac{1}{2}QV = \frac{1}{8\pi}\psi V \tag{22a}$$

The electrostatic energy per unit volume of an electric field may be written

$$w = \frac{DF}{8\pi} = \frac{kF^2}{8\pi} = \frac{D^2}{8\pi k} \tag{22b}$$

where k is the dielectric coefficient, F the magnitude of the electric field intensity or potential drop per unit distance, and D the magnitude of the dielectric flux density or flux per unit area perpendicular to the direction of the drop.

It should be noted that equations 22 to 22*b* are based on the assumption that k is a constant, independent of the value of F. When this condition does not hold, the energy required to establish the field is $\int_0^V Cv\,dv$, the evaluation of which depends upon the relation between C and v.

Mechanical Forces in an Electric Field. Experience shows that all bodies (conductors or insulators) in an electric field exert, in general, mutual mechanical forces upon one another tending to produce such a relative motion as will decrease the energy of the field. Let f be the component of the force tending to move any body in the field in a given direction, and let dW be the increase in the energy of the field due to displacing the body a distance dx in this direction; then

$$f = -\frac{dW}{dx} \tag{23}$$

provided this displacement does not cause a change in the existing electric charges in the field. As a consequence of this general relation it can be shown that every charged surface exerts a force of repulsion on every other surface charged with electricity of the same sign, and a force of attraction on every surface charged with electricity of the opposite sign.

In the special case of the two conductors forming a condenser the force of attraction exerted by one conductor on the other is

$$f = -\frac{V^2}{2}\frac{dC}{dx} \tag{23a}$$

where V is the p.d. across the condenser, C is the capacitance of the condenser, and dC represents the increase in the capacitance of the condenser when one conductor moves a distance dx away from the other. This relation results from the substitution of equation 22a in 23. For example, the capacitance of a parallel plate condenser is approximately

$$C = \frac{kA}{4\pi x}$$

where k is the dielectric coefficient, A the area of the smaller plate, and x the distance between the plates. Hence the force of attraction is

$$f = \frac{V^2kA}{8\pi x^2} \tag{24}$$

ALTERNATING-CURRENT CIRCUITS

19. GENERAL DEFINITIONS

The definitions given below are applicable to currents, electromotive forces, potential differences, or any other function of time. They are the definitions recommended by the sectional committee on electrical definitions of the A.I.E.E.

Periodic Quantities

An Oscillating Quantity is a quantity which as a function of some independent variable (such as time) alternately increases and decreases in value, always remaining within finite limits.

A Periodic Quantity is an oscillating quantity the values of which recur for equal increments of the independent variable.

The Period of a periodic quantity is the smallest value of the increment of the independent variable which separates recurring values of the quantity.

A Cycle is the complete series of values of a periodic quantity which occur during a period.

The Frequency of a periodic quantity, in which time is the independent variable, is the reciprocal of the period.

The Angular Velocity of a periodic quantity is the frequency multiplied by 2π.

An Alternating Quantity is a periodic quantity which has alternately positive and negative values.

As Examples and to avoid repetition the following statements will be given in terms of electric currents.

If a given current is represented by the equation

$$i = f(t) \tag{1}$$

and if the function $f(t)$ has the property that

$$f(t) = f(t + T) \tag{2}$$

in which T is a constant, then the current is said to be periodic in time and T is the period. If time is measured in seconds then $1/T$ represents the number of periods per second and is usually denoted by f. The frequency f may also be said to be the number of cycles per second. If, as often happens, the current is expressible more simply as

$$i = f(\omega t) \tag{3}$$

in which ω is defined by

$$f(\omega t) = f(\omega t + 2\pi) \tag{4}$$

then the constant ω, being equal to 2π divided by the period or 2π times the frequency, is the angular velocity as defined above. That is

$$\omega = 2\pi f = \frac{2\pi}{T} \tag{5}$$

Maximum, Average, and Rms or Effective Values

The Instantaneous Value of an alternating current is the value of the current at any instant. Instantaneous values of current, potential difference, and emf will be designated by small letters throughout this article, viz., i, v, and e.

The Maximum Value of an alternating current is the numerical value of its maximum instantaneous value. Maximum values will be designated by capital letters with the subscript m.

The Half-period Average Value of a symmetrical alternating current[*] is the absolute value of the algebraic average of the values of the current taken throughout a half period, beginning with a zero value. If the current has more than two zeros during a cycle, that zero shall be taken which gives the largest half-period average value. The expression for the half-period average of a symmetrical alternating current $i(t)$ having a period T is

$$I_{av} = \frac{2}{T}\int_{t_0}^{t_0+\frac{1}{2}T} i(t)\,dt \tag{6}$$

where t_0 is chosen such that $i(t) = 0$ at t_0 and I_{av} is the largest value obtainable.

The Rms or Effective Value. The square root of the means of the squares of the instantaneous values of an alternating current over a complete period is called the *rms* or the *effective* value of the alternating current. In specifying the value of an alternating current as so many amperes, this rms value is always meant unless specifically stated otherwise. In the same manner the square root of the mean of the squares of the instantaneous values of an alternating potential difference over a complete period is called the rms value of the alternating potential difference. When the value of an alternating potential difference is specified as so many volts, this rms value is always meant unless specifically stated otherwise.

The reason for selecting this particular function of the instantaneous values of an alternating current or a potential difference as a measure of the current or the potential difference, is that the deflection of all instruments used in alternating-current measurements is a function of this rms value. Moreover, the average power dissipated as heat in a resistance, r, when an alternating current of rms value I flows through it, is rI^2.

Rms values will be designated throughout this article by capital letters without subscripts. The general expression for the rms value of an alternating current is

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,dt} \tag{7}$$

and similarly for an alternating potential difference.

Form Factor, Crest or Peak Factor, Deformation Factor

The Form Factor of a symmetrical alternating current is the ratio of the effective value of the current to its half-period average value.

The Peak or Crest Factor of an alternating current is the ratio of the maximum value of the current to its effective value.

The Equivalent Sinusoidal Current of a given alternating current is a sinusoid having the same period and the same effective value as the given alternating current.

The Deformation Factor of an alternating current is the ratio of the maximum value of the equivalent sinusoidal current to the maximum difference between the corresponding values of the current considered and the equivalent sinusoid, when the two are superimposed in such a way as to make this difference a minimum.

Power, Power Factor, Volt-amperes, Reactive Power

Power. Let v be the value at any instant of the potential drop from any point 1 to any other point 2, and let i be the instantaneous value of the current from 1 to 2 at this same instant; then the *power input* at this instant is

$$p = vi \tag{8}$$

When v and i are both positive (i.e., in the direction from 1 to 2, say) or when they are both negative, the power input is positive; but when v is positive and i negative, or vice versa, the power input is negative, i.e., there is an actual power output.

The average value of the product vi over a complete period for both v and i (or over any whole number of periods) is the *average power* input or output, usually called simply the power input or output (input when the average of vi is positive, output when the average of vi is negative), the word average being understood. That is, the average power input is

$$P = \frac{1}{T}\int_0^T p\,dt = \frac{1}{T}\int_0^T vi\,dt \tag{9}$$

T being the time for a complete period.

Power Factor. Only in certain special cases (see below) is the average power input P equal to the product of the rms value V of the potential difference by the rms value I

---

[*] A symmetrical alternating quantity is one of which all values separated by a half period have the same magnitude but opposite sign. The term half-period average has no meaning for alternating currents which are not symmetrical.

of the current; it can never be greater and as a rule is less. The ratio of the average power P to the product of the rms value V of the potential difference by the rms value I of the current is called the *power factor* of the circuit between the terminals considered, i.e.,

$$\text{Power factor} = \frac{P}{VI} \tag{10}$$

When V is expressed in volts and I in amperes, then P must be in watts; when V is expressed in kilovolts and I in amperes, P must be in kilowatts.

Apparent Power. The product of the rms volts across the terminals of a circuit and the rms amperes through it is called the *volt-amperes* or *apparent power* taken by the circuit; this product divided by 1000 is called the kilovolt-ampere input. Or, when V is in volts and I in amperes

$$\text{Volt-amperes} = VI \tag{11}$$

$$\text{Kilovolt-amperes} = \frac{VI}{1000} \tag{11a}$$

Reactive power has no accepted definition when either the current or emf is non-sinusoidal. For reactive power with sinusoidal currents and emf's see below.

20. SINUSOIDAL CURRENTS AND VOLTAGES

A Simple Sinusoidal Current (simple harmonic current) is an alternating current the instantaneous values of which are equal to the product of a constant and the sine of an angle having values varying linearly with time. Thus

$$i = I_m \sin(\omega t + \theta) \tag{12}$$

where t represents time in seconds, measured from any arbitrarily chosen instant; I_m the maximum value of the current; $\omega = 2\pi f = 2\pi/T$, where f is the frequency in cycles per second and T the period as a fraction of a second; and θ a constant which depends upon the instant chosen as the zero of time.

The quantity I_m is often called the *amplitude* of the sinusoidal current.

The Phase of a periodic current for a particular value of the independent variable is the fractional part of a period through which the independent variable has advanced, measured from an arbitrary origin. For a simple sinusoidal current, the origin is usually taken as the last previous passage through zero from the negative to positive direction. The phase angle is the angle obtained by multiplying the phase by 2π if the angle is to be expressed in radians, or by 360° if the angle is to be expressed in degrees.

In general, when a sine-wave emf is impressed on a circuit the resulting current is likewise a sine function of time (transient state ignored) having the same frequency, but the emf and current do not reach their maximum values simultaneously. Let the current be represented by equation 12 and the voltage be given by

$$v = V_m \sin \omega t \tag{13}$$

where t is the time measured from the instant when $v = 0$, and is increasing in the positive direction. The voltage reaches its maximum value when $t = \frac{\pi}{2\omega}$; the current reaches its maximum value when $t = \frac{\pi}{2\omega} - \frac{\theta}{\omega}$. Hence when θ is positive the voltage or potential drop reaches its maximum value θ/ω seconds after the current reaches its maximum, or the current reaches its maximum value θ/ω seconds before the potential drop reaches its maximum; when θ is negative the current reaches its maximum value θ/ω seconds after the potential drop reaches its maximum. In the first case, the current is said to "lead" the potential drop; and in the second, the current is said to "lag" the potential drop. The angle θ is called the angular phase difference between the current and potential drop.

When the phase difference is zero the current and potential drop are said to be "in phase"; when the phase difference is $\pi/2$ radians or 90° the current and potential drop are said to be "in quadrature"; when the phase difference is π radians or 180° the current and potential drop are said to be "in opposition."

Power and Power Factor. Let the voltage drop from terminal 1 to terminal 2 through any piece of apparatus be $v = \sqrt{2}V \sin(\omega t + \theta_v)$, and the current from terminal 1 to terminal 2 be $i = \sqrt{2}I \sin(\omega t + \theta_i)$, where V and I are the rms values and $\sqrt{2}V$ and $\sqrt{2}I$ are the maximum values. Then the instantaneous power input is

$$p = vi = VI[\cos(\theta_v - \theta_i) - \cos(2\omega t + \theta_v + \theta_i)] \tag{14}$$

A study of Fig. 1 will show the physical meaning of this expression. The average power input is

$$P = VI \cos (\theta_v - \theta_i) \tag{14a}$$

where $(\theta_v - \theta_i)$ is the angular phase difference between the current and voltage.

Putting θ for this difference in phase, viz., $\theta = \theta_v - \theta_i$, equation 14*a* may be written:

$$P = VI \cos \theta \tag{14b}$$

Whence the power factor of the load supplied to the apparatus is (from equation 10):

$$\cos \theta = \frac{P}{VI} \tag{14c}$$

Since with sine-wave currents and voltages the power factor is equal to the cosine of the angle which expresses the difference in phase between them, this difference in phase is frequently called the "power-factor angle." If the wave shape is not a pure sine curve, the power factor cannot be interpreted as the cosine of the phase difference, for phase difference has no definite meaning except in reference to sine waves; see definitions above. A non-sinusoidal voltage and current may both reach their zero values at the same instant, and in a sense may be said to be "in phase," but the power factor as defined by equation 10 may be far from unity.

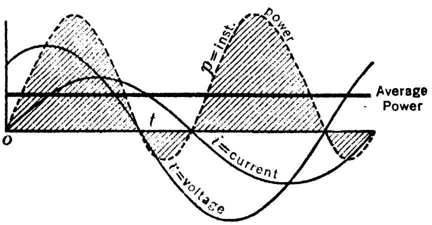

Fig. 1

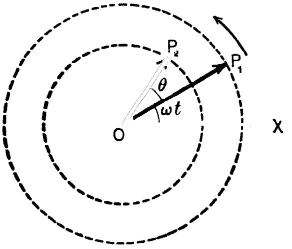

Fig. 2

The Reactive Power in a circuit in which a sinusoidal current is flowing is equal to the effective emf times the effective current times the sine of the phase difference between them. When the emf and current are in volts and amperes respectively the reactive power is in *vars*.

Vector Representation of Sinusoids. Consider any sine function

$$i = I_m \sin \omega t$$

The value of i at any instant may be represented graphically, see Fig. 2, by the vertical projection (i.e., the vertical distance from P_1 to OX) of a point P_1 at the end of a radius $OP_1 = I_m$ which revolves * at a constant angular velocity ω about a fixed point O, the angle ωt being measured from the horizontal fixed line OX. Similarly, any other sine function

$$v = V_m \sin (\omega t + \theta)$$

may be represented by the vertical projection of the point P_2 at the end of a radius $OP_2 = V_m$ also revolving about O with a constant angular velocity ω, the angle between OP_1 and OP_2, when the frequency of both i and v is the same, remaining fixed in value and equal to the difference in phase θ between v and i. That is, v and i may be represented by rotating vectors (q.v.). When v and i are of the same frequency the relative position of the two vectors remains fixed. Similarly any number of currents and voltages of the same frequency may be represented by rotating vectors which remain fixed with respect to one another.

Instead of referring the various rotating vectors to a fixed line OX, this line of reference may also be considered as rotating with the same speed as the various vectors, or any one of the vectors may be chosen as the line of reference, for example, the vector OP_1 in Fig. 2. The rotating vectors referred to this rotating line of reference are then fixed with respect to this line of reference, and the entire diagram may be considered as fixed, as in Fig. 3, the originally chosen fixed line of reference OX rotating in the opposite direction with an angular velocity ω.

Instead of making the vectors equal in length to the maximum values of the sine functions they may be chosen equal in length to their rms values. This merely introduces a factor $\sqrt{2}$ so that the instantaneous value of the quantity which any rotating vector is considered to represent is equal to $\sqrt{2}$ times the perpendicular distance from the end of the vector to the fixed line of reference.

---

* Counter-clockwise rotation was adopted (1911) as standard by the International Electrotechnical Commission.

Since the rms values and phase relations of sine-wave currents and voltages may be represented by vectors, sine-wave currents may be added in exactly the same manner as vectors are added, and similarly for sine-wave voltages. To add any two sine-wave currents or voltages not only their effective values but also their phase relation must be known; the resultant of two alternating voltages of rms values V_1 and V_2 is never the arithmetical sum of V_1 and V_2, except when the two voltages are exactly in phase, and similarly for alternating currents.

In Fig. 3, considering OI as equal to the rms value I of the current and OV as representing the rms value V of the voltage, the vector voltage **V** may be considered as made up of two components, viz.:

$$V_1 = V \cos \theta \text{ in phase with the vector } \boldsymbol{I}$$

$$V_2 = V \sin \theta \text{ in quadrature with the vector } \boldsymbol{I}$$

The average power corresponding to the component $V_1 = V \cos \theta$ is, from equation 14*b*, $V_1 I = VI \cos \theta$, and is equal to the total power corresponding to V and I. The average power corresponding to the component $V_2 = V \sin \theta$, since the angle between the current and this component of the voltage is 90°, is equal to zero. The voltage component $V_1 = V \cos \theta$ is therefore frequently called the "power" component of the voltage, and the component $V_2 = V \sin \theta$ is frequently called the "wattless" component of the voltage. These terms, however, are not recommended. It is preferable to refer to these two components as the in-phase and quadrature components respectively. The terms active and reactive components are also used.

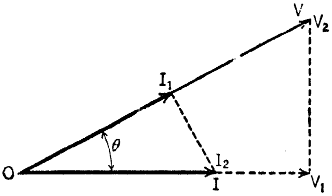

FIG. 3

Similarly, the vector current **I** may be considered as made up of two components, viz.:

$$I_1 = I \cos \theta \text{ in phase with } V$$

$$I_2 = I \sin \theta \text{ in quadrature with } V$$

The first component is called the in-phase component of the current and the second the quadrature component of the current.

21. NON-SINUSOIDAL PERIODIC CURRENTS AND VOLTAGES

Fourier Series, Harmonics. It can be shown that any single-valued, periodic function (which fulfills certain mathematical conditions always fulfilled by electric currents) may be represented by a sum of sinusoids of which the frequencies form an arithmetical progression. Hence any current $i(t)$ can be written

$$\begin{aligned} i(t) = A_0 &+ A_1 \sin 2\pi \frac{t}{T} + A_2 \sin 2\pi \frac{2t}{T} + \dots + A_n \sin 2\pi \frac{nt}{T} + \dots \\ &+ B_1 \cos 2\pi \frac{t}{T} + B_2 \cos 2\pi \frac{2t}{T} + \dots + B_n \cos 2\pi \frac{nt}{T} + \dots \end{aligned} \tag{15}$$

where the values of the coefficients A and B are given by the integrals:

$$A_n = \frac{2}{T}\int_0^T i\,(t) \sin 2\pi \frac{nt}{T}\, dt \tag{15a}$$

$$B_n = \frac{2}{T}\int_0^T i\,(t) \cos 2\pi \frac{nt}{T}\, dt \tag{15b}$$

The series (15) is called a *Fourier series.*

If an analytic expression for $i(t)$ is available and if the integrations (15*a*) and (15*b*) can be performed, the terms of the Fourier series (15) may be written out. In practice the function $i(t)$ will usually be obtainable only in the form of a plotted curve and the evaluation of the A's and B's must be carried out by graphical means. This process is called *harmonic analysis.* Various means of harmonic analysis have been devised, of which the Fisher-Hinnen method is perhaps the most convenient in ordinary cases. See Pender's Handbook for Electrical Engineers.

If the terms involving the same frequencies are combined, and if $\frac{2\pi}{T} = \omega$, (15) may be written

$$i(t) = I_1 \sin (\omega t - \theta_1) + I_2 \sin (2\omega t - \theta_2) + \ldots + I_n \sin (n\omega t - \theta_n) + \ldots \quad (16)$$

The term $I_1 \sin (\omega t - \theta_1)$ is called the *fundamental*, and the terms $I_n \sin (n\omega t - \theta_n)$ are called *harmonics*. The *order* of a harmonic is the ratio of the harmonic frequency to the frequency of the fundamental. Each harmonic is characterized by two constants, its amplitude I_n and the angle θ_n. It should be noted that this angle may be given in either of two ways:

$$I_n \sin (n\omega t - \theta_n) \quad (17a)$$

$$I_n \sin n (\omega t - \theta_n') \quad (17b)$$

In the first notation the angle θ_n is taken relative to the period of the harmonic, whereas in the second notation the angle θ_n' is taken relative to the period of the fundamental. It follows that

$$\theta_n = n\theta_n' \quad (18)$$

Rms Value of Non-sinusoidal Currents. The rms value of a non-sinusoidal current can be obtained directly from equation 7, Art. 19, or if the rms values I_1, I_2, I_3, etc., of the fundamental and harmonics are known the rms value of the resultant current is

$$I = \sqrt{I_1^2 + I_2^2 + I_3^2 + \ldots} \quad (19)$$

A like relation holds for the rms value of a non-sinusoidal voltage. Similarly, if for example a 25-cycle emf, say E_{25}, and a direct emf, say E_d, are acting in series in the same circuit, the rms value of the resultant emf of the combination is

$$E = \sqrt{E_{25}^2 + E_d^2}$$

The Power Corresponding to Non-sinusoidal Currents and Voltages may be computed as follows:

Let I_1 be the rms value of the fundamental of the current, V_1 the rms value of the fundamental of the voltage, and θ_1 the difference in phase between these two fundamentals, both being of the same frequency; let I_2, V_2, and θ_2 be the corresponding quantities for the second harmonic; let I_3, V_3, and θ_3 be the corresponding values for the third harmonic, etc. Then the average power is

$$p = V_1I_1 \cos \theta_1 + V_2I_2 \cos \theta_2 + V_3I_3 \cos \theta_3 + \text{etc.} \quad (20)$$

That is, each harmonic contributes an amount to the total power equal to the power it would develop were the other harmonics not present. If, for example, the third harmonic is not present in the current wave, then this harmonic contributes nothing to the average power even though there may be a large third harmonic in the voltage wave. Again, when a 25-cycle alternating emf E_{25} and a direct emf E_d are acting in series on the same circuit the power developed is the sum of the powers which each would develop if they acted separately, but the resultant emf of the combination is not $E_{25} + E_d$, but, as noted above, $\sqrt{E_{25}^2 + E_d^2}$.

22. CURRENT AND VOLTAGE RELATIONSHIPS

Electric Circuit Parameters. The following are restatements of principles given in foregoing articles:

(*a*) The flow of a current i through a resistance R is always accompanied by a drop of electric potential, or voltage drop, in the direction of this current, equal at each instant to the product of the resistance and the current.

$$v_r = Ri \quad (21)$$

(*b*) The flow of a current i through a self-inductance L is always accompanied by a voltage drop, in the direction of this current, equal at each instant to the product of the inductance and the rate of increase of the current.

$$v_L = L\frac{di}{dt} \quad (22)$$

(*c*) The flow of a current i_b through a conductor B which has, with respect to another conductor A, a mutual inductance M, is always accompanied by a voltage drop in the conductor A equal at each instant to the product of the mutual inductance and the rate of increase of the current in the conductor B.

$$v_M = M\frac{di_B}{dt} \quad (23)$$

The direction of the mutual inductive drop in the conductor A is such as to link *in the right-handed screw direction* the magnetic flux produced by the current in the conductor B.

(d) The flow of a (displacement) current i through a capacitance C is always accompanied by a time rate of change of voltage drop equal at each instant to the current divided by the capacitance.

$$\frac{dv_C}{dt} = \frac{i}{C} \tag{24}$$

The voltage v_C is therefore equal to the integral of i/C from the instant at which v_C was zero up to the instant under consideration

$$v_C = \int_{t_0}^{t} \frac{i}{C}\, dt \tag{24a}$$

Since the value of this integral is always zero at the lower limit, it is customary to omit the limits of integration and write simply

$$v_C = \frac{1}{C}\int i dt \tag{24b}$$

The quantities R, L, C, and M are called *electric circuit parameters.*

Operative Impedance. Any portion of an electric circuit which contains a resistance, an inductance, or a capacitance, or which contains two or more of these quantities, is said to offer an impedance to the flow of an electric current.

The drop of electric potential through any portion of an electric circuit due solely to its resistance, inductance, and capacitance is called the *impedance drop* in this portion of the circuit.

The impedance drop through an impedance formed by a resistance R, inductance L, and capacitance C in series, due to the flow of a current i through it, is

$$v = Ri + L\frac{di}{dt} + \frac{1}{C}\int i dt \tag{25}$$

The drop of potential

$$v_A = M\frac{di_B}{dt}$$

in any conductor A due to the mutual inductance between A and any other conductor B is called the *mutual impedance drop* in A due to the current i_B in B.

The group of operations represented by the three terms in the right-hand member of 25 is often represented by the single symbol $\mathbf{Z}$.

$$\mathbf{Z} = R + L\frac{d}{dt} + \frac{l}{C}\int dt \tag{25a}$$

The operator $\mathbf{Z}$ is referred to as the *operative impedance* of the portion of the circuit under consideration.

The term *operative mutual impedance* is used when the mutual impedance drop is written $\mathbf{Z}_m i$, where

$$\mathbf{Z}_m = M\frac{d}{dt} \tag{25b}$$

It is customary in electric circuit theory to use the notation $p = \frac{d}{dt}$. Thus $\mathbf{Z}$ defined above is often written $Z(p)$.

Emf. Electromotive force has been defined as that property of a device which tends to produce an electric current in a circuit. It is convenient in electric circuit theory to narrow this definition to include only those sources of potential difference not defined as impedance drops. Making use of this restricted definition of emf, Kirchhoff's second law is stated: " The sum of the emf's is, at any instant, equal to the sum of the impedance drops," whereas making use of the more general definition this law is stated: "The sum of the emf's is at any instant equal to the sum of the resistance drops."

Impedance Equations for a Network. Kirchhoff's second law applied to mesh 1 of Fig. 4 gives

$$Z_{12}i_{12} + Z_{13}i_{13} + Z_{14}i_{14} + Z_{15}i_{15} = e_{12} + e_{13} + e_{14} + e_{15} \tag{26}$$

where the Z's are the operative impedances of the several branches which make up this mesh, the i's are the *branch currents*, and the e's are the emf's, if any, in the respective branches of the mesh, the positive sense of each emf being taken as clockwise around the mesh.

In terms of the *mesh currents* defined in Art. 7, the equation may also be written

$$(Z_{12} + Z_{13} + Z_{14} + Z_{15})i_1 - Z_{12}i_2 - Z_{13}i_3 - Z_{14}i_4 - Z_{15}i_5 = e_{12} + e_{13} + e_{14} + e_{15} \tag{27}$$

This relation may be simplified by putting

$$Z_{11} = Z_{12} + Z_{13} + Z_{14} + Z_{15} \tag{27a}$$

and

$$e_1 = e_{12} + e_{13} + e_{14} + e_{15}$$

Equation 27 then becomes

$$Z_{11}i_1 - Z_{12}i_2 - Z_{13}i_3 - Z_{14}i_4 - Z_{15}i_5 = e_1 \tag{28}$$

In this equation the operator Z_{11} is the sum of the operative impedances of the several branches of mesh 1, and e_1 is the algebraic sum, in the clockwise direction, of all emf's in this mesh.

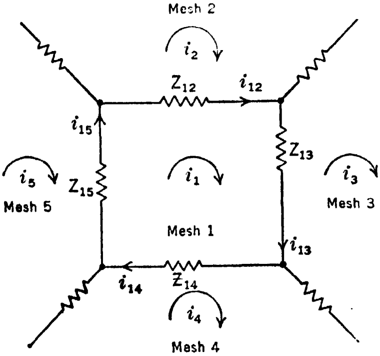

FIG. 4

If as many independent mesh equations, of the form 28, as there are mesh currents in a given network, are written down, the set of equations can be solved for the various currents. Such equations are called the *impedance equations* of the network.

Differential Equations in Terms of Quantity of Electricity. When capacitances exist in any of the meshes of the network the impedance equations contain some derivatives and some integrals. Equations of this type are more difficult to handle than true differential equations. It is often more convenient therefore to express the relation shown by equation 28 in terms of the quantity of electricity q. If we write

$$i_r = \frac{dq_r}{dt} \tag{29}$$

then equation 28 becomes

$$Z'_{11}q_1 - Z'_{12}q_2 - Z'_{13}q_3 - Z'_{14}q_4 - Z'_{15}q_5 = e_1 \tag{30}$$

in which

$$Z'_{rs} = \left(Z_{rs}\frac{d}{dt}\right) = \left(\frac{1}{C_{rs}} + R_{rs}\frac{d}{dt} + L_{rs}\frac{d^2}{dt^2}\right) \tag{31}$$

Equation 30 is a true differential equation.

Superposition. *Linear differential equations* are differential equations, such as the above, having coefficients which are constants, or which are functions of the independent variable only. They have the property that the sum of the solutions is also a solution. That is, if x_1 and x_2 are two solutions of a given linear differential equation then $x_1 + x_2$ is also a solution of the given equation.

Suppose the equation to be non-homogeneous, and let the non-homogeneous term be A_1. Call the particular solution of the equation corresponding to this condition x_1. Now let the non-homogeneous term be given the value A_2, the remainder of the equation remaining the same, and let the particular solution corresponding to this condition be x_2. Then it can be shown that $x_1 + x_2$ is a solution of the equation when the non-homogeneous term is given the value $A_1 + A_2$.

The above principles jointly are called the *principle of superposition.* Electrical networks in which this principle holds are called *linear networks.*

Exponential Emf, Charge, Current, and Impedance. Derivatives and integrals of the simple exponential function bear simple relationships to the function itself. Furthermore, any arbitrary function may be expressed in terms of a sum of exponential terms. For these reasons, and especially because the simple sinusoidal function is simply expressible as a sum of exponential terms, it is customary to formulate the solution of electric circuit problems in terms of exponential currents.

It has been shown that, when the parameters of a given network (the factors R, L, M, and C) are constants, the electric charge equations for this network are a set of simultaneous, linear differential equations with constant coefficients. The complete solution of such a set of equations is a sum of terms of the form

$$q = Q\, t^g\, \epsilon^{\beta t} \tag{32}$$

where Q, g, and β are constants, the values of which can be expressed in terms of the applied emf's, the parameters of the network, and the conditions which existed in the network at the time of application of the emf's. The solutions of the current equations of the network may therefore likewise be expressed as a sum of the terms of the form

$$i = I\, t^g\, \epsilon^{\beta t} \tag{33}$$

The general forms (32) and (33) rarely occur, and so the usual case in which $g = 0$ will be assumed here. In the exponential current

$$i = I \epsilon^{\beta t}$$

the quantities I and β are often called the *initial value* and the *periodicity* of the current respectively.

From equation 25*a* the impedance drop corresponding to the current

$$i = I\, \epsilon^{\beta t}$$

is

$$v = Zi = \left(R + L\beta + \frac{1}{\beta C}\right) I\, \epsilon^{\beta t} \tag{34}$$

The factor in the parenthesis is a *constant* for any given value of β. That is, for a current of the form $I\ \epsilon^{\beta t}$ the operative impedance

$$Z = R + L\frac{d}{dt} + \frac{1}{C}\int dt \tag{35}$$

reduces to the simple algebraic quantity

$$Z(\beta) = R + \beta L + \frac{1}{\beta C} \tag{35a}$$

This quantity will be referred to as the *exponential impedance*.

From the above it is evident that an exponential voltage drop is always associated with an exponential charge and current.

23. STEADY-STATE SOLUTION

Definition of a Steady State. The complete solution of a non-homogeneous linear differential equation having constant coefficients, consists of a particular function which satisfies the given equation plus the most general solution of the homogeneous equation (see Section 11).

In stable * electrical systems the charges and currents represented by the solutions of the homogeneous equations decrease rapidly with time. After a brief interval following the application of emf's to such a system the currents and charges are represented by the particular solutions of the non-homogeneous equations only. When this condition has been reached the system is said to have attained a *steady state*. During the interval before this condition is reached the system is said to be in a *transient state*.

In linear electrical systems the steady-state currents and usually the charges have the same wave form (i.e., are represented by time functions of the same type) as the impressed voltages.

Sinusoidal Emf's. A sinusoidal emf given by

$$e = \sqrt{2}E\cos(\omega t + \phi) \tag{36}$$

may be written as the sum of the two exponential components

$$e' = \mathbf{E}'\epsilon^{j\omega t} \tag{37}$$

$$e'' = \mathbf{E}''\epsilon^{-j\omega t} \tag{37a}$$

in which $j = \sqrt{-1}$ and in which

$$\mathbf{E}' = \frac{1}{\sqrt{2}}E\epsilon^{j\phi} \tag{37b}$$

$$\mathbf{E}'' = \frac{1}{\sqrt{2}}E\epsilon^{-j\phi} \tag{37c}$$

In equation 36 the constant E is the rms value of the emf, and ω is its angular velocity.

In electric circuit theory the phase differences between various quantities having the same frequency are of importance. Since these differences in phase are independent of the instant at which they are evaluated, it is customary to refer to the angle ϕ (which is the phase angle when $t = 0$) as the phase angle of the emf. The two constants $\mathbf{E}'$ and $\mathbf{E}''$ in equations 37 are the initial values of the two exponential components of e, and $j\omega$ and $(-j\omega)$ are the periodicities of these two components. Note that the two initial values $\mathbf{E}'$ and $\mathbf{E}''$ are conjugate complex numbers,† and that the two periodicities $j\omega$ and $(-j\omega)$ are conjugate imaginaries.

---

* For a definition of stability refer to Art. 25.

† Complex numbers will be printed in bold-face type throughout this article.

Complex Number Solution. It can be proved that during steady state an exponential current having a given periodicity exists in a stable linear network when and only when there is impressed upon the network an exponential emf having the given periodicity.

Each current which flows in a given network due to the application of a sinusoidal emf is therefore composed of two exponential components, each due to one of the exponential components of the sinusoidal emf. The superposition theorem states that these two components may be computed separately.

Let the sinusoidal emf, given by equation 36, be applied to a mesh (say mesh 1) of a network, and consider the currents flowing due to the component e', equation 37. Each of these currents will be of the form

$$i_k' = I_k' \epsilon^{j\omega t} \tag{38}$$

and each self-impedance drop (see 35*a*) will have the form

$$Z_{kk}i_k' = \left(r_k + j\omega L_k + \frac{1}{j\omega C_k}\right) I_k' \epsilon^{j\omega t} \tag{39}$$

Mutual impedance drops will be of a similar form. Hence any one of the impedance equations such as 28 will contain the factor $\epsilon^{j\omega t}$ in every term, and this factor can be divided out. This results in a set of equations containing as unknowns the complex numbers representing the initial values of the exponential currents and as coefficients the complex numbers obtained by putting $p = j\omega$ in the various operative impedances.

The initial value of the exponential current i_k' flowing in the kth mesh may be written

$$I_k' = A_k \epsilon^{j\theta_k} \tag{40}$$

The currents which flow in the network due to the other component e'' of the sinusoidal emf will be of the form

$$i_k'' = I_k'' \epsilon^{-j\omega t} \tag{41}$$

The initial values of these currents will be obtained from a set of complex number equations in which every term is the conjugate of the corresponding term in the set of equations for I_k'. The initial value of any one of these currents, say I_k'', can be shown to be the conjugate of the initial value, I_k', of the corresponding current, viz.,

$$I_k'' = A_k \epsilon^{-j\theta_k} \tag{42}$$

The actual steady-state sinusoidal current flowing in the kth mesh due to the application of the sinusoidal emf to the first mesh is the sum of the two exponential currents i_k' and i_k'',

$$i_k = i_k' + i_k'' = 2A_k \cos(\omega t + \theta_k) \tag{43}$$

If, in solving the mesh equations, the initial values 37*b* and 37*c* were replaced by the values $E\epsilon^{j\phi}$ and $E\epsilon^{-j\phi}$, then a new value of A_k equal to $\sqrt{2}$ times the value in equation 43 would be obtained. Let this value be called I_k, i.e.,

$$I_k = \sqrt{2}\, A_k \tag{44}$$

In terms of the quantity I_k the current i_k is

$$i_k = \sqrt{2}\, I_k \cos(\omega t + \theta_k) \tag{45}$$

From the above we have the following simple procedure for finding the steady-state currents produced in a network by a group of sinusoidal emf's of a given frequency:

(*a*) Write the operative impedance equations 27 and 28 described in Art. 22.

(*b*) Replace each emf in the network by a complex number having a modulus equal to the rms value of the given emf, and a phase angle equal to the phase angle of the given emf (when expressed in cosine form).

(*c*) Replace the self- and mutual operative impedances of the several meshes of the network by complex numbers obtained by putting $p = (j\omega)$, where ω is the angular velocity of the given sinusoidal electromotive forces.

(*d*) Replace each current in the network by an unknown complex number, and solve for these complex numbers.

(*e*) The rms values of the various currents are the moduli of the corresponding complex numbers, and the phase angles of the currents (when expressed in cosine form) are the phase angles of these complex numbers.

This method is known as the *complex number method* for alternating currents.

The complex numbers obtained from the operative impedances are usually referred to as *vector impedances* or often simply as *impedances*. Although the term impedance is used for both the differential operator and the complex number, the term used without qualification usually means the complex number. A still more general definition of impedance is given below. The algebra of complex numbers is treated in the section on mathematics.

Impedance, Admittance, Reactance, Susceptance. In previous paragraphs the terms operative impedance and vector impedance were defined. Although the term *impedance* is loosely used to designate either of these, the accepted definition of impedance is: The impedance of a portion of an electric circuit, to a completely specified periodic current and potential difference, is the ratio of the effective value of the potential difference between the terminals to the effective value of the current, there being no source of emf in the portion under consideration.

Impedance defined in this way is a real number which in a sinusoidal current and voltage reduces to the modulus value of the vector impedance defined above.

Admittance is defined as the reciprocal of the impedance. The *vector admittance* is the reciprocal of the complex number representing the vector impedance.

Impedance and admittance, as thus defined, both depend upon the frequency and wave shape of the current. Impedance is expressed in the same units as resistance (e.g., ohms), and admittance in the same units as conductance (e.g., mhos).

The *reactance* of a portion of a circuit for a sinusoidal current, and hence for any one of the frequencies of a periodic current, is the ratio of the quadrature component of the potential difference for a particular frequency to the value of the current for that frequency, there being no source of emf in the portion of the circuit under consideration.

The *susceptance* of a portion of a circuit for a sinusoidal potential difference, and hence for any one of the frequencies of a periodic potential difference, is the ratio of the quadrature component of the current for a particular frequency to the value of the potential difference for that frequency, there being no source of emf in the portion of the circuit under consideration.

From the definitions given above it may be shown that for sine-wave currents and voltages of a given frequency the following relations hold for any portion of a circuit:

$$\left.\begin{aligned} \boldsymbol{Z} &= r + jx & \boldsymbol{Y} &= g - jb \\ Z &= \sqrt{r^2 + x^2} & Y &= \sqrt{g^2 + b^2} \\ Z &= \frac{1}{Y} & Y &= \frac{1}{Z} \\ r &= \frac{g}{Y^2} & g &= \frac{r}{Z^2} \\ x &= \frac{b}{Y^2} & b &= \frac{x}{Z^2} \end{aligned}\right\} \qquad (46)$$

where r = effective resistance, x = reactance (taken positive when inductive and negative when capacitive), g = effective conductance, b = susceptance (taken positive when inductive and negative when capacitive), Z = impedance, Y = admittance, $\boldsymbol{Z}$ = vector impedance, and $\boldsymbol{Y}$ = vector admittance, all for the given portion of circuit.

Vector Impedances in Simple Circuits. The vector impedances of the various circuit elements to a sinusoidal current having an angular velocity ω are:

In a resistor $\boldsymbol{Z}_r = R$

In an inductor $\boldsymbol{Z}_L = j\omega L$

In a capacitor $\boldsymbol{Z}_C = \frac{1}{j\omega C} = -j\left(\frac{1}{\omega C}\right)$

The mutual impedance in a device having mutual inductance is

$$\boldsymbol{Z}_M = j\omega M$$

The product (ωL) or (ωM) corresponding to a self-inductance L, or to a mutual inductance M, is called the *reactance* of this inductance at the angular velocity ω. Similarly the expression $-\frac{1}{\omega C}$ corresponding to a capacitance C is called the *reactance* of this capacitance at the angular velocity ω. Note that the reactance of a capacitance is always negative. These statements are in agreement with the previous definition of reactance.

In general, then, the vector impedance of any mesh, or the mutual vector impedance of any two meshes, may be written in the form

$$\boldsymbol{Z} = r + jx \qquad (47)$$

where r is the sum of the effective resistances and x is the algebraic sum of the reactances of the several portions of the network which make up this impedance.

The vector impedance $(r + jx)$ may also be expressed in the form

$$\boldsymbol{Z} = Z\angle\theta \qquad (48)$$

where

$$Z = \sqrt{r^2 + x^2} \qquad (48a)$$

is the modulus of the complex number $(r + jx)$ and

$$\theta = \tan^{-1}\left(\frac{x}{r}\right) \tag{48b}$$

is the phase angle of this complex number.

In equation 48 the symbol $\angle$ is read " at an angle of " and has the same mathematical significance as ϵ^j. Thus $Z\angle\theta$ is identical with $Z\epsilon^{j\theta}$.

When two or more vector impedances Z_1, Z_2, etc., are connected in series, so that the same current I flows through each the total impedance drop through the group is

$$\begin{aligned} V &= Z_1I + Z_2I + \dots \\ &= (Z_1 + Z_2 + Z_3 \dots)\,I \end{aligned} \tag{49}$$

hence two or more vector impedances in series are equivalent to a single vector impedance equal to the sum of the several impedances.

When two or more vector impedances Z_1, Z_2, etc., are connected in parallel, so that the voltage drop is the same for each, the total current through the group is

$$\begin{aligned} I &= \frac{V}{Z_1} + \frac{V}{Z_2} + \dots \\ &= \left(\frac{1}{Z_1} + \frac{1}{Z_2} + \dots\right) V \end{aligned} \tag{50}$$

It is customary to express this law in terms of the vector admittances Y_1, Y_2, ... Two or more vector admittances in parallel are equivalent to a single vector admittance equal to the sum of the several admittances.

Calculation of Power. The average power in a circuit in which the current is i and the voltage drop is v is

$$P = \frac{1}{T}\int_0^T vi\,dt$$

With a sinusoidal current and voltage

$$v = \sqrt{2}V\cos(\omega t + \theta_v) \quad \text{and} \quad i = \sqrt{2}I\cos(\omega t + \theta_i)$$

this power is equal to $\quad P = VI\cos(\theta_v - \theta_i)$

The vector voltage and vector current in this case are

$$V = V\epsilon^{j\theta_v}$$
$$I = I\epsilon^{j\theta_i}$$

of which the product *is not* the average power. The average power is given by the *real part* of the product of the vector voltage by the *conjugate* of the vector current.

$$P = \text{real part of } (V\,\epsilon^{j\theta_v})\,(I\,\epsilon^{-j\theta_i}) \tag{51}$$

This may be expressed in terms of the components of the vector current and voltage as follows:

Let $\quad V = V_1 + j\,V_2$

$\quad I = I_1 + j\,I_2$

then $\quad P = V_1I_1 + V_2I_2 \qquad (52)$

Complicated Circuits. The vector impedance equations described give the complete steady-state solution of any complicated electrical network. If there are n meshes in the network these equations are

$$\left.\begin{aligned} Z_{11}I_1 - Z_{12}I_2 - Z_{13}I_3 \dots - Z_{1n}I_n &= E_1 \\ -Z_{12}I_1 + Z_{22}I_2 - Z_{23}I_3 \dots - Z_{2n}I_n &= E_2 \\ -Z_{13}I_1 - Z_{23}I_2 + Z_{33}I_3 \dots - Z_{3n}I_n &= E_3 \\ -Z_{1n}I_n - Z_{2n}I_2 - Z_{3n}I_3 \dots + Z_{nn}I_n &= E_n \end{aligned}\right\} \tag{53}$$

which can be solved either by successive substitutions or by the method of determinants. If the number of equations is small the solution by substitution usually results in less labor. If there are many meshes the method of determinants often results in a saving of time. These methods for solving algebraic equations in complex numbers are described in the section on mathematics.

Resonance. It has been pointed out that the reactance of a circuit is positive when it contains inductances only and negative when it contains capacitances only. The reactance under both conditions is a function of frequency. It is apparent therefore that the net reactance of a circuit containing both inductance and capacitance may vary through wide limits as the frequency of the current varies over a given range. If the resistance is small the current in a circuit for a given magnitude of potential difference may be excessive at a particular frequency of the applied voltage. This phenomenon is known as *resonance.* More generally, resonance exists between one coordinate of a system, which is executing oscillations, and a periodic agency, which maintains the oscillations, when a small amplitude of the periodic agency produces in the system a relatively large amplitude of oscillation.

Amplitude resonance exists when the resonance is such that any change in the period of the emf without changing its amplitude produces a decrease in the amplitude of the current.

Natural resonance exists when the period of the applied emf is the same as the natural period of oscillation of the system.

Phase resonance exists when the angular phase difference between the fundamental components of the current and the emf is 90°.

The two simplest cases of resonance, called parallel resonance and series resonance, occur when a capacitor and an inductor both having negligible resistance are connected in parallel and have impressed on them an emf having a frequency

$$f = \frac{1}{2\pi\sqrt{LC}}$$

With parallel resonance the current is zero; with series resonance the current is infinite. These are limiting values applicable when the resistances are zero.

TRANSIENTS

24. GENERAL EQUATIONS

Definition of a Transient State. The currents in an electric circuit are said to be in a transient state in the interval of time between a change in the emf or impedance conditions in the circuit and the establishment of a steady state (q.v.). During this interval, currents flow which usually decrease rapidly with time. Some transient currents persist for a comparatively long period of time.

Natural Periodicities, Characteristic Determinant. In Art. 23 it was stated that steady-state exponential currents of a given periodicity could exist in a stable linear network only when there was impressed on the network an emf having the given periodicity. This is not true of transient currents. If there are no emf's whatever applied to a network having n meshes the exponential impedance equations are

$$\left.\begin{aligned} Z_{11}(\beta)\,I_1 - Z_{12}(\beta)I_2 - \ldots - Z_{1n}(\beta)I_n &= 0 \\ -Z_{21}(\beta)\,I_1 + Z_{22}(\beta)I_2 - \ldots - Z_{2n}(\beta)I_n &= 0 \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots & \\ \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots & \\ -Z_{n1}(\beta)I_1 - Z_{n2}(\beta)I_2 - \ldots + Z_{nn}(\beta)I_n &= 0 \end{aligned}\right\} \tag{1}$$

The condition that this set of homogeneous equations be consistent (i.e., that the currents are not all zero) is that the determinant formed of the coefficients be zero. The values of β which make the determinant zero are the periodicities of current which can exist in the network when no emf of a corresponding periodicity is impressed on the network.

These values of β are called the *natural periodicities* of the network. The determinant coefficient will be called the *characteristic determinant* of the network and will be written $D(\beta)$. This determinant is a polynomial in β because each of the Z's is a polynomial in β. Since each of the Z's may be of second degree, the characteristic determinant may be a polynomial of the $2n$th degree in β giving rise to $2n$ natural periodicities.

Nature of the Roots of the Characteristic Determinant. The roots of the characteristic determinant are usually real or complex; in some cases (for example, in an idealized network having no resistances) they may be pure imaginaries.

Since all the coefficients of the polynomial $D(\beta)$ are real numbers the imaginary or complex roots always occur in conjugate pairs. Thus if a given root has the value

$$\beta_k = \alpha_k + j\omega_k \tag{2}$$

one of the other roots will have the value

$$\beta_k' = \alpha_k - j\omega_k \tag{2a}$$

The roots may all have different values or some may be repeated. With repeated roots the form of the transient currents is different from that occurring in networks for which the characteristic determinant has no repeated roots.

The various natural periodicities will be denoted by

$$\beta_1, \beta_2, \ldots, \beta_k, \ldots, \beta_M$$

where M is the total number of different values of the roots. If a given root, say the kth, is repeated r_k times, then the factor $(\beta - \beta_k)$ occurs $r_k + 1$ times in the expression for $D(\beta)$, hence the following equation expresses the characteristic determinant as a function of the roots:

$$D(\beta) = (\beta - \beta_1)^{r_1+1}(\beta - \beta_2)^{r_2+1}\ldots(\beta - \beta_k)^{r_k+1}\ldots(\beta - \beta_M)^{r_M+1} \qquad (3)$$

Form of Transient Current, No Repeated Roots. When all the roots of the characteristic determinant are different, the current in, say, the w mesh will have a component with periodicity β_1 and initial value I_{w1}, a component with periodicity β_2 and initial value I_{w2}, etc. The current in this mesh can therefore be written

$$i_w = \sum_{k=1}^{M} I_{wk}\,\epsilon^{\beta_k t} \qquad (4)$$

The initial values of I_{wk} depend upon the conditions which existed in the network at $t = 0$, as explained in the last paragraphs.

If the conjugate pairs of complex or pure imaginary roots be added together, sine or cosine terms result. The current in the w mesh can then be written

$$i_w = \sum_{k=1}^{s} I_{wk}\,\epsilon^{\alpha_k t} + \sum_{k=s+1}^{M} I_{wk}\,\epsilon^{\alpha_k t}\cos(\omega_k t + \theta_k) \qquad (4a$$

in which s is the number of real roots and $M - s$ is the number of roots which are complex or pure imaginary.

Form of Transient Current, Repeated Roots. It can be shown that the component of transient current in the w mesh having the periodicity β_k, where β_k is a repeated root of the characteristic determinant, is

$$i_{wk} = I_{wk0}\,\epsilon^{\beta_k t} + I_{wk1}\,t\epsilon^{\beta_k t} + \ldots + I_{wkr_k}\,t^{r_k}\epsilon^{\beta_k t}$$

where r_k is the number of times the root is repeated. Hence in general

$$i_{wk} = \sum_{k=1}^{M}\sum_{g=0}^{r_k} I_{wkg}\,t^{g}\epsilon^{\beta_k t} \qquad (5)$$

The initial values I_{wkg} depend upon the conditions which existed in the network at $t = 0$.

Boundary Conditions. The character of the time functions representing the transient currents were stated above, but the initial values of the exponential currents were undetermined. The number of these initial values to be determined is always equal to the degree of the characteristic determinant $D(\beta)$ multiplied by the number of mesh currents in the impedance equations. This number can never exceed $2n^2$ where n is the number of mesh currents. The set of equations 1 provides a means of reducing this number; if in each equation the term involving a given current, say I_k, be transferred to the right-hand side and the equations be considered as non-homogeneous in $(n-1)$ currents, then it is possible to find each of the $(n-1)$ currents in terms of I_k. This results in a reduction in the total number of undetermined initial values to the degree of the determinant $D(\beta)$. Hence as many additional conditions as the degree of the characteristic determinant must be specified in order to make the statement of the problem complete. *Mathematically* the additional statements required are called *boundary conditions* and may take various forms. *Physically* these additional statements represent a specification of the condition of the electrical network at the instant of occurrence of the change which initiated the transient under consideration. Practically it is convenient to specify the various charges and currents existing in the network at $t = 0$. Special circumstances arise in which the number of charges and currents in the network may exceed the degree of $D(\beta)$; a number equal to the degree of $D(\beta)$ only may then be specified, the others being determined by the impedance equations.

A particular set of boundary conditions which is of importance is that set which specifies an electrical system initially without energy. They are called the *equilibrium conditions*, and a system for which they are applicable is said to be in equilibrium.

Indicial Admittance. The current response in a mesh of an electrical network initially in equilibrium to a unit emf applied to a pair of terminals in the given mesh is called the *input indicial admittance* of the network at those terminals. The current response in another mesh of the network under the same conditions is called the *transfer indicial admittance* from the mesh in which the emf is inserted to the mesh in which the current is considered. The indicial admittance consists of a sustained or steady-state term plus a transient term, the boundary conditions for the transient term being those of equilibrium. The indicial admittance has the important property that an expression for the total current (including both sustained and transient currents) which flows in a network due to the application of an emf of any type whatever can be found when the indicial admittance is known. This expression, known as the Duhamel integral, is

$$i_k(t) = \frac{d}{dt}\int_0^t h_{jk}(t-\lambda)\, E_j(\lambda)d\lambda \qquad (6)$$

in which $i_k(t)$ = the total current in the kth mesh.

$E_j(t)$ = the emf impressed in the jth mesh.

$h_{jk}(t)$ = the transfer indicial admittance from the jth mesh to the kth mesh.

λ = a variable of integration.

Various means for obtaining the indicial admittance have been devised, some of which are:

(*a*) *Direct solution* of the differential equations for the network when the emf is put equal to unity and equilibrium boundary conditions are imposed. This method is extremely cumbersome in complicated cases, and indeed reduces to method (*b*).

(*b*) *Partial fraction expansion* method, so called because the method of its derivation.

$$h_{ij}(t) = \sum_{k=1}^{M}\sum_{g=0}^{r_k}\frac{B_{kg}^{ij}}{g!}t^g\,\epsilon^{\beta_k t} \qquad (7)$$

in which the constants B_{kg}^{ij} are the constants in the partial fraction expansion

$$\frac{A_{ij}(\beta)}{D(\beta)} = \sum_{k=1}^{M}\sum_{g=0}^{r_k}\frac{B_{kg}^{ij}}{(\beta-\beta_k)^{g+1}} \qquad (7a)$$

where $A_{ij}(\beta)$ is the cofactor corresponding to the ij element of the determinant $D(\beta)$. In equations 7 and 7*a*

M = the number of different valued roots.

r_k = the number of times the kth root is repeated.

k, g = variables of summation.

(*c*) Solution of the *infinite integral equation*

$$\frac{1}{\beta Z(\beta)} = \int_0^\infty \epsilon^{-\beta t}\, h(t)\, dt \qquad (8)$$

in which $Z(\beta)$ is the exponential impedance for any periodicity β.

(*d*) The *operational method* of obtaining a power series for $h(t)$; if $\frac{1}{Z(\beta)}$ admits of an asymptotic expansion of the form

$$\frac{1}{Z(\beta)} = \sum_{n=0}^{\infty}\frac{a_n}{\beta^n} \qquad (9)$$

then the indicial admittance is given by

$$h(t) = \sum_{n=0}^{\infty}\frac{a_n t^n}{n!} \qquad (9a)$$

in which the coefficients a_n have the same values as in equation 9.

25. CIRCUIT STABILITY

Stable and Unstable Systems. Let a given dynamical system be supposed to be moving under the action of applied forces in some known manner described by a set of differential equations. If any small disturbing influences be applied to the system it may deviate only slightly from the previous condition of motion or it may depart from it further and further. If the deviation is slight the system is said to be *dynamically stable*, otherwise the system is *dynamically unstable*. It is clear that a given motion might be stable for one type of disturbance and unstable for another type. The disturbance will be supposed to be general in nature so that the motion will be considered stable only if it is stable for all kinds of disturbances.

An electrical network in which currents flow under the action of applied emf's may be stable or unstable in the sense defined above depending upon the character of the parameters of the network.

Two over-compounded direct-current generators operating in parallel without an equalizer connection have the property that a disturbing influence which increases the emf of one machine slightly results ultimately in a considerable increase in emf and an unbalance of load which renders the system inoperative. Such a system is said to be unstable. Other examples of electrical systems which may be unstable are: electric arcs, vacuum-tube amplifiers or oscillators, alternators in parallel, discharges in gas-filled tubes, etc.

In electric power systems protective equipment, which is designed to maintain continuous operation, is always provided. When such equipment is actuated as the result of some abnormal condition, the system is electrically different before and after such device has performed its function. The differential equations are therefore changed, and a system which might have been unstable is often transformed into one in which no current or emf departs further and further from its normal value. The term stable is usually applied to a system which *with its protective equipment* will not be rendered inoperative by any small disturbance. For other special meanings ascribed to stability and not consistent with *dynamical stability* see Electric Circuits and Electric Lines in Pender's Handbook for Electrical Engineers.

Method of Small Oscillations. Let the variables in the system of differential equations describing a dynamical system be $q_1, q_2, q_3, \ldots q_n$, and let the disturbances applied to the system be such that these variables are replaced by

$$(q_1 + S_1), (q_2 + S_2), \ldots, (q_n + S_n)$$

The quantities $S_1, S_2, \ldots, S_n$ are initially small since the disturbance was assumed to be small. A quantity is said to be small when it is in absolute value less than some quantity λ which is such that its square may be neglected.

If, after the disturbance, $S_1, S_2, \ldots, S_n$ always remain small, the motion is stable, otherwise unstable. The investigation of the stability of a given motion by a study of the behavior of the S's has proved extremely fruitful. The method is known as the *method of small oscillations.*

Criteria for Stability. An inspection of the time functions representing the transient currents in an electrical system indicates that the given system will be unstable if the characteristic determinant has:

(*a*) Real roots which are positive.
(*b*) Complex roots having positive real parts.
(*c*) Pure imaginary roots which are repeated.

Certain criteria for the existence of any of the above were deduced by Routh and later developed independently and in a somewhat different form by Hurwitz. These criteria are somewhat difficult to apply in practice and are applicable only to systems described by differential equations having constant coefficients. They are useful, however, in electrical systems which are approximately linear and are valuable in various other dynamical systems, such as the dynamical system of airplanes.

Test Functions of Routh and Hurwitz. Let the characteristic determinant be written in the form

$$D(\beta) = a_0\beta^m + a_1\beta^{m-1} + a_2\beta^{m-2} + \ldots + a_{m-1}\beta + a_m$$

then the conditions that there be no complex root having a positive real part or a real root which is positive are:

1. A necessary but not sufficient condition is that all the a's have the same sign.
2. A necessary and sufficient condition is that the following test functions all are positive when the equation $D(\beta) = 0$ is put in such form that a_0 is positive.

$$T_1 = a_1 \tag{10}$$

$$T_2 = \begin{vmatrix} a_1 & a_0 \\ a_3 & a_2 \end{vmatrix} \tag{10a}$$

$$T_3 = \begin{vmatrix} a_1 & a_0 & 0 \\ a_3 & a_2 & a_1 \\ a_5 & a_4 & a_3 \end{vmatrix} \tag{10b}$$

$$T_4 = \begin{vmatrix} a_1 & a_0 & 0 & 0 \\ a_3 & a_2 & a_1 & a_0 \\ a_5 & a_4 & a_3 & a_2 \\ a_7 & a_6 & a_5 & a_4 \end{vmatrix} \tag{10c}$$

$$T_5 = \begin{vmatrix} a_1 & a_0 & 0 & 0 & 0 \\ a_3 & a_2 & a_1 & a_0 & 0 \\ a_5 & a_4 & a_3 & a_2 & a_1 \\ a_7 & a_6 & a_5 & a_4 & a_3 \\ a_9 & a_8 & a_7 & a_6 & a_5 \end{vmatrix} \tag{10d}$$

and so on, until a determinant which is identically zero is obtained. The total number of test functions required is in general equal to the degree of $D(\beta)$. A set of conditions which are often encountered in electric circuits can be shown to be sufficient but not necessary for the system to be stable. These conditions are:

(*a*) All resistances, inductances, and capacitances are positive.

(*b*) The total resistance in any mesh is greater than the sum of the mutual resistances of the given mesh with respect to the various other meshes.

(*c*) The total capacitance in any mesh is greater than the sum of the mutual capacitances of the given mesh with respect to the various other meshes.

(*d*) The product of the self-inductances in any two meshes is greater than the square of the mutual inductance between the two meshes.

26. EXAMPLES OF SIMPLE TRANSIENTS

Transient with Resistance and Inductance. The establishment of a direct current in a coil having resistance r and inductance L due to the action of a constant emf E is of practical importance. Let the current in the coil at the instant of impressing the emf be I_0. Then the current t seconds after closing the switch is

$$i = \frac{E}{r} + \left(I_0 - \frac{E}{r}\right)\epsilon^{-(r/L)t} \tag{11}$$

In equation 11 the term E/r is the sustained current and $\left(I_0 - \frac{E}{r}\right)\epsilon^{-(r/L)t}$ is the transient current. The ratio L/r is a measure of the time required for the transient current to become negligible; this ratio is often called the *time constant* of the circuit.

If the current is initially zero the conditions are those of equilibrium, and if E is put equal to unity equation 11 becomes the indicial admittance.

$$h(t) = \frac{1}{r}(1 - \epsilon^{-(r/L)t}) \tag{12}$$

The short circuit current of a coil which has resistance and inductance only and in which a current I_0 is flowing is given by equation 11 when E is put equal to zero:

$$i = I_0\epsilon^{-(r/L)t} \tag{13}$$

Transient with Resistance and Capacitance. The charging of a condenser of capacitance C through a resistor of resistance r due to the action of a constant emf E will be considered here. It is assumed that the conductance of the condenser and the inductance of the resistor are zero. The condenser is assumed to have a charge q_0 at the instant of closing the switch. The current t seconds after the switch is closed is

$$i = \left(\frac{E}{r} - \frac{q_0}{rC}\right)\epsilon^{-(1/rC)t} \tag{14}$$

The charge on the condenser at the same instant is

$$q = CE + (q_0 - CE)\epsilon^{-(1/rC)t} \tag{15}$$

The time constant of this circuit is rC, this product being a measure of the time required for the transient current to become negligible.

If the conditions of equilibrium are imposed, i.e., $q_0 = 0$, and if E is put equal to unity, equation 14 becomes the indicial admittance.

$$h(t) = \frac{1}{r}\epsilon^{-(1/rC)t} \tag{16}$$

The discharge of a condenser, initially charged to a potential $V_0 = q_0/C$, through a resistor is given by equation 14 when E is put equal to zero. The current is

$$i = -\frac{V_0}{r}\epsilon^{-(1/rC)t} \tag{17}$$

The potential on the condenser at any instant is equal to the negative of the ri drop.

$$V = V_0\,\epsilon^{-(1/rC)t} \tag{18}$$

Transient with Resistance, Inductance and Capacitance in Series. If a single series circuit containing parameters r, L, and C is closed upon an emf E at the instant $t = 0$, and if the charge on the condenser is q_0 and the current through the circuit is I_0 at $t = 0$, the current t seconds after the switch is closed is

$$i = I_0\,\epsilon^{-\alpha t}\cos\omega t - \left[\frac{\alpha}{\omega}I_0 + \frac{\alpha^2 + \omega^2}{\omega}(q_0 - CE)\right]\epsilon^{-\alpha t}\sin\omega t \tag{19}$$

and the charge on the condenser is

$$q = CE + \frac{I_0 + \alpha(q_0 - CE)}{\omega} \epsilon^{-\alpha t} \sin\omega t + (q_0 - CE)\epsilon^{-\alpha t} \cos \omega t \tag{19a}$$

in which

$$\alpha = \frac{r}{2L} \tag{19b}$$

$$\omega = \sqrt{\frac{1}{LC} - \frac{r^2}{4L^2}} \tag{19c}$$

If the conditions of equilibrium are imposed ($I_0 = 0$, $q_0 = 0$) and E is put equal to unity in equation 19 the indicial admittance is obtained

$$h(t) = \frac{1}{\omega L} \epsilon^{-\alpha t} \sin \omega t \tag{20}$$

The term $\epsilon^{-\alpha t}$ appearing in equations 19 and 20 produces a decrease with time of the function which it multiplies; it is called the *damping factor* of the current or charge in which it appears. The constant ω is the natural angular velocity of the network. This constant can have a real or imaginary value depending upon the relative values of $\frac{1}{LC}$ and $\frac{r^2}{4L^2}$. When the resistance is extremely small α may be negligible in comparison with $\frac{1}{LC}$ and ω may be taken as $\frac{1}{\sqrt{LC}}$. This value of ω is called the undamped angular velocity of the circuit. If the resistance is increased, the amount of damping may be increased to such an extent that ω is zero. This condition is known as *critical* damping and is the borderline between oscillatory currents and non-oscillatory currents. If the resistance is increased further, over-damping results, ω becomes imaginary, and the current and charge are represented by hyperbolic functions instead of by trigonometric functions of time.

CONDUCTION OF ELECTRICITY IN SOLIDS AND FLUIDS

By Carl C. Chambers

27. CONDUCTION IN SOLIDS

The Solid State. The solid state is characterized by the possession of a structure. That is, each atom or molecule in the solid state has permanent neighbors. Most of the physical properties of solids depend markedly upon the atomic arrangement in the solid. Therefore any satisfactory discussion of these physical properties must be based upon the structure of the solid state. By far the major part of solid matter is crystalline, where, by crystalline, we mean built up out of some fundamental unit which repeats itself identically at regular intervals in three dimensions.

The crystalline form of the solid state is divided into three classes: (1) the ionic form, which includes most inorganic salts and minerals, (2) the molecular form, which includes the organic crystals and a few inorganic substances, and (3) metals.

In the ionic form of crystal structure, the crystal lattice points are occupied by the separate ions of the salt. For instance, in NaCl the Na ions are at certain points in the lattice and the Cl ions are at other points to form the rocksalt crystal. In this class are included many salts involving radicals such as $SO_4^{=}$, ClO_3^-, $CO_3^{=}$, and NO_3^-. In many of the complex minerals, such as silicates, the structure becomes very complicated, the unit cell often containing several hundred atoms.

In the molecular form of crystal structure, the atoms are held together within the molecule by direct valence bonds (homopolar), and the molecules are held together by the relatively weaker bonds (van der Waals forces, etc.) to form the crystals. The low melting point of these solids is due directly to the fact that the crystal bonds are comparatively weak.

Metals differ from this last group by being made up of metallic atoms occupying the lattice points. These atoms are packed very close together, being held together by electrostatic fields due to the charges on the atoms arising from the loss of the valence electrons, and the concentration of these electrons between the positive ions. These electrons easily move about within the crystal from atom to atom and are to be identified with the so-called *free electrons*. In general, the true metals are characterized by simple unit crystal cells. Manganese is an exception to this generalization, having in one form 58 atoms in the unit cell. So far as Mn is concerned it should be classed in crystal structure with the intermetallic compounds (alloys) since it appears as four different kinds of atoms corresponding to manganese in four different states. In general, the intermetallic compounds are more complicated than the true metals. These compounds always have fewer free electrons than there are valence electrons in the separate atoms.

The structures of the borderline metals such as Se, Te, Sb, Bi are quite different from those of the true metals. In these substances the atoms are bound to one another in much the same way that molecules are held together. One atom can be considered as replacing a missing electron in the valence energy level of each of its nearest neighbors.

There are but few non-crystalline solids. The various glasses now appear to be the only definite example of an amorphous solid. The atoms in these solids are held together in much the same way as in crystalline forms of the same material except that the bonding is so flexible that the bonding conditions can be satisfied without building up a regularly repeated structure. With respect to conduction of electricity, non-crystalline substances are best treated as liquids.

Theory of Conduction in Crystalline Solids. The general scheme which is used in describing the behavior of electrons in a crystal is that which is sometimes known as the "method of copies." Each free electron is considered to move in the same field of force without interaction with the other electrons. This omission of any mutual interaction between the electrons is partially compensated for by supposing that the field in which an electron moves is that due to the ions at the lattice points, modified by a contribution equal to the average field produced by all the other electrons. When the allowable quantum states of energy of an electron in such a field have been determined, the electrons are supposed to be assigned to the various states in a manner governed by the temperature and in such a way that the Pauli exclusion principle (no more than one electron occupying a given quantum state) is satisfied.

Because of the periodic nature of the field in a crystal, certain energy levels must be excluded, so that there are very definite and finite energy states allowable for the free electrons. According to wave mechanical theory in its simplest form, an electron moving in a certain direction with a velocity v has associated with it a set of waves moving in the same direction and having a wave length $\lambda = \frac{h}{mv}$, where h is Planck's constant and m is the mass of the electron. The motion of an electron in a field of force can be studied by following the motion of a system of de Broglie waves; in particular, the scattering of the waves in a field of force, analogous to the scattering of light in a non-homogeneous medium, is interpreted as the probability that the electron will travel in the direction of the various scattered waves. Thus, if the wave-length λ is such that it satisfies a Bragg relation (see x-rays) with respect to the field of force (the periodic potential due to the crystal structure), then the waves are so greatly scattered or reflected that they are really not propagated through the crystal at all. Thus an electron with a momentum $p = mv = h/\lambda$, where λ satisfies a Bragg relation in every direction, would not move about within the crystal. In general, it is found that these excluded energies form bands of finite width in the energy scale separated by bands of allowed energies.

The difference between insulators and conductors is based upon the energy levels of these bands of prohibited states and on the number of electrons available. In an insulator all the energy levels in an allowed band are filled while no electrons are in the next higher allowed band. Thus no electron can have its energy increased unless the increase is of sufficient magnitude to raise the electron energy above that of the forbidden energy band directly above the highest filled band. The application of an emf to the material cannot raise the electron energy enough to make such a jump except for very narrow bands. In a true metal, because of the small size of the unit cell, the wave length λ is very small. The forbidden bands are therefore at such high energy levels that the electrons do not fill the energy states in the lowest energy band so that all the electrons can be considered as free. In alloys which are good conductors even though the unit cell is large, the conductivity is explained on the basis that the forbidden bands are so narrow as to be essentially non-existent. The presence of these bands explains the decrease in conductivity due to impurities in metals as well as the lower conductivity of alloys. In the so-called semi-conductors (q.v.) absorbed radiation (light) or heat causes electrons to jump over the forbidden band forming free electrons. In addition, after these electrons have left the lower energy band, the remaining electrons have a certain freedom of motion.

On the basis of the theory, heat affects the conductivity by means of two processes. First, it tends to increase the energy level of the electrons which in insulators and semiconductors increases the number of electrons in the unoccupied bands. Second, it causes an oscillation of the atoms about the lattice points, causing a departure from the periodic form of the field. This perturbation of the periodic structure splits the forbidden bands and tends to introduce new forbidden bands. Both these effects tend to decrease the resistance in insulators and semi-conductors where the forbidden bands are already of major importance. In metals the first has a negligible effect while the introduction of forbidden bands due to the second causes the resistance to increase with temperature.

Quantitative calculations using this theory are very complex, but approximations applicable to metals, except at very low temperatures, have made the calculation of conduction in metals reasonable.

Conduction in Metals. Metals, as discussed above, are characterized by the fact that the free electrons can exist in practically any energy state from zero energy up to an energy well above that ever reached by the electrons. Because of the finite volume of the metal the waves representing the electrons must have certain wave lengths in order to set up standing waves in the metal (if they were not standing waves the average resultant at any point would be zero). Thus the electron energies cannot take on a continuous set of values but can exist only in those energy states satisfying this condition. The statistical distribution in energy of particles satisfying this condition as well as the Pauli exclusion principle is called the Fermi-Dirac statistics.

If the periodic variation of the field within the crystal is neglected, the resulting constant potential is such that, considering this potential as zero, the piece of metal is conceived as a region populated with electrons obeying the Fermi-Dirac statistics and surrounded by a potential wall, the barrier. This barrier prevents the electrons from escaping from the metal. The Fermi-Dirac distribution function is

$$f = \frac{2}{h^3}\frac{1}{e^{(\epsilon - W_i)/kT} + 1} \tag{1}$$

$$W_i = \frac{h^2}{2m}\left(\frac{3n}{8\pi}\right)^{2/3}$$

where e is napierian base, ϵ is the energy of the electron, k is Boltzmann's constant, h is Planck's constant, T is the absolute temperature, m is the mass of the electron, and n is the number of electrons per unit volume. When T is zero, f is either zero or $2/h^3$, depending on whether ϵ is greater or less than W_i. Thus W_i is the maximum energy level occupied by an electron when all the lower energy levels are filled. If v_m is the velocity of the electron in the maximum energy level, $\frac{1}{2} m v_m{}^2 = W_i$ or

$$= \frac{h}{m}\left(\frac{3n}{8\pi}\right)^{1/3}$$

The specific heat is obtained from any distribution law by integrating to find the total energy and differentiating this energy with respect to T. On the basis of a Maxwellian gas distribution, as assumed by Drude in the old theory of the electron gas in metals, the specific heat was $3/2\,k$ which for n, of such a value to give reasonable conductance, was greater than the measured total specific heat of the metal for most temperatures. But the specific heat of the atoms alone agreed with the experimental specific heat. This was the notorious difficulty with the older theory. The new theory as presented here avoids this, since the specific heat of the electron gas is given by

$$\frac{2\pi m}{3}\frac{(2\pi k)^2}{h^2}\left(\frac{3n}{8\pi}\right)^{1/3} T$$

a value which is negligible compared with the specific heat of the atoms alone for all reasonable values of T.

In order to find the conductivity of the metal, the change in the distribution function f due to the presence of an electric field must be determined. This was originally done by Lorentz for the Maxwellian distribution in connection with the Drude theory. This method has been carried over into the new theory.

The distribution function $f(v)$ is isotropic, a function of v in magnitude only. Taking the electric field in the x direction, Lorentz postulated that the new distribution function could be approximated by

$$f = f_0(v) + v_x g(v) \tag{3}$$

where $f_0(v)$ is the distribution function without an applied field and $g(v)$ is a function to be determined, depending upon the electric field, by the conditions that the total number of free electrons remain the same and that f should remain constant in time. The postulated form (3) is clearly only an approximation argued to be valid since (3) differs only slightly from $f_0(v)$.

Since the energy of the electrons is increased because of the application of the electric field, there will be a distortion of the standing wave pattern within the metal. This causes definite permitted energy changes in the electron. Since these are difficult if not impossible to calculate, the classical idea of mean free path is borrowed to avoid this difficulty. Using the above conditions $g(v)$ becomes

$$g(v) = \frac{l}{v^2}\frac{eE}{m}\frac{df_0}{dv} \tag{4}$$

where e is the charge on an electron, l is the mean free path, and E is the electric field intensity.

The current density is given by the number of electrons times their velocity in the direction of the current times the charge on an electron, or

$$J = e\int_{-\infty}^{\infty} v_x f dw = e\int_{-\infty}^{\infty} v_x^2\, g(v) dw \tag{5}$$

where the single integral sign replaces a triple integral and $dw = dv_x\, dv_y\, dv_z$.

Substituting from (4)

$$J = \frac{le^2E}{m}\int_{-\infty}^{\infty} \frac{v_x^2}{v^2}\frac{df_0(v)}{dv}\, dw$$

carrying out the integration

$$J = \frac{8\pi}{3}\frac{e^2l}{h}\left(\frac{3n}{8\pi}\right)^{2/3} E$$

or the conductivity is

$$\sigma = \frac{8\pi}{3}\frac{e^2l}{h}\left(\frac{3n}{8\pi}\right)^{2/3} \tag{6}$$

In an analogous manner the heat current (rate of flow of heat) is given by

$$W = \frac{1}{2}m\int_{-\infty}^{\infty} v_x^2v^2 g(v) du$$

$g(v)$ is here calculated with the condition that J the electric current is zero. This condition results in the presence of both an electric field and a rate of change of T in the direction of the field. (W_i in equation 1 is a first approximation for the calculation of $g(v)$. Here it is necessary to use the second approximation in order that W shall differ from zero.) Calculation of $g(v)$ and integration gives for the heat current

$$W = \frac{8\pi^3}{9}\frac{lk^2T}{h}\left(\frac{3n}{8\pi}\right)^{2/3}\left(\frac{dT}{dx}\right) \tag{7}$$

The coefficient of $\frac{dT}{dx}$ is the *thermal conductivity*, usually denoted by κ.

An important ratio, the Wiedermann-Franz ratio, is the ratio of the heat conductivity to the electric conductivity

$$\frac{\kappa}{\sigma} = \frac{1}{3}\pi^2\left(\frac{k}{e}\right)^2 T$$

$$= 7.1 \times 10^{-11} \qquad \text{at } T = 291^\circ\text{ K } (18^\circ\text{ C.})$$

This value agrees remarkably with the measured value for many metals.

Thermionic Emission. A piece of metal has been pictured as a region of depressed potential in space, occupied by an electron gas obeying the distribution law given by equation 1. If the value of this depression of the potential is W_a in energy units, only those electrons with a velocity component perpendicular to the barrier corresponding to a kinetic energy greater than W_a can get over the wall. If the barrier is taken in the yz plane then those electrons with a velocity such that $^1/_2 m\, v_x^2 > W_a$ can get out of the metal. Let $^1/_2\, m\, v_0^2 = W_a$; then the current due to all of the electrons escaping (the saturation thermionic current) is given by

$$i = 2e\left(\frac{m}{h}\right)^3\int_{v_x=v_0}^{\infty}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{v_x dv_y dv_z dv_x}{e^{(\epsilon - W_i)/kT} + 1}$$

Integrating, the current becomes

$$i = \frac{4\pi em}{h^3}(kT)^2e^{-(W_a - W_i)/kT} \tag{8}$$

provided that W_a is considerably greater than W_i. Experimentally $W_a - W_i$ is the so-called work function which varies from 1 to 6 equivalent volts. If there are as many free electrons as there are atoms in the metal, W_i is about 6 volts. The experiments of Davisson and Germer indicate that W_i is such that there are twice as many electrons as there are atoms.

The constant A, when equation 8 is written

$$i = A\,T^2 e^{-(W_a - W_i)/kT} \tag{8a}$$

is calculated on the basis of this theory to be 120.4 amperes per square centimeter per degree squared. The classical thermodynamic theory predicts half this value or 60.2. Experimentally several metals indicate that 60.2 is right while some are very much less and some are very much more, a few even greater than 120.4. In order to explain this variation in A, Fowler and Nordheim have postulated that the metal is not only a depression of potential but that it is also surrounded on its surface by a wall. That is, W_a is greater than W_0, the value of potential outside of the metal. They have shown that even though the energy of the electron is less than W_a, there is a certain probability that it would get out of the metal, and likewise even though the energy of the electron is greater than W_a there is a probability that it would not get out of the metal. Thus in the determination of equation 8 the integration must extend over all energies and the selection must be obtained by means of a probability function $D(\epsilon)$ times the integrand.

Photoelectric Effect. Photoelectric effect is explained in a manner similar to thermionic emission except that here the emitted electrons gain the energy necessary to traverse the barrier not by heat but from the absorption of a photon of light energy. The energy of each photon of frequency ν is given by $h\nu$ (see Photons). Thus any electron within the metal which absorbed a photon of frequency ν would have an energy $\epsilon + h\nu$ where ϵ was the energy of the electron before absorbing the photon. If the component of the velocity of this electron perpendicular to the barrier corresponds to an energy greater than W_a, the electron will escape. For cold metals the maximum value of ϵ is W_i. Thus the minimum frequency which will cause an electron to escape, the *threshold frequency*, $h\nu_{\text{min}}$, is given by

$$W_a = W_i + h\nu_{\text{min}}$$

In order to calculate the current for any given light it is necessary to know how and where the light is absorbed by the electrons as well as the probability that an electron having absorbed a photon will retain that energy until it gets to the barrier. This subject is too complex to treat here.

Photoconductivity. Photoconductivity is the increase in the conductivity of a semiconductor due to the incident light. This phenomenon is attributed to the absorption of photons by electrons in one band causing them to jump over the prohibited band into a free band in which they can freely move. Very little quantitative theory has been developed for photoconductivity. Experimentally, threshold frequencies have been determined indicating a width for the prohibited bands.

Photovoltaic Effect. The photovoltaic effect is the development of an emf due to incident light at the boundary between certain semi-conductors and metals. Although this phenomenon is probably in some manner connected with photoconductivity, no satisfactory quantitative or even qualitative theory has been presented.

Effect of Temperature on the Resistance of Metals. Equation 6 does not contain the temperature explicitly; however, both l the mean free path and n the density of the free electrons may vary with temperature. Measurements of the resistance show that it does vary with temperature. The resistance of a metal for small ranges can be written

$$r = r_0 + \alpha T$$

where r_0 and α are independent of T, although α is not truly constant over wide ranges. In general, α increases with temperature, large changes being observed in the neighborhood of melting points. Lindeck finds that $r\alpha$ is constant for metals.

Roughly the resistance decreases as the absolute temperature or a little more rapidly than the temperature. At temperatures in the neighborhood of 100° K and 200° K the curves of resistance versus temperature point toward a vanishing resistance at some temperature above absolute zero. On continuing the curves below 100° K, it is found that for most metals they flatten out and approach some small finite resistance at absolute zero. With some metals, however, the resistance curve begins to flatten out, but then at some low temperature it suddenly drops rapidly so that below this temperature the resistance is so low that a current set up in a coil would still be $^2/_3$ of its initial value after a lapse of 4 days. This phenomenon is called *superconductivity* or *supraconductivity*. It has been found that superconductivity is destroyed by too large currents. However, if after superconductivity is so destroyed a magnetic field is set up to counteract the field due to the current in the cold wire, the wire again becomes superconducting. No accepted theory of conduction in metals fits this phenomenon.

Conductivity of Alloys. Each component of an alloy contributes to the conductivity. If the alloy is purely a mechanical mixture its conductivity is an additive property of the volume percentages of the components. Isomorphous mixtures have a conductivity

always less than that calculated from the mixture law, as would be expected from the general theory of conduction in solids. The formation of a solid solution is accompanied by considerable increase in resistance which also increases with concentration. The presence of foreign substances always increases the resistance, for alloys of relatively high conductivity. The temperature coefficients of intermetallic compounds are about the same as for metals, but of solid solutions they are much less. The temperature coefficients are sometimes used to determine the constitution of alloys.

28. CONDUCTION IN FLUIDS

Conduction in Liquids. The most important liquids from the point of view of electrical conduction are salts in solution. The theory of Arrhenius is the outstanding theory of conduction in such liquids (*Trans. Farad. Soc.*, 15, 10, 1919). According to Arrhenius, salts in solution are extensively broken up into ions. In very dilute solutions the number of ion pairs, which increases with dilution, is in many cases practically equal to the number of molecules. With regard to the controlling factors in this ionization, there is no satisfactory theory. The current in such solutions is due to the actual migration of these ions. The question of the mobility of ions plays an important rôle but is too complex to treat here.

The conductivities of pure liquids are very small, so small in fact that the presence of impurities is believed by some investigators to be the explanation of what conductivity there is.

Conductivity in Gases. A normal gas is supposed to consist of molecules of the substance distributed at random throughout the gas having a density of distribution small compared with that of either the liquids or the solids. These molecules dart back and forth within the gas in a chaotic manner, colliding and rebounding from one another. The activity depends upon the temperature. The separation between these molecules except at the instant of a collision, is very great compared with the dimensions of the individual molecules. At distances as great as a few thousandths of a centimeter from one of these molecules the molecule can be considered an electrically neutral particle. An electric field in such a gas would therefore cause a negligible drift of these molecules.

If some of the molecules are broken up to form electrons and ions (ions are atoms or molecules which have lost or gained one or more electrons) an electric field would cause these particles to move through the gas. An electric field set up between two conducting electrodes, an anode and a cathode, the positive and negative electrodes respectively, causes the positive ions (ions which have lost electrons) to tend to move toward the cathode, and it causes the electrons and negative ions (ions which have gained electrons) to move toward the anode. These positive charges moving in one direction and negative charges moving in the opposite direction add to form a resultant positive current in the direction of motion of the positive charges.

These charged particles collide with the other molecules of the gas or with other charged particles. At each of these collisions one of several results may occur, depending upon the circumstances under which the collision occurs. A charged particle colliding with a molecule may rebound, continuing to be attracted as before; it may split the molecule into two separate ions; or it may knock an electron out of the molecule, resulting in a new ion and a new molecule, or in an electron, the original ion, and a molecular ion. A charged particle colliding with a charged particle of opposite sign may recombine to form a neutral particle. The probabilities for these various processes are very complicated in ordinary discharges.

Production of Electrons and Ions in Gases. A molecule is supposed to consist of the nuclei of the several atoms forming the molecule around which the atomic electrons or at least some of the atomic electrons rotate in orbits having associated with each orbit a definite energy. In order for an electron in one of these orbits to absorb energy it must move to one of the other orbits having a certain definite higher energy. Thus an electron in an atom or molecule can absorb energy only in very definite quantities called quantums of energy. The electrons in normal molecules are in very definite and particular orbits. When one or more of these electrons have jumped into orbits of higher energy levels, the molecule is said to be in an excited state. If still more energy is absorbed by these electrons they are freed entirely from the field of the molecule and become free electrons. Thus there is a definite minimum quantity of energy which will free an electron from an atom or molecule in the normal state, that is, ionize it. The minimum energy is usually called the *minimum ionizing potential* since it is usually measured in terms of the potential difference through which an electron must move in order to acquire this minimum ionizing energy.

The processes by means of which these electrons can be made to absorb this ionizing energy may be divided into six classes: (1) ionization by *electron impact*, (2) *photoionization*, (3) *cumulative ionization*, (4) ionization by *positive ion impact*, (5) ionization by *collisions of the second kind*, and (6) *thermal ionization*. There are several other processes of ionization, which are not known to occur often enough to warrant their discussion.

When electrons are emitted from the cathode in an electron tube by means of thermionic emission, photoelectric effect, or cold emission, they are accelerated toward the anode through the gas owing to the electric field. If before an electron collides with a molecule it moves through a potential greater than the minimum ionizing potential, there is a certain finite probability that when it does collide with a molecule that molecule will be ionized. This process of ionization is called ionization by electron impact.

If a photon of light having a frequency such that $h\nu$ is greater than the minimum ionizing potential collides with a molecule, there is a finite probability that the molecule will be ionized. For molecules of most gases the minimum ionizing potential is of such a value that only the shorter ultra-violet light and x-rays have a ν great enough to cause ionization. This process is called photo-ionization.

When an atomic electron absorbs only enough energy to raise the atom or molecule to an excited state, it could be ionized by means of another collision with a particle having less energy than the regular minimum ionizing potential. Thus it is possible for ionization to take place without even the minimum ionizing potential. This process of ionization is called cumulative ionization. Cumulative ionization does not occur as often as one would expect because an atom remains in the excited state for only a very small interval of time. The atom returns to its normal state, that is, having orbits of stable energy levels, radiating the resulting freed energy in the form of light. This is the process by which the light in a neon sign is produced.

Ionization by positive ion impact is similar to the process of ionization by electron impact, the ions being first formed by means of one of the other processes of ionization.

Ionization by collisions of the second kind is the name given to the collision, usually due to their normal Brownian motion, of two atoms or molecules one or both being in the excited state. One atom returns to the normal state, the liberated energy being used to ionize the other atom.

When the temperature of a gas reaches several thousand degrees, the Brownian motion of the molecules may become great enough so that they ionize upon collision. This form of ionization is supposed to occur in the sun and other hot stars. This process is called thermal ionization.

In any of these several ways, gases can be made conductors. In fact, it is practically impossible to have a gas in which there are no ions. In the earth's crust are many radioactive substances giving off radiation having the same characteristics as very hard x-rays. In addition to this, cosmic rays have been shown to be a major cause of residual ionization in gases.

Recombination of Ions. Ions, after having been produced in a gas, dart back and forth owing to their Brownian motion, the electric field, and their own attraction for one another of opposite charge. When two ions of opposite charge get near to each other they will tend to combine to form a neutral particle. This process of recombination goes on so fast in a gas that in order for there to be many ionized molecules, the production of ionization must go on at a correspondingly rapid rate. If the process for the production of ions is stopped, the gas soon loses all its ionization and is no longer in a conducting state.

The Effect of Pressure on the Conduction in Gases. In a gas the electrons, ions, and molecules move between collisions distances that are distributed at random from zero to a comparatively long distance. Very few go a long distance and very few go a short distance. The average distance that a particle moves without a collision is called the *mean free path*. The mean free path gives a simple quantitative measure of the distances that a particle moves between collisions. It is customary to calculate or measure the mean free path and then assume that all the particles move just that distance between collisions. On this assumption a rough estimate of the electric field intensity necessary for ionization by electron and ion impact can be made. If E is the electric field intensity in volts per centimeter, l is the mean free path in centimeters, and V is the minimum ionizing potential in volts then $E = V/l$ is the field intensity necessary to cause ionization. l is found to be practically inversely proportional to the pressure. At normal atmospheric pressure, air has a mean free path of approximately 10^{-5} cm. The values of other gases are of the same order of magnitude while V is of the order of 10 volts. Thus at pressures greater than a few millimeters of mercury the field must be large to produce ionization. At high vacuums (a small fraction of a millimeter) the free paths are so long that very little ionization takes place so that, unless electrons or ions come out of the electrodes, the gas (or vacuum) makes a good insulator.

Space-charge Effect. The velocity of drift of the ions through a gas is comparatively small. Therefore when even a small current flows the density of the charges of the ions is great enough to affect appreciably the electric field due to the electrodes. These charges in the space between the electrodes are called the *space charge.* Predictions of space charge are very complex so that the engineering of discharge tubes proceeds mostly by trial and error.

RADIATION, LIGHT, ACOUSTICS AND METEOROLOGY

THEORY OF RADIATION

By Ernst Weber

1. FUNDAMENTALS

Radiation is the transportation of energy through space; a detectable medium of transmission has not been discovered as yet. The assumption of an all-pervading ether as the carrier of radiated energy has proved unsatisfactory; it is, however, not impossible that ether or some other medium, not yet known, does exist.

The Nature of Radiation. At one time, all radiations were believed to be electromagnetic waves of various wavelengths (see Art. 3). At present the corpuscular nature of radiation must be conceded, as many phenomena can be explained only if the energy of radiation is associated with particles, like electrons or atoms (see Art. 4). The wave and corpuscular points of view are now being adopted alternatively as required by the occasion. The common basis of both aspects, the true nature of radiation, has not been established.

Radiation travels with a velocity v which depends on the medium through which it is propagated. Since the frequency ν of radiation is dependent only on the source, it does not vary with the medium. The ratio $v/\nu = \lambda$ is called the wavelength of radiation and depends like v on the medium.

Fundamental Definitions

Total Emissive Power is the time rate of total radiant energy emitted per unit area of the radiating body. It is measured in ergs per second per square centimeter or in watts per square centimeter.

Spectral Distribution of Emissive Power. The total emissive power of a body may be composed of radiations of many wavelengths. The graph of the emissive power as a function of wavelength is called the spectral distribution of emission. This spectrum is continuous if emissive power is a smooth continuous function of wavelength, or discontinuous if emission occurs only over small ranges of wavelengths. The discontinuous spectral distribution can have the character of lines, if a sharp selective radiation at certian wavelengths is evident, or of bands if many lines are so close that the discontinuity is apparent only on a very large scale of wavelength. The total emissive power is the integral of the spectral emissive power over all wavelengths from zero to infinity, and is, of course, identical with the area under the spectral distribution curve.

Monochromatic Emissive Power is the time rate of radiant energy emitted per unit area of a radiating body, at a particular wavelength. It can be determined most conveniently from the spectral distribution of emissive power as the ordinate at this particular wavelength.

Intensity of Radiation is the amount of power transmitted through unit area perpendicular to the direction of propagation of radiation.

Density of Radiation is the total radiant energy contained in unit volume. The radiation of the sun has an energy density at the earth's surface of approximately 4.3×10^{-5} erg per cu. cm.

Absorption. Radiation of incident intensity I_0 passing through matter of thickness δ loses intensity according to the exponential law

$$I = I_0 \varepsilon^{-\mu\delta} \qquad (1)$$

where μ is called the absorption coefficient and has the dimension $[\mu] = [L]^{-1}$. The extinction coefficient, or index of absorption, is defined as the numerical parameter

$$\kappa = \frac{\lambda}{2\pi}\mu \qquad (2)$$

where λ is the wavelength of radiation within the absorbing medium. Since the wavelength in vacuum is $\lambda_0 = n\lambda$, where n is the index of refraction, another coefficient can be defined as

$$k = n\kappa = \frac{\lambda_0}{2\pi}\mu \tag{2a}$$

The use of the various definitions is not standardized, and many confusing statements have resulted.

Absorptivity, A, is the ratio of absorbed energy to incident energy of radiation and is a pure numeric always less than unity. A perfectly absorbing body, $A = 1$, is usually referred to as a *black body.*

Scattering is a particular kind of absorption whereby the radiation is diffusely reflected in all directions by the interaction with the inner structure of the substance and thus reduced in intensity in the direction of propagation.

Spectral Distribution of Absorptivity. The absorptivity varies greatly with wavelength. The graph of absorptivity against wavelength gives the spectral distribution of the absorption characteristics of a particular substance, and can be continuous (gradually changing) or discontinuous (selective). In case of discontinuous spectral distribution it can have the character of lines, if a sharp selective absorption at certain wavelengths is evident, or of bands, if many lines are so close that the discontinuity is apparent only on a very large scale of wavelength.

Mass Absorption Coefficient μ_d is the absorption coefficient μ divided by the density d of the absorbing substance, $\mu_d = \mu/d$. Its unit is cm^2 per gram.

Reflection. If radiation is incident upon a surface of a substance, part of it will enter the substance, part of it will be turned back, reflected. If the surface is rough, reflection will occur in all directions, and the radiation is said to be *diffusely* reflected. If the irregularities in the surface are small compared with the wavelength, the radiation will be *regularly* reflected, i.e., the reflected radiation will propagate in a definite direction determined by the equality of the angle of reflection and the angle of incidence. The angle of reflection is the angle which the outward normal to the surface makes with the direction of propagation of the reflected radiation; the angle of incidence similarly is the angle which the inward normal to the surface makes with the direction of propagation of the incident radiation.

Reflectivity or the Coefficient of Reflection, R, is the ratio of reflected to incident energy of radiation and is a pure numeric always less than unity. A perfectly reflecting body, $R = 1$, is usually referred to as a *perfect mirror.* The reflectivity depends upon the angle of incidence (see Reflection) as well as upon the wavelength. If for a particular wavelength $R = 1$ the reflecting body is said to act like a perfect mirror at this wavelength.

Total Reflection. If radiation comes from a medium of higher refractive index and enters a medium of lower refractive index, total reflection may occur, i.e., for angles of incidence larger than a certain critical value θ_c all the radiation is reflected; the critical angle is designated as the angle of total reflection.

Lambert's Law. If radiation falls perpendicularly upon a surface which reflects diffusely, the intensity of the reflected radiation varies approximately with the cosine of the angle made with the normal to the surface; for larger angles with the normal, the approximation becomes poor.

Transmissivity, T, of a body is the ratio of the intensity of radiation leaving the body to the incident intensity of radiation; it is a numerical value, and varies greatly with the thickness of the body and wavelength. If, for any particular wavelength, $T = 0$, i.e., no radiation is transmitted, the body is said to be *totally opaque* for this wavelength; if on the other hand $T = 1$, i.e., all the radiation is transmitted without loss of intensity, the body is said to be *totally transparent* for this wavelength. Obviously, the sum of the three characteristic numerics must always be equal to unity

$$A + R + T = 1 \tag{3}$$

Refraction. Radiation changes its direction and velocity of propagation with the medium in which it travels. The ratio of the velocity in vacuum to that in a medium is called the *refractive index,* or the *index of refraction* for that medium. It is a numeric always larger than unity and varies greatly with the wavelength.

Refractivity is defined as the difference between refractive index and unity, $n - 1$. Like the refractive index, it varies with the wavelength. *Specific refractivity* is the quotient of refractivity of a medium and its density.

Snell's Law of Refraction. If radiation in one medium is incident upon the surface of another medium at an angle α, it will proceed into this medium with an angle β between the normal to the surface and the direction of propagation. β is called the angle of refrac-

tion, and the ratio of the sines of the two angles is the relative index of refraction of the second medium against the first

$$n_{21} = \frac{\sin \alpha}{\sin \beta} = \frac{n_2}{n_1} \tag{4}$$

The *relative index of refraction* is equal to the quotient of the absolute indices of refraction of each medium.

Dispersion. The fact that the refractive index varies with wavelength is called dispersion of radiation. Polychromatic radiation (containing radiation of many wavelengths) can be separated into its monochromatic components by utilizing the fact of dispersion (see Spectroscopy). Historically, normal and anomalous dispersion are differentiated. The former covers the cases of increasing index of refraction with decreasing wavelength; the latter refers to the converse dependents.

Diffraction. The normal laws of refraction and reflection cease to be valid if the objects in the path of radiation are of a size comparable with the wavelength of the radiation. The peculiar disturbance caused by such an object is called diffraction. A regular array of diffracting objects is usually referred to as a *diffracting grating*, and is used to determine the wavelength of the incident radiation.

2. TYPES OF RADIATION

The various types of radiation that are known can be grouped either according to their characteristics or according to their origin. The more important kinds of radiation, grouped according to their most evident nature, are briefly defined below.

a. Wave Radiations

Thermal Radiation is that radiation emitted by solids or liquids, which depends only on the temperature of the substance. The spectral distribution of emissive power is continuous (see Art. 12) and changes smoothly with temperature. Thermal radiation is thought to be produced entirely by the thermal agitation of atoms or molecules.

Characteristic Line Radiation is emitted by gases and vapors if properly " excited." Excitation may occur in the flame (by thermal agitation), in electric arcs or sparks, by bombardment with electrons or atoms, and by absorption of radiation of suitable wavelength. The spectral distribution of emissive power in this case is discontinuous and either of distinct line character or in the form of bands (see Art. 10).

X-Rays. The term x-rays is applied to the secondary radiation of a substance upon which high-speed electrons are impinging. The energy distribution has the same character for all elements and consists of a continuous energy spectrum upon which is superimposed a line spectrum which in its details is characteristic of the element serving as the secondary emitter (see Art. 14). The very hardest x-rays produced in the course of natural disintegration of radioactive substances are called γ-rays and show again a characteristic line spectral distribution in energy.

Fluorescence and Phosphorescence are the secondary emission of characteristic visible radiation if a substance is excited by radiation of suitably shorter wavelength even without perceptible rise of the temperature of the emitter. In the case of fluorescence the secondary radiation ceases with the primary radiation; in the case of phosphorescence the secondary radiation persists for an appreciable time after the primary radiation has been stopped.

Cosmic Rays are the extremely penetrating type of radiation which is supposed to originate in the interstellar spaces. Their exact nature is not yet explored, and various points of view are current.

b. Corpuscular Radiations

Electron Radiation is the emission of corpuscular electrons from the atoms or molecules of substances. As primary radiation, it may be caused by thermal agitation (thermionic emission, especially in electron tubes), by very high electric fields (cold emission, corona discharge, and cathode rays), and by the natural decay of radioactive substances (as β-rays). As secondary radiation, it can be produced by ultraviolet rays and x-rays (photo-electricity), or by bombardment with high-speed ionized atoms or molecules.

Positive Radiation is the emission of corpuscular positively charged particles from atoms or molecules of substances. If these particles have a small mass approximately corresponding to that of electrons, they are called *positrons*; as secondary radiation they are produced by bombardment of heavy metals with high-energy γ-rays or high-speed α-particles. *Proton radiation* is the emission of positively charged hydrogen nuclei with a mass approximately corresponding to that of the hydrogen atom; it occurs as secondary

radiation if substances are bombarded with high-speed α-rays. ***α-rays*** **are positively charged particles identified as helium nuclei with approximately the mass of helium atoms; as primary radiation they may be produced by the natural decay of the heaviest elements (radioactivity), by intense electric fields in the very low-pressure discharge tube (canal rays). As secondary radiation, they are the result of artificial atomic disintegration by bombardment with high-speed protons.**

Neutron Radiation is the secondary emission of corpuscular electrically neutral particles from atoms of substances if bombarded with very high-speed α-rays so as to produce artificial disintegration. The mass of the neutron corresponds approximately to that of the hydrogen atom.

3. WAVE ASPECTS OF RADIATION

Definition of Wave. The simplest type of a wave is the sinusoidal wave which is presented by any phenomenon the intensity of which varies sinusoidally with time at any point in space, as well as with distance at any particular instant of time (see Fig. 1). The mathematical formulation for a one-dimensional (or plane) wave is given by

$$a = A \sin \frac{2\pi}{\lambda} (x \pm vt) \tag{5}$$

This form is symmetrical in x and vt so that the variation in space and time is sinusoidal. A is the amplitude or crest value of the wave, λ is called the wavelength; if $(x \pm vt) = n\lambda + \phi$, where n is any integer and ϕ any arbitrary quantity, the variable a takes on the same values, thus demonstrating its periodicity. The velocity with which the wave propagates in space is v, the upper sign denoting progression in the direction of the negative x-axis, the lower sign in the direction of the positive x-axis.

$$\nu = v/\lambda \tag{6}$$

is the frequency of the local variation in time.

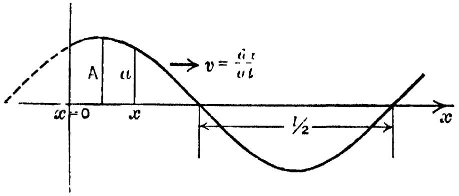

FIG. 1. Definition of a Wave. Distribution in Space at a Particular Instant of Time.

More complex, yet periodic, wave forms can be obtained by an algebraic superposition of several waves of different parameters. Instead of plane waves, cylindrical or spherical waves can arise if the origin of the waves is a linear infinitely long emitter or a point source, respectively.

Definition of Wave Packet. In dispersive media (see Dispersion, Art. 1), the velocity of propagation of radiation is a function of the frequency, and is related to the velocity in vacuum by $v = c/n$, if n is the refractive index. The superposition of a number of waves with infinitesimally different frequencies will, at a certain time t, give an absolute maximum for a point x. It can be shown that the progressing individual waves will superimpose at any other instant to give a maximum which appears to travel with a velocity $U = \dfrac{c}{\dfrac{d}{d\nu}(n\nu)}$, which is called the group velocity of the wave train. The more individual waves are superimposed, the sharper will be the maximum, and reversely.

Longitudinal and Transverse Waves. The oscillation constituting the radiation can be either in the direction of propagation or perpendicular to it. In material substances waves of both types are possible; in vacuum only transverse waves are known. Radiation proper, which does not need any specifically known medium for its propagation, is composed of transverse waves.

The Electromagnetic Wave. The simplest case is the plane electromagnetic wave which is progressing in one direction and entirely homogeneous in all directions perpendicular to the direction of propagation. It is characterized by the electric field vector $\boldsymbol{E}$, the magnetic field vector $\boldsymbol{H}$, and the velocity of propagation v, which form a right-handed coordinate system (see Fig. 2). The wave is transversal, which means that both field vectors are oscillating in time perpendicularly to their direction of propagation. The velocity of propagation in any medium is given by

$$v = \frac{c}{\sqrt{\epsilon\mu}} \tag{7}$$

where c is the velocity of electromagnetic waves in vacuum (identical with the velocity of light); ϵ and μ are the relative dielectric constant and magnetic permeability of the medium, respectively.

The superposition of various plane electromagnetic waves leads to more complex forms of electromagnetic vibrations, and the theory can easily be extended to cylindrical and spherical electromagnetic waves.

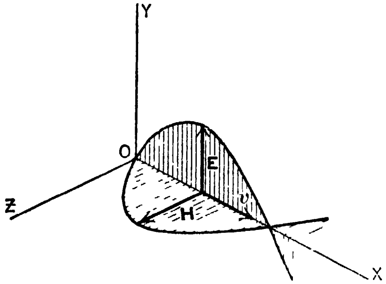

FIG. 2. The Plane Electromagnetic Wave

Characteristics of the Wave Nature of Radiation

Certain phenomena can be explained only if a wave nature of radiation is assumed.

Interference is the property by which waves of the same frequency but traveling in different directions superimpose in such a manner that they give alternate regions of stationary high and low (or zero) intensities. In the case of light, dark and light spots or bands will alternate on a screen. Interference can be produced by diffraction through narrow slits (Young, 1801), reflection from mirrors under different angles (Fresnel, 1811), diffraction from ruled gratings (Rowland, 1885), and reflection from mirrors at different distances (Michelson, 1895). The interference patterns can serve to determine the wavelength of the radiation, as was first done for light by Young in 180 . The most recent applications were the confirmation of the wave nature of electrons by Davisson and Germer (1927), and of protons and helium atoms by O. Stern (1930).

Polarization. If radiation is a transverse wave phenomenon the oscillations may occur in any direction whatsoever. In the case of perfect symmetry about the direction of propagation, the radiation is said to be unpolarized or natural. If the oscillations constituting the radiation occur in one plane only, the radiation is said to be *plane polarized*, and the plane of oscillation is called plane of polarization. If the oscillations are uniformly rotating without change in amplitude, the radiation is said to be *circularly polarized*, either left-handed or right-handed according to the direction of rotation as seen by an observer. If the oscillations rotate and change in amplitude with the same period as they rotate, the radiation is said to be *elliptically polarized*, either left-handed or right-handed according to the direction of rotation as seen by an observer. Circularly polarized radiation can be decomposed into two plane-polarized radiations at right angles to each other, of equal amplitude, and in quadrature time phases. Elliptically polarized radiation can be decomposed into two plane-polarized radiations in the direction of two conjugate diameters with proper time phases. Plane-polarized radiation can be decomposed into two oppositely rotating circularly polarized radiations. Any experiment establishing polarization of a radiation suggests transverse waves.

Velocity of Propagation in Different Media. From the laws of refraction (see Art. 1) it follows that the velocity of propagation of waves in media should decrease with increasing refracting index. This was first established experimentally by Foucault in 1850 for light radiation and therefore serves to support the wave aspect of radiation in general.

The Electromagnetic Spectrum of Radiation

Electromagnetic Theory of Light. Maxwell was the first to assume the identity of light and electromagnetic waves, and Hertz demonstrated it by showing the phenomena of reflection and interference for short electromagnetic waves. Further experiments have shown that the state of polarization is determined by the properties of the field vector H which with the direction of propagation determines the plane of polarization. If the vector H is oscillating without changing direction, the electromagnetic wave is said to be plane polarized; if it is rotating, the wave can be circularly or elliptically polarized (see Polarization, above). The photographic action of light is due to the electric field vector E. The index of refraction is identified with $n = \sqrt{\epsilon\mu}$, where, of course, ϵ and μ, the dielectric constant and the magnetic permeability, have to be chosen as variable with the wavelength in order to account for the fact of dispersion.

Bohr's Model of Atoms. To account for the origin of the characteristic line radiation (spectra), Bohr assumed a model for the atom with the mass concentrated in the center, the nucleus, composed of positive particles and a few " nuclear " electrons, so that a positive charge $Z \cdot e$ results (e is the charge of the electron). This nucleus is thought to be surrounded by electrons in orbital motion where Z is the atomic number of the element.

In the permanent state the orbits of the electrons are definite ones, determined by the matrix quantum rules of Heisenberg and Born, or the stationary solutions of Schroedinger's wave equation. By one of various processes of absorption, the orbital electrons can be thrown transiently into certain wider orbits and on returning will emit an electromagnetic wave of definite frequency ν determined by

$$h\nu = E_2 - E_1 \tag{8}$$

where $E_2 > E_1$ are the energy values connected with the two orbits marking the ends of the journey, and h is the quantum of action of Planck. The number of frequencies for an atom is finite, as are the number of possible energy states, so that the spectral lines can be described. This principle applies not only to the visible light, but equally well to ultraviolet, x- and γ-radiation, as shown in Table I.

TABLE I. The Electromagnetic Spectrum

(From L. B. Loeb and A. S. Adams: The Development of Physical Thought, John Wiley & Sons, New York, 1933.)

Wavelength Range	Source	Name	Name of Discoverer and Means of Detection and Study
∞ to 100 cm	Movements of electricity in large systems with capacity and self-inductance	Radio waves	Predicted by Maxwell, discovered by Hertz
100 cm to 0.022 cm	Electrical oscillations of minute systems, metal filings	Very short electromagnetic waves	Nichols and Tear. Large gratings, interferometers, electrical detectors. Also Giagoliewa-Arkadiewa
0.022 cm to 7×10^{-5} cm	Oscillations or vibrations of charged atomic or molecular systems, ions in crystals or gas molecules; rotation of dipoles	Infra-red or heat waves	Rubens and Bayer. Paschen. Gratings and residual rays
7×10^{-5} cm to 4×10^{-5} cm	Loosely bound outer valence electrons	Visible light	Prisms, gratings, interferometers
4×10^{-5} cm to 1.6×10^{-5} cm	Outer electrons more tightly bound	Ultraviolet	Schumann and Lyman gratings
1.6×10^{-5} cm to 1.2×10^{-6} cm	Inner electrons of light atoms, or electrons in stripped light atoms or shells next to valence shells of heavy atoms	Extreme ultraviolet or soft x-rays	Millikan and Bowen. Vacuum spectrograph and gratings
1.2×10^{-6} cm to 1.6×10^{-8} cm	Interior electrons of elements	Very readily observed by all methods	Thibaud reflected from glass gratings at grazing incidence
1.6×10^{-8} cm to 1.25×10^{-9} cm	Innermost electrons of atoms, shorter waves apply to heaviest elements	X-rays hard and soft, K and L series	Crystal gratings. Method of Laue, Bragg and also from $Ve = 1/2\, mv^2 = h\nu$; $\nu = c\lambda$.
1.25×10^{-9} cm to 5.56×10^{-11} cm	Nuclear electrons. Latter are hardest ones from RaC	γ-rays	Robinson, deBroglie, Ellis, Meitner. From $1/2\, mv^2 = h\nu$, ν from magnetic fields
? $\times 10^{-12}$ cm to ? $\times 10^{-13}$ cm	Possibly creation of nuclei of complex atoms in space	Cosmic rays	Absorption coefficients in water and air. Kohlhörster, Hess, Millikan. Estimated from absorption. May be neutrons or particles

Debye's Model of Molecules. The valence of an atom is determined by the number of electrons in the outermost electronic layer in Bohr's model of atoms. Molecules formed with atoms of the same kind (polyatomic substances) or of different kinds (chemical compounds) incorporate their valence electrons into a stable new structure, which in general will show certain symmetries. Vibrations of the atoms within a molecule on account of absorption by thermal agitation, or rotations, give rise to radiation of relatively long wave-lengths, the thermal or infra-red radiation with a distribution of the frequencies in bands (band spectrum).

Wave Nature of Matter. The attempts to explain the interaction of matter and radiation led to the conclusion that any particle of mass m moving with a speed v can be thought to be associated with a wave the frequency of which is given by the interrelation of energy:

$$h\nu = W = \frac{mc^2}{\sqrt{1 - (v/c)^2}} \tag{9}$$

where h is the quantum of action of Planck and c the velocity of light in vacuum. The velocity of propagation of the wave is defined as

$$V = c^2/v > c$$

in order to satisfy the wavelength relation for radiation (10)

$$\lambda\nu = V \tag{11}$$

but no physical meaning can be attached to a velocity larger than the velocity of light in vacuum. The associated wave for electrons has a wavelength similar to those of very hard x-rays, and this has been verified by interference experiments on crystals by G. P. Thomson.

Electromagnetic Spectrum of Radiation. Table I shows the completely closed range of electromagnetic radiations from longest to shortest wavelengths with the supposed sources of radiation.

4. CORPUSCULAR ASPECTS OF RADIATION

A Corpuscle is defined as that which possesses a momentum (as a vector quantity) of amount $p = mv$ and a kinetic energy $W = {}^1/_2\, mv^2$ according to Newtonian, or $p = \frac{mv}{\sqrt{1 - (v/c)^2}}$ and $W = \frac{mc^2}{\sqrt{1 - (v/c)^2}}$ according to relativistic mechanics. Its presence becomes obvious by collisions with other particles which can be made visible in certain cases (Wilson's cloud chamber).

The Photon. Electromagnetic radiation transports energy in amounts which are integer multiples of fundamental quanta ($h\nu$). Einstein suggested that a quantum of radiation, $h\nu$, be considered as associated with the characteristics of a corpuscle of velocity c, the velocity of light in vacuum. From the relativistic expression of energy (equation 9) it is seen that the mass of a photon must approach zero as its velocity approaches c. The momentum of a photon is defined as $p = h\nu/c$.

The Photon Gas. There are as many distinct types of photons as there are different wavelengths in the radiation spectrum. Radiation as a corpuscular phenomenon can then be treated with statistical methods similar to the kinetic theory of gases with the fundamental difference that the distribution in frequency ν takes the place of the distribution in velocity of gas molecules; each photon is assumed to have the same velocity c in vacuum. For statistical methods radiation is called the photon gas.

Characteristics of the Corpuscular Nature of Radiation

Rectilinear Propagation of Radiation. The most striking corpuscular characteristic of radiation is its propagation along straight lines so that definite shadows are cast. This led Newton to his corpuscular theory and initiated the whole field of geometrical optics (see Art. 5).

Collision of Radiation and Electrons. If monochromatic radiation of quantum $h\nu_1$ falls upon a scattering substance, the secondary radiation from the substance is of longer wavelength than the incident radiation, $\nu_2 < \nu_1$. This can be explained only if the photon colliding with an electron, or atom, loses some of its energy (its speed c cannot change) to the electron or atom which will be accelerated and proceed in a direction determined by the law of the conservation of momentum. The experimental evidence is due to A. H. Compton, and the phenomenon is consequently named *Compton effect.*

If monochromatic radiation of quantum $h\nu$ falls upon metals, electrons will be liberated with a kinetic energy given by the Einstein relation

$${}^1/_2\, mv^2 = h\nu - \omega_0 \tag{12}$$

where ω_0 is the amount of energy necessary to free the electron from its surroundings within the metal, and is independent of the frequency of the incident light. This *photoelectric effect* is explainable only by assuming corpuscular collision of radiation and electrons according to the laws of conservation of energy and momentum.

Penetrating Power of Radiation. Einstein's hypothesis attributes a momentum $p = h\nu/c$, proportional to frequency ν, to the photon, so that a radiation will be the more penetrating from the corpuscular point of view the shorter its wavelength is. This agrees well with experimental facts. It is customary to measure the penetrating power by the absorption coefficient (see Art. 1) in a standard material.

The Corpuscular Spectrum of Radiation. The proportionality of momentum (corpuscular aspect) and frequency (wave aspect) of the photon leads to the same scheme of identification as Table I for the electromagnetic spectrum.

GEOMETRY OF RADIATION

By Ernst Weber

Geometry of radiation deals with "rays" which are identical with the directions of propagation of the electro-magnetic waves in the wave picture and with the paths of the photons in the corpuscular picture of radiation. It is applicable only if the interaction of radiation and matter involves objects whose dimensions are large compared with the wavelengths of the radiation considered. Thus, any problem of electromagnetic radiation from antennas can be treated by the geometrical method if the objects can be considered as large compared with the wavelength. Historically the first, and still the most important, application of the geometric method lies in the field of optics, although with proper interpretation the results can be applied to any other type of radiation.

5. PRINCIPLES OF GEOMETRICAL OPTICS

The ray from the light source is called the *incident* ray. If light in air is incident upon a polished surface of a transparent medium part of it will be regularly reflected, the other part will enter the medium. Referring to Fig. 1, the point of incidence P is the point where an incident ray strikes the surface of the medium. The plane determined by the outside normal n to the surface at this point, and the incident ray, is called the plane of incidence, and the angle α which these two directions make is the angle of incidence.

Laws of Reflection and Refraction. Both the reflected and refracted rays lie in the plane of incidence, on opposite sides of the surface of the medium. The angle γ of the reflected ray with the outside normal, the angle of reflection, is equal to α, $\gamma = \alpha$; the angle β of the refracted ray with the inside normal, the angle of refraction, is determined from the law of Snell

$$\frac{\sin \alpha}{\sin \beta} = n \qquad (1)$$

where n is the relative index of refraction of the medium against air. $n > 1$ for all transparent media. For normal incidence and regular optical behavior $\alpha = \beta = \gamma = 0$, no deviation of the ray occurs. If a plane surface is totally reflecting it is called a plane mirror.

Real and Virtual Image. Referring to Fig. 2, if MN indicates the surface of a plane mirror, the rays issuing from the source P and striking the mirror at the points A and B will be reflected and reach the eye as the rays C and D. To the eye these rays will appear as coming from the point Q behind the mirror. Q is called the "image" of P and more specifically a virtual image because the rays C and D do not actually pass through Q and therefore cannot be received there on a screen and be made visible. A real image is, then, one that can be received on a screen and be made visible.

Total Reflection. If light passes from a medium of large refractive index into one of small refractive index, the relative index of refraction according to equation 1 becomes less than unity. The angle α_c for which $\sin \beta = 1$ so that $\sin \alpha_c = n$ is called the critical angle because no light enters the second medium. For angles $\alpha > \alpha_c$, the light is said to be totally reflected as there is no refracted ray.

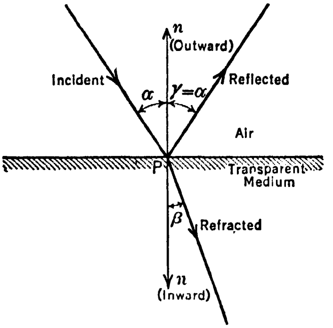

FIG. 1. Reflection and Refraction of a Ray

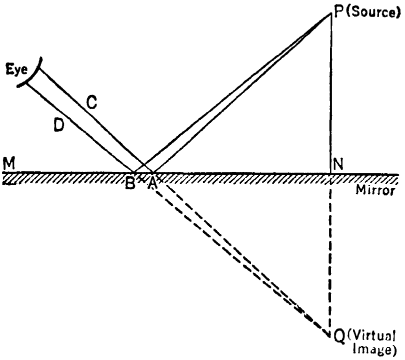

FIG. 2. Virtual Image from a Plane Mirror

Optical Distance of two points in a medium of refractive index n is the actual length of the path l covered by the ray between the two points multiplied by the value of the refractive index. If a ray passes through different media, the optical distance between any two points is the sum of the optical paths within each medium, $\sum_i l_i n_i = \sum_i o_i$. A surface is called *aplanatic* if for each of its points the sum of the optical paths to two fixed points has a constant value.

Fermat's Principle. Using the definition of the optical distance, the laws of refraction and reflection can be expressed, according to Fermat, in a single principle: rays of light (and for that matter, of any radiation) travel along such lines that the optical distance between any two points of the rays is a minimum.

6. SPHERICAL MIRRORS AND LENSES

Concave Spherical Mirrors (Fig. 3). A spherical mirror is concave if its center of curvature C is on the side from which the light is incident. By the general law of reflection, a point source P will form a real image at a point Q so that PCQ lie on a straight line, the optical axis, and that the angle of incidence is equal to the angle of reflection. Rays through the center C are reflected in themselves; rays parallel to the optical axis converge at a point F midway between C and M, the principal focus, or simply *focus*, of the mirror. If the distances are designated as $MF = f$, $MP = p$, and $MQ = q$, the relation exists

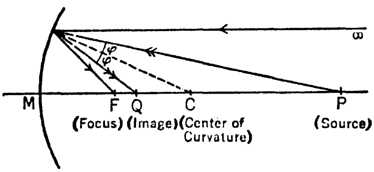

FIG. 3. Reflection from a Concave Spherical Mirror

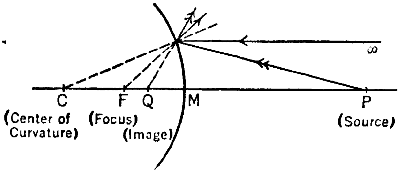

FIG. 4. Reflection from a Convex Spherical Mirror

$$1/p + 1/q = 1/f \tag{2}$$

which holds for any position of P if p, q, and f are counted positive on the right-hand side and negative on the left-hand side of the mirror center M. For negative values of q the images become virtual.

Convex Spherical Mirrors (Fig. 4). A spherical mirror is convex if the center of curvature C is on the side opposite to that from which the light is incident. The same relations hold as for the concave mirror, except that the focal distance f has negative values in accordance with the proper interpretation of equation 2.

Images Formed by Spherical Mirrors (Figs. 5 and 6). The position of the image Q' of any point P' near but not in the optical axis of a mirror is found most expediently by the intersection of two principal rays, the ray through the center of curvature C and the reflected ray through the focus F. Any object PP' perpendicular to the optical axis will produce an image QQ' again vertical to the axis and of definite characteristics; Table I shows all the possibilities of position and character of images formed by spherical mirrors.

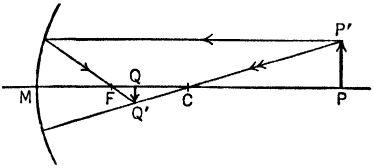

FIG. 5. Image Formed by a Concave Spherical Mirror

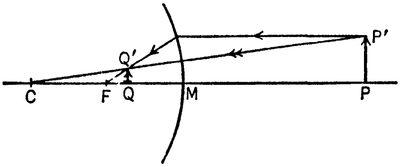

FIG. 6. Image Formed by a Convex Spherical Mirror

Table I. Images Formed by Spherical Mirrors

(Figs. 3 and 4)

Mirror	Position of Object (PP') P	Position of Image (QQ') Q	Character of Image
Concave	At ∞	At F	Real
	Between ∞ and C	Between F and C	Real, inverted, diminished
	At C	At C	Real, inverted, same size
	Between C and F	Between C and ∞	Real, inverted, magnified
	At F	At ∞	
	Between F and M	From ∞ behind M to M	Virtual, erect, magnified
	At M	At M	erect, same size
Convex	At ∞	At F	Virtual
	Between ∞ and M	Between F to M	Virtual, erect, diminished
	At M	At M	erect, same size

Thin Spherical Lenses. A lens is a portion of a refracting medium which is bounded by two spherical surfaces or by one spherical and one plane surface. The straight line through the center of curvature of the two surfaces is called the axis of the lens. If one of the surfaces is a plane, then the axis is a straight line perpendicular to this plane and going through the center of the spherical surface. Any plane through the axis is said to be a principal section of the lens; Fig. 7 shows the principal sections of the common types of lenses.

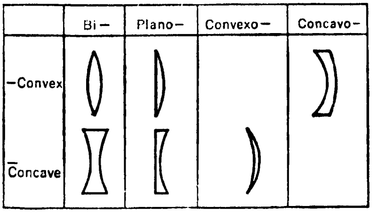

FIG. 7. Principal Sections of Spherical Lenses

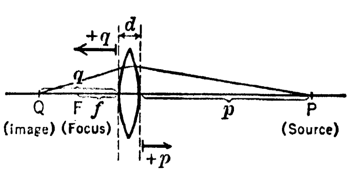

FIG. 8. Refraction by Thin Convex Lens

Thin Convex Spherical Lenses (Fig. 8). By the general laws of refraction, a ray coming from the point source P in the axis of the lens will be refracted twice as it passes through the lens and form an image at the point Q. For thin lenses (large radii of curvature) relation 2 will hold true if the distances p and q are measured from the nearest surface of the lens and if both are taken positive when on opposite sides of the lens. f is the focal length and is defined by

$$1/f = (n - 1)(1/r_1 - 1/r_2) \tag{3}$$

where r_1 and r_2 are the radii of curvature of the two surfaces, both taken positive if on the same side of the lens, and n is the refractive index of the lens. All rays parallel to the axis converge at a point F the principal focus, or simply focus, at a distance f from the nearest surface. Rays passing through the optical center will not be deviated. For thin lenses the optical center can be approximately identified with the two points where the axis meets the surfaces of the lens.

Thin Concave Spherical Lenses (Fig. 9). The same relations hold as for the convex lens, the only difference being that the focus is on the same side as the light source so that the rays, after passing through the lens, diverge; for this reason the concave lens is often called diverging lens.

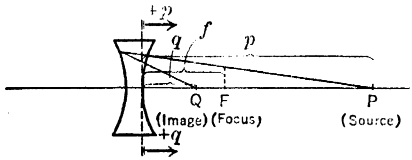

FIG. 9. Refraction by Thin Concave Lens

Images Formed by Thin Spherical Lenses (Figs. 10 and 11). The form of the image Q' of any point P' near but not in the axis of the lens is found approximately but most expediently by the intersection of two principal rays, the ray through the optical center and the ray parallel to the axis, refracted through the focus. For the actual construction it suffices to consider the plane through the optical center and perpendicular to the axis as the refracting plane. Any object PP' perpendicular to the axis will produce an image QQ' again perpendicular to the axis and of definite characteristics; Table II shows the possible positions and characteristics of images formed by convex and concave lenses.

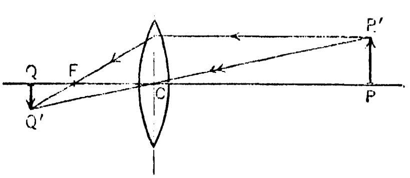

FIG. 10. Image Formed by Thin Convex Lens

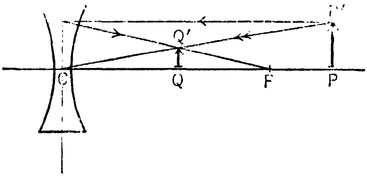

FIG. 11. Image Formed by Thin Concave Lens

Table II. Images Formed by Spherical Lenses
(Figs. 8 and 9)

Lens	Position of Object	Position of Image	Character of Image
Convex	$u = +\infty$	$v = f$	Real
	$\lvert 2f \rvert < u < +\infty$	$f < v < 2f$	Real, inverted, diminished
	$u = \lvert 2f \rvert$	$v = 2f$	Real, inverted, same size
	$\lvert f \rvert < u < \lvert 2f \rvert$	$2f < v < \infty$	Real, inverted, magnified
	$u = \lvert f \rvert$	$v = \infty$	
	$0 < u < \lvert f \rvert$	$-d < v < -\infty$	Virtual, erect, magnified
Concave	$u = +\infty$	$v = f$	Virtual
	$0 < u < +\infty$	$0 < v < f$	Virtual, erect, diminished

Spherical Aberration. The rays of light incident, for example, upon a spherical mirror, from a light source P (Fig. 3), form an image at point Q; this is approximately true if the angle between light ray and optical axis is small. For larger angles the image points occupy all the points on the axis between Q and M instead of meeting at a single point; an image line will be formed which constitutes the longitudinal spherical aberration. If a screen is placed at point Q the reflected rays will, for the same reason, illuminate a circular area instead of a sharp point image; this is referred to as lateral spherical aberration. The same holds for all types of spherical mirrors and lenses.

Chromatic Aberration. Since the refractive index varies with wavelength, the image produced by white light from a convex lens, for example, will be, in fact, a superposition of many monochromatic images at slightly different foci. The yellowish green image is the brightest, and the one upon which the screen will be focused, so that the other images superimpose slightly out of focus and thus blur the resultant white image. This effect is known as chromatic aberration, and can be minimized by using several lenses instead of a single one. An arrangement which tends to refocus the monochromatic images into a single sharp image is called achromatic. Chromatic aberration is produced with any type of single lens.

The Focal Length of a convex lens can most readily be determined on an optical bench. In front of a light source fine cross-wires are placed. The light, after passing through the lens, forms an image on a screen which is clearly focused. If p is the distance of the cross-

wires, q that of the screen, from the center plane of the lens, then by equation 2 the focal length can be computed. With a concave lens it is necessary to use a convex lens also. From the resultant focal length F and the known focal length f of the convex lens that of the concave lens, f', can be determined by

$$1/f' = 1/F - 1/f$$

7. OPTICAL INSTRUMENTS *

Magnification, increasing visibility of detail, is secured by bringing the image of an object nearer to the eye, or by any other means of increasing the visual angle which the object subtends. Vision with the unaided normal eye is, however, most distinct at a distance of 25 to 30 cm because the accommodating mechanism of the eye is unable to focus sharply on the retina points nearer than this. A magnifying optical system produces in effect the required increase in the visual angle while forming an image (real or virtual) farther from the eye than the least distance of distinct vision. Often the arrangement is such that the eye views a virtual image at an infinite distance, so that the muscles of accommodation may be completely relaxed.

The Simple Microscope (Fig. 12). A single converging lens if placed closer to an object than the principal focal length produces an enlarged virtual image, which is seen on looking through the lens. The magnification produced is $1 + d/f$ for an eye whose least distance of distinct vision is d. A simple plano-convex lens, with the plane side toward the eye, gives good images for magnification less than eight diameters, that is, with focal lengths greater than about 3 cm. The image may be much improved, especially where the magnification is considerable, by the use of special combinations of lenses designed to reduce spherical and chromatic aberration so as to give a fairly large field of view approximately free from distortion and color.

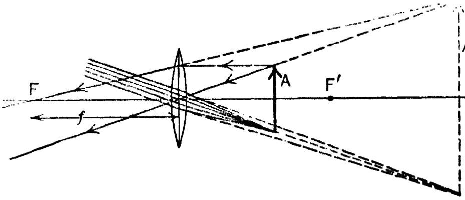

FIG. 12

The Ramsden or Positive Eyepiece. (Fig. 13) consists of two converging lenses, usually plano-convex, with their convex surfaces facing each other, of equal focal length, and separated by $^2/_3$ the focal length of either. A virtual image of the object or real image A is formed by the field-lens L_1 at A'. The eye-lens L_2 forms an image of this at infinity. This eyepiece is fairly, but not quite, achromatic.

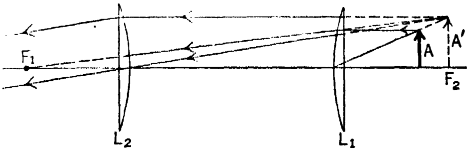

FIG. 13

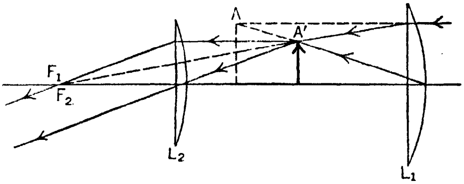

FIG. 14

Huyghens or Negative Eyepiece (Fig. 14). Two converging lenses, usually plano-convex, with the plane surfaces toward the eye, are so arranged as to divide equally between them the deviation produced on incident light parallel to and close to the axis. The field-lens L_1 has three times the focal length of the eye-lens L_2, and the two are separated by the difference in their focal lengths. Light which if unhindered would converge at A is deviated by L_1 to form an image at A', of which L_2 forms an image at infinity. This eyepiece is highly achromatic and free from disturbing spherical aberration.

For Measuring Microscopes and Telescopes in which the eyepiece is fitted with cross-hairs, the positive eyepiece is far more suitable than the negative because the image of the hairs being formed by both lenses is corrected for both chromatic and spherical aberration, and because the cross-hairs can be easily adjusted to suit different eyes by altering their distance from the eyepiece.

The Compound Microscope (Fig. 15) in its simplest form consists of two converging lenses. The objective L_1 forms within the tube a real, inverted, magnified image A' of the object A. This image is viewed through the eyepiece L_2 and further magnified. A microscope is usually fitted with either a Huyghens or a Ramsden eyepiece, according to the purpose for which it is to be used. The objective is also generally a combination of several lenses to overcome spherical and chromatic aberration while admitting as much light as possible. In microscopes of the highest power a drop of oil of cedar is placed between the slide and the objective; this is known as "immersion." The smallest interval that can be optically resolved is about 0.00005 mm, and the limit of resolution of the microscope is attained when the total magnification is about 1200.

---

* From the American Civil Engineers' Handbook, by Merriman and Wiggin, 5th Edition.

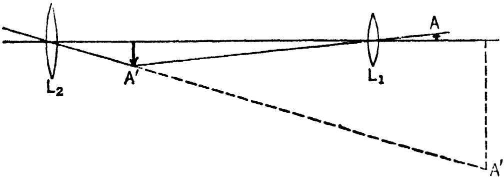

FIG. 15

The Astronomical Refracting Telescope differs from the compound microscope in that the objective forms a reduced image of a distant object. The objective is generally a compound lens consisting of a convex lens of crown and a concave lens of flint glass. A Huyghens or a Ramsden eyepiece is ordinarily used; but the best instruments employ eyepieces embodying later improvements.

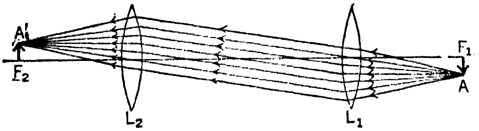

FIG. 16

The Terrestrial Telescope (Fig. 16) produces an erect image by an inverting system between the eyepiece and the inverted image formed by the objective. One form of inverting system consists of two converging lenses of equal focal length so placed that the inverted image A formed by the objective is at the principal focus of the first lens. An erect image A' is then formed at the principal focus of the second lens, and is magnified by an eyepiece.

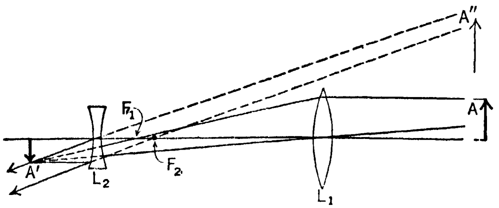

FIG. 17

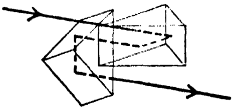

FIG. 18

Galileo's Telescope (Fig. 17) consists of a convex lens L_1 for objective and a concave lens L_2 for eyepiece. The light from L_1, converging so that if unhindered it would form at A' a real, inverted image of the distant object A, is intercepted by L_2 and rendered parallel or slightly divergent as if it came from A'', which is a virtual, erect image of A. The use of the diverging eye-lens limits considerably the angular field of view. Ordinary field-glasses and opera-glasses are Galilean telescopes.

The Prism Binocular (Fig. 18) secures the wide field of view that accompanies the use of a converging eyepiece, at the same time avoiding the inconvenient length of the ordinary terrestrial telescope. This is accomplished by employing four total reflections within two right-angled prisms to invert the image formed by the objective. Otherwise the construction is the same as that of the astronomical telescope. This prism construction permits a considerable shortening of the telescope by separating the prisms, since the light traverses the distance between them three times. In addition the stereoscopic effect due to binocular vision may be greatly increased by placing the centers of the objectives much farther apart than the pupils of the eye. The increased field of view is obtained at a sacrifice of illumination.

In Reflecting Telescopes the object lens is replaced by a concave mirror with parabolic surface. The mirror is of glass and coated with a thin film of either silver or aluminum. The parabolic surface of the mirror renders it completely achromatic and, therefore, of special value in astronomic photography. The first reflecting telescope was constructed by Newton, in 1670, and is known as the Newton Reflector. The largest reflecting telescope in actual use is at the Mount Wilson Observatory in California; it is 100 inches in diameter and 43 feet in focal length. A new reflecting mirror of 200 inches in diameter has just been completed and will also be installed at the Mount Wilson Observatory.

PHYSICS OF RADIATION

By Ernst Weber

For electromagnetic radiation from resonating circuits and antennas, and thermionic emission, see the volume *Electrical Communication* of this handbook series.

8. PROPAGATION OF LIGHT

The Velocity of Light* in vacuum is approximately 186,000 miles per second, and was first determined in 1675 by O. Roemer, a Danish astronomer. According to recent measurements by Michelson (1926), the velocity of light in vacuum is $2.99796 \pm 0.00004 \times 10^{10}$ cm per sec, but a slight variation is suspected to take place.

The Color of Light is determined by its spectral distribution. The range of visible light extends from about $\lambda = 380\ m\mu = 3800$ A (extreme violet), to about $\lambda = 780\ m\mu = 7800$ A (extreme red).

The Refractive Index of light varies considerably with wavelength, normally increasing in value with decreasing wavelength (normal dispersion). It is customary to give refractive indices for yellow light of $\lambda = 589.3\ m\mu$ wavelength (bright radiation of sodium vapor) in order to facilitate comparison. For *gases* the refractive index is not much different from unity and varies only slightly with wavelength; Table I gives some representative values. For *liquids* the refractive index lies between 1 and 2 and shows variation with temperature as well as with wavelength. Table II gives some representative values.

Table I. Index of Refraction of Gases

(From Smithsonian Tables; reduced to 0° C and 760 mm Hg, at wavelength $\lambda = 589.3\ m\mu$, sodium light.)

Substance	Symbol	Index of Refraction	Substance	Symbol	Index of Refraction
Hydrogen.	H_2	1.000 132	Carbon monoxide	CO	1.000 346
Water vapor.	H_2O	1.000 249 to 1.000 259	Carbon dioxide. .	CO_2	1.000 448 to 1.000 454
Oxygen.	O_2	1.000 271	Sulfur dioxide. . .	SO_2	1.000 686
Air.	. . . . .	1.000 2926	Benzene.	C_6H_6	1.001 700 to 1.001 823
Nitrogen.	N_2	1.000 296 to 1.000 298			

Table II. Index of Refraction for Liquids

(At 20° C and at wavelength $\lambda = 589.3\ m\mu$, sodium light; various sources)

Substance	Symbol	Index of Refraction	Substance	Symbol	Index of Refraction
Water.	H_2O	1.332 99	Benzene.	C_6H_6	1.501
Ethyl ether.	$C_2H_5OC_2H_5$	1.351	Phenol.	C_6H_5OH	1.550
Ethyl alcohol. . . .	C_2H_5OH	1.361	Bromine.	Br	1.654
Gylcerin.	$C_3H_8O_3$	1.474			

Table III. Index of Refraction of Glass

(From the Handbook of Chemistry and Physics, 1933)

Variety of Glass	Wavelength in Millimicrons							
	361	434	486	589	656	768	1200	2000
Zinc crown.	1.539	1.528	1.523	1.517	1.514	1.511	1.505	1.497
Higher dispersion crown.	1.546	1.533	1.527	1.520	1.517	1.514	1.507	1.497
Light flint.	1.614	1.594	1.585	1.575	1.571	1.567	1.559	1.549

Heaviest flint.	. . . .	1.945	1.919	1.890	1.879	1.867	1.848	1.832

Transparent Solids, if optically *isotropic*, refract regularly. The most important representative is glass, which has very marked dispersive properties in the visible range; this fact is utilized in prism spectroscopy. Table III shows the variation of the refractive index with wavelength for various standard kinds of glass in general use for optical purposes.

---

* The expression "light" is commonly used to designate monochromatic visible radiation (scientific usage) or total visible radiation from a light source.

Transparent Crystals, if optically anisotropic, have, in general, different propagation properties in all three space directions and therefore must be characterized by three principal refractive indices. They exhibit certain symmetries with respect to two definite crystallographic directions, called the optical axes; the crystals themselves are called *optically biaxial.*

Certain *transparent crystals* exhibit rotational symmetry with respect to a single crystallographic direction, called the optical axis; the crystals themselves are called *optically uniaxial* and must be characterized by two principal refractive indices. The most widely known representatives are quartz and Iceland spar. Very complete tables of the indices of refraction can be found in the International Critical Tables.

Metals absorb as well as reflect light; in general, they are entirely opaque, except when used in very thin films. The optical behavior of metals is characterized by refractive index n, index of absorption K, and reflectivity R. The optical indices of metals are not directly measurable; they must be computed from the observation of changes of polarization (see Art. 9) in the reflected light. In general, the metals show an apparent irregular and large variation of their optical indices with the wavelength of the incident light; this has led to a theory of resonance of the conduction electrons. Table IV gives the optical indices for a few metals at a wavelength $\lambda = 589.3$ mμ (sodium light) as determined by Drude.* All metals show low reflectivity for ultraviolet, increasing values through the visible spectrum, and act as almost perfect mirrors for infra-red and longer wavelengths.

Table IV. Optical Constants of Metals

(At a wavelength $\lambda = 589.3$ mμ; various sources)

Metal	Symbol	Index of Refraction n	Index of Absorption K	Reflectivity R	Metal	Symbol	Index of Refraction n	Index of Absorption K	Reflectivity R
Aluminum	Al	1.44	5.32	0.83	Nickel	Ni	1.79	1.86	0.62
Bismuth	Bi	1.90	1.93	0.65	Silver	Ag	0.18	20.2	0.95
Copper	Cu	0.64	4.08	0.73	Steel	......	2.7	1.28	0.57
Gold	Au	0.36	7.70	0.85	Tungsten	W	3.46	0.94	0.54
Mercury	Hg	1.73	2.87	0.78					

Table V. Diffuse Reflecting Power

(For visible spectrum; various sources)

Material	Reflecting Power in Per cent	Material	Reflecting Power in Per cent
Cloth		Paper—*Continued*	
White linen, dull finish	81	Olive green	15
Red cotton (diamine fast red)	44	Ultramarine blue	3.5
Blue woolen (lanacyl)	25	Black	5
Blue woolen (salacine)	15	Pigment	
Blue flannel	17.5	Chromium oxide, Cr_2O_3	27
Blue linen (navy blue)	17	Cobalt oxide, Co_2O_3	3
Black cotton (diamine)	33	Lead oxide, PbO	52
Black cotton (columbia)	29	Lead carbonate, $PbCO_3$	90
Black cotton (sulfur)	2.4	Magnesium oxide, MgO	86
Black felt	14	Red iron oxide, Fe_2O_3	52
Black velvet	1.8	Zinc oxide, ZnO	82
Black woolen (salacine)	12	Stone and minerals	
Green leaf (tulip tree)	22	Asphalt (pavement)	15
Lampblack (paint)	3.2	Macadam road	12
Paints		Granolith (pavement)	17
White lead	75	Bluestone (sandstone)	18
Zinc lead	69	Limestone (Indiana)	43
Paper		Brick, light buff	48

Buff	60	Slate (dark clay)	6.7
Chocolate brown	20		

---

* P. Drude, *Wied. Annalen,* 1890, vol. 36, p. 885; vol. 39, p. 481.

Most common materials reflect diffusely. Table V gives the diffuse reflective power for the more important engineering materials. Rather complete tables of spectral reflectivity of pigments and transmissivity of dyes can be found in M. Luckiesh, The Basis of Color Technology, *Journal of the Franklin Institute*, vol. 184, p. 73, 1917; and M. Luckiesh, The Measurement of the Transmission Factor, *Journal of the Franklin Institute*, vol. 186, p. 111, 1918.

9. POLARIZATION OF LIGHT

Double Refraction and Polarization. The fact that optically uniaxial crystals propagate light selectively with respect to their optical axis can best be explained by the assumption of the polarization of light. As defined in Art. 3, a light wave is called plane polarized if the oscillations of each of the electromagnetic field vectors occur in a fixed plane. In the case of optically uniaxial crystals (in relation to which the concept of polarization was originally introduced), double refraction takes place; that is, an incident pencil of light, propagating in a direction other than the optical axis, is broken up into two pencils: the ordinary and the extraordinary " ray," both of which travel with different velocities within the crystal. The two resulting rays, on emerging, are plane polarized in two perpendicular planes. It is customary to call " ordinary ray " that ray which is plane polarized *in* the principal plane (a plane parallel to the optical axis and the incident ray); this ray is uniformly refracted in all directions and thus behaves like ordinary light. It is customary to call "extraordinary ray" that ray which is plane polarized perpendicular to the principal plane; this ray is non-uniformly refracted, the refractive index varying symmetrically about the optical axis. The extraordinary ray thus behaves differently from ordinary light. Upon leaving the crystal, the two plane-polarized waves have, on account of their different velocities within the crystal, a phase difference

$$\delta = \frac{2\pi d}{\lambda}(n_1 - n_2) \qquad (1)$$

where d is the length of the path within the crystal, λ the wavelength in air, and n_1 and n_2 the refractive indices for the two rays in the directions of propagation. The resulting light from a uniaxial crystal is, therefore, in general, elliptically polarized.

Production of Plane-polarized Light. Double refraction provides a means of producing plane-polarized light from natural light by suppressing the ordinary ray, as for example, in a Nicol prism. In the case of tourmaline the high value of absorptivity for the ordinary ray naturally suppresses it so that the plane-polarized extraordinary ray remains. If light falls upon transparent substances at such an angle of incidence that reflected and refracted rays are perpendicular to each other, the reflected light will be almost completely plane polarized (Brewster's law).

Photoelasticity. Isotropic transparent substances, if subjected to strain, become doubly refracting. Plane-polarized light, in passing through the substance, is then decomposed into two rays, polarized, respectively, parallel and perpendicular to the direction of stress. On account of their different velocities of propagation they suffer a relative phase difference, so that the light leaving the medium is, in general, elliptically polarized (see Art. 3). The amount of the phase difference is proportional to the stress and the thickness of the medium, so that a stress analysis can be performed. For practical purposes, models of the structure to be investigated are cut out of xylonite,* and subjected to stresses proportional to those acting on the original.

Optical Rotation. In many substances plane-polarized light experiences a rotation of the plane of polarization proportional to the length of the path within the substance. According to Fresnel, it is thought that the plane-polarized ray decomposes into two oppositely rotating circularly polarized rays which propagate with different velocities, so that they suffer a relative phase difference; on leaving the substance, they combine into a plane-polarized ray, the plane of polarization of which appears to be rotated with respect to that of the incident light. The specific rotation is measured in angular degrees per decimeter for liquids and solutions, and in angular degrees per millimeter in solids; it is called negative if the rotation is left-handed, and positive if it is right-handed, as seen by an observer. Substances exhibiting optical rotation are called *optically active*. Applications are found in commerce and medicine in the test for sugar. Instruments used to measure the optical rotation are called saccharimeters or polarimeters. Table VI shows the values of specific rotation of a few common substances at 20° C, for sodium light. Quartz shows a very marked increase of the specific rotation with decreasing wavelength. Rather complete tables can be found in the International Critical Tables, Volume 7.

---

Maltose	+138.3	" " " "
Sucrose (cane sugar)	+ 66.3	" " " "

* Solvent; water (1 g in 100 g).

Magnetic Rotation. Optically isotropic substances, when exposed to a strong magnetic field, rotate the plane of polarization of plane-polarized light. This is called the *Faraday effect* after its discoverer (1845), and depends on the magnetic field intensity H. It is termed positive if the rotation occurs in the direction of the current which produces the magnetic field. The angle of rotation in angular minutes is given by

$$\theta = r.l.H \cos \alpha$$

where r is Verdet's constant (see Table VII), l (centimeters) the length of the path of light within the magnetic field of intensity H (oersteds), and α the angle which H makes with the ray of light.

Table VII. Magneto-optic Rotation

(At 20° C and wavelength λ = 589.3 mμ, sodium light; various sources)

Substance	Verdet's Constant	Remarks
Solids:		
Flint glass (medium)	+ 0.0420	
Quartz (⊥ to optical axis)	+ 0.0172	
Liquids and solutions:		
Benzene	+ 0.0297	
Ethyl alcohol	+ 0.0107	
Ferric chloride	− 0.2026	Aqueous solution, 1.4331 g per cm³
Ferrous chloride	+ 0.0025	" " 1.6933 "
Sodium carbonate	+ 0.0140	" " 1.1006 "
Water	+ 0.0130	
Gases (at atmospheric pressure):		
Air	+ 6.83 × 10^{-6}	
Carbon dioxide	+13.00 "	
Nitrogen	+ 6.92 "	
Oxygen	+ 6.28 "	

Kerr Effect. Transparent substances, when subjected to a strong electrostatic field, become doubly refracting. Plane-polarized light, in passing through the substance, is decomposed into two rays polarized in the direction of the electric field and perpendicular to it, respectively. On account of their different velocities of propagation, they suffer a relative phase difference, so that the light leaving the medium is in general elliptically polarized. A high-voltage condenser with liquid dielectric (preferably nitrobenzene), employing this electro-optical effect, is called a *Kerr cell*, and is of use in some phases of television.

10. LIGHT SPECTROSCOPY

The Visible Spectrum* is the graphic arrangement of the visible radiant energy against wavelength or frequency. The wavelength is usually measured in millimicrons, 1 mμ = 10^{-7} cm, or in angstroms, 1A = 10^{-8} cm (practically). Three different kinds of spectra are commonly distinguished: the emission spectrum, representing the spectral distribution of emissive power of a light source; the reflection spectrum, representing the spectral distribution of reflectivity of a regularly reflecting surface; and the absorption spectrum, representing the spectral distribution of the absorbing power of transparent substances. The best-known representative of the last type is the solar absorption spectrum, or the Fraunhofer lines, discovered in 1817.

---

* The term visible spectrum is also used to designate the band of colors constituting white light.

Spectroscopy. The spectral distribution of radiant energy composing light can be directly observed in a spectroscope. The most common type of spectroscope, first used by Newton (1666), utilizes the dispersion of light passing through a prism of glass (see Fig. 1). Later types of spectroscopes use the diffraction of light by fine gratings (Rowland, 1882), and the interference patterns resulting from reflections by mirrors (interferometer by Michelson). A very high-power spectroscope, using an echelon grating (Michelson, 1898), has been particularly successful in finding the fine structure of spectral lines. Monochromatic radiations are located by comparison with standard radiations. Table VIII gives a few of the wavelengths useful for the calibration of spectroscopes and their respective sources. The primary standard for absolute wavelength measurements is the wavelength of the red cadmium line determined by Benoist, Fabry, and Perot (1907), as 6438.4696 angstroms, and adopted internationally.*

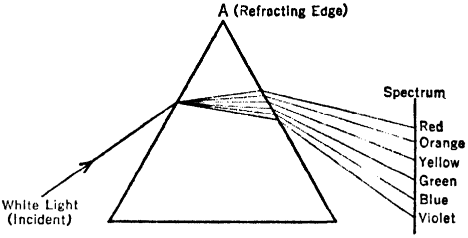

FIG. 1. Dispersion of White Light by a Glass Prism

Table VIII. Wavelengths for Calibration of the Spectroscope

(Selected from R. A. Houstoun, A Treatise on Light)

Source	Wavelength mμ	Color	Corresponding Fraunhofer Absorption Line
Potassium nitrate on Pt wire in Bunsen flame	770.2 766.8	Red	
Lithium sulfate on Pt wire in Bunsen flame	670.78	Red	
Hydrogen vacuum tube (α line)	656.28	Red	C
Sodium bicarbonate on Pt wire in Bunsen flame	589.00 589.59	Orange	D_2 D_1
Mercury arc	546.07	Green	
Thallium chloride on Pt wire in Bunsen flame	535.07	Green	
Hydrogen vacuum tube (β line)	486.14	Greenish blue	F
Hydrogen vacuum tube (γ line)	434.04	Indigo	f
Cadmium spark in air	396.84	Violet	H

The Performance of a Spectroscope is judged by the brightness of the spectrum, which depends in the first place on the aperture of the instrument, i.e., the ratio of diameter to focal length of the collimator lens which is the convex lens between light source and prism or grating; and by the *resolving power*, which is the ratio of any given wavelength λ to the smallest increment $d\lambda$ that can be distinctly observed, i.e., $\lambda/d\lambda$. The resolving power varies with the wavelength and spectroscope; it is largest for diffraction and echelon gratings, where it can reach 250,000.

Origin of Line Spectra. The most important part of spectroscopy is the one dealing with the line emissions or characteristic spectra of the various chemical elements. The occurrence of distinct frequencies of the emitted energy (lines) indicates a definite vibratory origin within the atom and is attributed to electronic oscillations of some rather vague kind (see Art. 3). The grouping of lines into series was first established empirically for the hydrogen spectrum, and a formula was given by Balmer (1885), later generalized by Rydberg (1890) as

$$n = N\left(\frac{1}{(m_1 + \beta_1)^2} - \frac{1}{(m + \beta)^2}\right) \tag{2}$$

---

* The adoption of the wavelength standard as exactly 6438.4696 angstroms represents, in fact, an absolute definition of the unit angstrom which is slightly different from the practical definition $1\text{A} = 10^{-8}$ cm as derived unit. It is, therefore, generally preferred to give wavelengths in millimicrons.

where N is a universal constant, the Rydberg constant, and n are the wave numbers (number of wavelengths per centimeter) of the various lines of any one series obtained by letting m take all integer values from unity on. The constants β and β_1 are characteristic for each individual series, and m_1 is a definite integer which determines the type of a series; thus $m_1 = 1$ gives the Lyman (ultraviolet), $m_1 = 2$ the Balmer (visible), $m_1 = 3$ the Paschen, and $m_1 = 4$ the Brackett (the last two in the infra-red), series of the hydrogen atom. In general each spectral line can be either a singlet, if even with largest resolving power only a single line can be detected, or a doublet, triplet, up to octet. The whole series is then referred to as a multiplet series, its order being equal to that of the highest order line that occurs in the series.

Energy Level Diagrams. For all elements the wave numbers of their characteristic line radiations can be brought into a form similar to equation 2 which was interpreted by Bohr (see Art. 3) as the difference of two definite energy terms. If multiplied by hc (h = Planck's constant, c = velocity of light in vacuum), equation (2) becomes

$$hcn = h\nu_{rs} = W_r - W_s \tag{3}$$

where ν_{rs} is the frequency of the spectral line. The energy terms can be computed from the known wavelengths of the radiations, and if arranged systematically, ascending from lower to higher absolute values of energy, the whole system of terms for an element is called its *energy level diagram*, which can be represented graphically. In the diagram each energy level is a *term* and belongs to a *sequence* which is designated by a capital letter as S (sharp), P (principal), D (diffuse), F (fundamental). The main terms of each sequence are differentiated by integer order numbers (the values m or m_1 in equation 2) in front of the letter symbols; a superscript indicates the multiplicity of the sequence (determined by the highest order multiple in the sequence); and a subscript designates the component of the multiple within the main term. For example, 3^4P_2 is the second component of the third main term of the principal sequence which is a quadruplet. The spectral lines, then are given by transitions like $3^4P_2 \rightarrow 2^3D_1$, the difference in the corresponding energies determining uniquely the frequency of radiation emitted according to equation (3). Empirical selection rules prohibit certain lines so that transitions are possible only between neighboring sequences, and only if the changes of the subscripts are $\pm$ 1 or 0.

Excitation of Line Spectra. Emission of the characteristic radiation occurs when electrons " fall " from higher to lower energy levels. For this to happen, atoms must first absorb energy and be " raised " to higher energy levels, which can be done either by bombardment with high-speed electrons (arcs, sparks), irradiation with x-rays, resonance radiation (incident radiation of same frequency as emitted radiation), or by collisions with atoms of the same or other elements.

Doppler Effect. A light source moving towards an observer with a relative radial velocity s appears to emit radiations of wavelength λ'

$$\lambda' = \frac{v - s}{v} \cdot \lambda$$

where v is the velocity of light and λ the absolute wavelength emitted by the source (Doppler, 1843). Spectroscopic identification of stars and planets reveals their relative velocities, s, when the spectral lines are compared with earthly sources. At very low gas pressures the thermal velocity of molecules can also produce a Doppler effect.

Zeeman Effect. Strong magnetic fields resolve the spectral lines of elements into a varying number (two to seventeen), of finer lines showing different states of polarization with, however, a typical structure for all lines. Zeeman (1896) first discovered this effect and propounded a simple theory. Quantum mechanics tries to explain it by means of a magnetic moment resulting from assumed " electron spins." A similar effect occurs when observing absorption lines in a strong magnetic field. This effect is called the *inverse* Zeeman effect, and occurs in the sunspots, indicating vast magnetic storms.

Stark Effect. Stark (1913) discovered that strong electric fields resolve spectral lines of various elements into a varying number of finer lines showing different states of polarization. The transverse effect upon different lines is different and depends either linearly or squarely on the field strength. A longitudinal effect (electric field parallel to light) has also been found. Explanations have been tried by assuming a change in the electrical potential energy of the orbital electrons.

Raman Effect. Transparent substances, if illuminated with strictly monochromatic light, can exhibit in their spectrum in addition to the strong line of the incident frequency (the only one to be expected according to the classical theory of scattering light) fainter lines of lower and higher frequencies (Raman, 1928). The presence of the new frequencies is explained by assuming that light is composed of photons which either lose energy to molecules or gain energy from excited molecules, as they pass through the substance.

11. ULTRAVIOLET RADIATION

The ultraviolet spectrum extends from approximately 380 mμ wavelength down to the softest x-rays. The longer ultraviolet rays, of vital importance for organisms, are often called *actinic rays*.

Absorption. Most optically transparent substances absorb ultraviolet radiation. Thus ordinary window glass does not transmit wavelengths shorter than approximately 350 mμ, whereas uviol glass, 1 cm thick, stops transmitting at approximately 300 mμ as do ordinary crown and flint glass. Quartz 1 mm thick is transparent for ultraviolet radiation down to a wavelength $\lambda = 170$ mμ, fluorite even to 100 mμ. One millimeter of air (at a pressure of 760 mm Hg) absorbs all wavelengths below $\lambda = 170$ mμ; the solar spectrum as measured on the surface of the earth stops at 250 mμ on account of the absorption by the air.

Refraction and Reflection. The refractive indices of the ultraviolet-transparent glasses and crystals show normal dispersion. Metals are highly absorbing and have low reflectivity in the ultraviolet region.

Spectroscopy of Ultraviolet. Since all glass absorbs ultraviolet radiation to a considerable extent, prisms and lenses for ultraviolet spectroscopy must be made of quartz or fluorite. In using quartz, correction must be made for the effects of double refraction and optical rotation. For spectrophotographic investigations of ultraviolet radiation of the shorter wavelengths, a vacuum spectrograph must be used on account of the absorption characteristics of air. Convenient sources of ultraviolet radiation are electric sparks between metals; each metal has a definite and characteristic spectral line distribution, one of which can be used as a standard for wavelength measurements. The most efficient source is the mercury-vapor arc.

The ultraviolet spectrum can be made visible by fluorescent screens or by photography.

Fluorescence. Many organic substances in solution emit characteristic monochromatic visible radiation, that is fluorescent, when illuminated by white light or ultraviolet radiation. These fluorescent substances strongly absorb radiations in the near and extreme ultraviolet region. Hence, to explain fluorescence, quantum theory assumes that this range will excite the electrons and raise them to high energy levels from which they may fall back in one or in several energy steps; in the latter case this gives rise to characteristic visible radiations. Table IX gives a few organic substances exhibiting strong fluorescence (from Handbook of Chemistry and Physics, 1933). Inorganic gases and vapors, as well as crystals, show fluorescence under certain conditions. Much valuable information can be found in R. W. Wood's Physical Optics. Practical use of fluorescence is made in luminous paints and in the analysis of paints, oils, and rubber, whereby impurities in composition can be detected by differences in fluorescent properties.

Table IX. Fluorescence of Organic Substances in Solution

(From Handbook of Chemistry and Physics)

Substance	Solvent	Wavelength (mμ)	Color
Anthracene	Alcohol	400, 430, 436	Violet
Quinine sulfate	Water	437	Violet
Esculine	Alcohol	460	Blue
Fluorescin	Water (alkaline)	542	Green
Rhodamin	Water	554	Yellow
Eosine	Alcohol or water	589	Yellow
Naphthalin, red	Alcohol	632	Orange
Resorcin, blue	Water	650	Red

Phosphorescence. A number of crystals show persistent fluorescence, even after the exciting source has been removed. Usually any prolonged luminescence of crystals is called phosphorescence;; however, a substance is truely phosphorescent only if small metallic impurities cause the storage of radiation energy.

Photography. Light-sensitive emulsions of silver bromide in gelatin on glass are capable of forming pictures by chemical action. Certain very small sulfur-containing organic bodies present in the gelatin react with the incident light and upon " development " form centers for the reduction of silver bromide to metallic silver. Ordinary dry plates are light sensitive in the wavelength range of 220 to 500 mμ with a maximum of sensitiveness in the violet. Below 250 mμ the gelatin begins to absorb strongly so that special plates are necessary. By utilizing fluorescence of organic substances in the various ranges of the visible spectrum, emulsions can be formed which are sensitive up to 720 mμ (known as verichromatic or panchromatic plates or films).

12. THERMAL (INFRA-RED) RADIATION

Thermal Radiation is assumed to be produced by the agitation of the molecules or atoms of a substance and extends continuously over a wavelength range from a characteristic minimum frequency up to wavelengths in the far ultraviolet. It represents a continuous energy distribution depending only upon, and being characteristic of, the temperature of the body. The term infra-red radiation refers to that part of the spectrum which extends from approximately 780 mμ up to the very shortest electromagnetic oscillations produced in electric circuits.

Kirchhoff's Law. For any body in thermal equilibrium at a certain temperature T the ratio of monochromatic emissive power E_λ to absorptivity A_λ is the same function of wavelength, or in other words, every substance emits as much heat radiation as it receives for any wavelength and temperature. This law was deduced analytically by Kirchhoff (1860) and has been verified experimentally.

Black-body Radiation. A black body is defined as being perfectly absorbing for all wavelengths, $A_\lambda = 1$. In this case Kirchhoff's law leads to $(E_\lambda/A_\lambda)_b = E_{\lambda b}$, or the characteristic function of Kirchhoff is identical with the spectral distribution of emissive power of a black body. For practical purposes, Lummer and Pringsheim showed that the characteristics of the black body are closely approximated by a heated hollow sphere with blackened inner surface. Through a small hole in the surface of the sphere the internal state of radiation can be observed with a bolometer. The experimental curve of the spectral distribution of black-body radiation is given in Fig. 2 for several absolute temperatures.

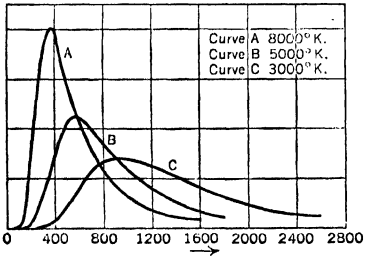

FIG. 2. Spectral Energy Distribution of a Black Body. The Ordinates of the Curves B and C must be divided by 6 and 50, respectively, in order to obtain the proper relative values.

Wien's Displacement Law. The wavelength of the black-body spectrum at which maximum radiation occurs for any particular temperature is connected with this temperature by the relation

$$\lambda_m T = 2900\ \mu^0 K \tag{4}$$

formulated by Wien. With this law, Wien also showed that, given a spectral distribution of radiation energy for one temperature T_1, the distribution curve for any other temperature T_2 can be constructed.

Spectral Distribution of Thermal Radiation. Introducing the concept of the "quantum" $h\nu$ as a definite fundamental unit of energy associated with the frequency ν, Planck (1900) formulated a theory of black-body radiation in which the various molecules are considered as oscillators having the same frequency but different and integer multiples of the energy unit. The monochromatic emissive power obtained as the statistical average over the contributions of all the molecules is then given by the exponential form

$$E_{\lambda b} = \frac{c_1}{\lambda^5} \cdot \frac{1}{e^{c_2/\lambda T} - 1} \tag{5}$$

where c_1 and c_2 are universal constants. Equation 5 gives very accurately the experimental curves obtained by Lummer and Pringsheim. For very small values of (λT) this leads to Wien's approximate expression for the spectral emissive power

$$E_{\lambda b} \approx c_1 \lambda^{-5} e^{-c_2/\lambda T} \tag{5a}$$

which is much simpler to use and gives good approximation even for the maxima of the spectral curves. For very large values of (λT) equation 5 leads to Rayleigh's approximate form for the spectral emissive power

$$E_{\lambda b} \approx \frac{c_1 T}{c_2 \lambda^4} \tag{5b}$$

which, again, is simpler to use than Planck's form.

Stefan-Boltzmann Law. Stefan showed empirically that for thermal radiation the total emissive power of a body varies with the fourth power of the absolute temperature. If two bodies of different temperatures exchange heat radiation, the rate of flow of energy per unit area from the higher temperature T_1 to the lower T_2 is given by $[\sigma \cdot (T_1^4 - T_2^4)]$, where σ is the Stefan constant of radiation, $\sigma = 5.735 \times 10^{-5}$ erg per sec per sq cm per deg Kelvin to the fourth power. This law was tested experimentally by Lummer and Pringsheim over a range from 100 to 1300 deg cent, and found to hold accurately.

Optical Pyrometry. The temperature of glowing solids and vapors can be determined by using the radiation characteristics of a black body. In many cases the emitter can be considered approximately as a black body, so that Wien's displacement law, equation 4, can be applied directly if λ_m is determined; or Stefan's law can be applied if a thermocouple is used to measure the total radiation. In the visible range, a photometer calibrated in terms of known temperatures may be employed. For emitters deviating appreciably from the black-body characteristics, corrections have to be made according to the method used. The temperature of the sun was found to be 6000 deg cent; that of the carbon arc crater, between 3500 and 4000 deg cent.

Measurement of Heat Radiation. Small energies, radiated for example by glowing bodies, can best be measured by a thermocouple which by the heat absorbed in the junction generates a small thermal electromotive force indicated by a galvanometer. To increase the deflection, a *thermopile*, a series arrangement of a number of thermocouples, can be used. The *bolometer* utilizes the increase of resistance of a thin blackened wire with the absorption of the heat rays; the wire forms one arm in a Wheatstone bridge. The *radiometer* measures the torque exerted when the heat rays fall upon small mica vanes in a low-pressure tube, the torque being produced by the unequal pressures set up on the two sides of the vanes.

Transmission of Infra-red Radiation. Most kinds of glass do not transmit wavelengths longer than about 2.5 μ; quartz will transmit up to 4 μ and fluorite up to 11 μ. The best material for use in infra-red spectroscopy is rock salt and sylvin, which transmit wavelengths up to 18 μ. Metals show, in general, high reflectivity over the infra-red spectrum, and act as almost perfect mirrors.

Spectroscopy in the Infra-red. The spectral distribution of emissive power in the infra-red spectrum is best determined by bolometric or thermocouple measurements. The refracting system must use fluorite, or rock salt, in order to avoid absorption of the infra-red rays. The calibration of the infra-red range is best accomplished by reference to the known absorption bands of water which extend beyond 6μ. Tungsten lamps or straight Nernst lamps serve as sources of infra-red spectra. For photographic spectroscopy specially prepared plates are required.

Residual Rays. Quartz, fluorite, and rock salt reflect certain wavelengths in the far infra-red almost perfectly. If, therefore, heat radiation is reflected several times from the surfaces of such crystals, all other radiations will be weakened considerably and almost pure monochromatic radiation remains, which is called *residual rays*.

13. PHOTOELECTRICITY

Photoelectric Effect. When a metallic surface is illuminated by light (preferably ultraviolet), x-rays, or γ-rays, electrons are emitted from the surface. Their number is strictly proportional to the intensity, their velocity is proportional to the frequency, of the incident radiation. This phenomenon was discovered first by Hertz, and later by Hallwachs, and is often referred to as *Hallwachs' effect*.

Einstein's Relation. If the photoelectric discharge is influenced by a supporting or counteracting potential, a definite negative stopping potential is found for each frequency, at which no emission occurs however strong the intensity of the incident light may be. This indicates that the frequency of the incident light is an essential factor in the liberation of the electrons. Einstein (1905) propounded a theory of light quanta in analogy to Planck's energy quanta of thermal radiation and proposed the relation

$$\tfrac{1}{2} mv^2 = h\nu - p \tag{6}$$

for the kinetic energy and thus the velocity of an emitted electron. The kinetic energy, therefore, appears as the difference between the energy $h\nu$ of the incident light quantum, $h = 6.55 \times 10^{-27}$ erg sec (Planck's quantum of action), and the work function p, i.e., the amount of energy needed to just force an electron from the metal; obviously p determines the stopping potential. The work p can be divided into one part ω needed to detach an electron from the atom and, therefore, a function of the position of the electron within the atom; and another part p' constituting the work to liberate the electron from the metal as a whole and, therefore, in close relation to Richardson's work function for thermionic emission (see Thermonics). Equation 6 has been found true even for incident x-radiation, the electrons liberated coming then from the inner shells of the atoms; consequently ω may now assume the most prominent part.

Photoconductivity. When a semi- or non-conductor with an electrical voltage applied at its ends is exposed to light, either transverse or parallel to the direction of the electric field, its resistance is instantaneously lowered and an appreciable current will flow. The primary effect is a true photoelectric effect, following the relation of equation 6, but many superimposed secondary effects mask it. In general, photoconductivity refers to any phenomenon wherein light influences the conductivity of the substance. Selenium and zincblende are the most striking materials exhibiting photoconductive properties.

Photoionization. Many gases and vapors when illuminated by light of short wavelength, preferably from the ultraviolet, show marked ionization phenomena as a result of the instantaneous absorption of photons. The vapors of the alkali metals being readily ionizable amplify the photoelectric effect normally present.

Photoelectric Cells. The industrial utilization of the photoelectric and photoconductive effects has resulted in various devices called photoelectric cells. In general, these cells are evacuated or gas filled and shielded from light except for a glass or quartz window through which the incident radiation enters and falls upon a target substance; the resulting photoelectric current is then indicated by a meter. According to the application of the cell, the window material can be used to correct the light sensitiveness of the target substance either to approximate that of the human eye, or to restrict it to some definite portion of the spectrum. Such cells are used as intensity meters in illumination design, as protective or active relays in power circuits, as regulating or governing devices, and in the transmission of pictures (television) and sound. Complete information is furnished by the catalogs of the manufacturing companies.

Spectrophotometry. Photoelectric cells are especially well adapted for comparative measurements of the spectral energy distribution of radiations, particularly in transmission and reflection spectra. Individual observation can be replaced by automatic recorders; color analyses as well as spectral line analyses are thus greatly facilitated.

14. X-RAYS

The X-ray Region in the electromagnetic spectrum extends from the shortest ultraviolet wavelengths at about 0.8 mμ down to 0.008 mμ. X-rays are essentially a secondary radiation produced when very high-speed electrons impinge upon a metallic target. They were discovered accidentally by Roentgen (1895).

Absorption of X-rays. X-rays are absorbed by all substances to a varying degree, depending upon wavelength and absorber. Usually a specimen of aluminum is taken as the reference standard for absorption measurements, and the mass absorption index μ_d of this specimen is used as a measure of the hardness of x-rays; the smaller μ_d, the harder the x-rays. A related measure is the penetration power giving the thickness of aluminum required to reduce the intensity of x-rays to a definite fraction of the incident intensity. The mass absorption coefficient shows very marked peak values for certain wavelengths which depend on the atomic number of the element and indicate a relation to the structure of the inner, more closely bound, electrons of the K, L, and M levels (see X-ray Spectroscopy).

Refraction of X-rays. The refractive index of most substances for x-rays is very slightly less than unity and shows in general normal dispersion. The measurement of the refractive index is extremely difficult and is mainly based upon the critical angle for total reflection. In the region of the wavelengths corresponding to the characteristic line radiation of substances, x-rays show very distinct anomalous dispersion which can be used for examining the structure of matter.

Ionization by X-rays. Quantitative measurements of x-ray intensities are in general based upon the ionization effects in air or gases. For this purpose special ionization chambers are used which give an indication of the rate of ionization produced by, and proportional to the intensity of, the x-rays.

Photographic Action of X-rays. X-rays produce in emulsions used for photographic purposes the same effects as ultraviolet light. On account of their relatively low intensity, the time of exposure is long, but can be shortened considerably by using " intensifying " screens, usually coverings of fluorescent character. Since x-rays cast shadows, and by their penetrating power render most substances transparent in varying degrees, photographs can be made which reveal the inner structural outlines of organisms. This application of x-ray photography is especially valuable in the medical sciences as a fundamental diagnostic help.

Diffraction of X-rays. An x-ray passing through a thin crystal plate produces on a photographic plate a bright central spot in the direction of the incident ray surrounded by a regular pattern of spots of distinctly different intensities. This pattern changes with the relative orientation of x-ray and crystal plate and obviously is caused by the diffractive interaction of the crystal structure and the x-ray photons. It is usually referred to as a *Laue pattern* and forms the basis of x-ray crystallography since its arrangement gives an indication of the internal structure of the crystals.

Bragg's Law. In order to explain the regularity of the pattern, Bragg assumed that each plane of atoms within the crystal individually reflects the x-rays, and he arrived at the relation

$$n\lambda = 2d \sin \theta \qquad (7)$$

where n is a variable integer, λ the wavelength of the incident x-rays, d the spacing between parallel atomic planes, and θ the angle between an atomic plane and the incident x-rays. The angle θ can be observed or computed from the distances between spots in the Laue pattern, so that equation 7 gives the relation between wavelength λ and grating space d of the atomic planes.

X-ray Crystallography. Bragg's law provides the means of exploring the atomic structure of crystals by observation of the Laue pattern. If the wavelength of the x-rays is known and the reflection angle θ observed, equation 7 leads to values for d. From Laue patterns with the x-rays incident in normal directions to the principal crystallographical planes, the distances of all possible atomic planes can be computed and finally the arrangement of the chemical atoms can be constructed. In locating the atomic planes the *Miller indices* are used; these constitute a triplet of numbers each designating the reciprocal of the intersects of the plane with a cartesian coordinate system. The triplet (2, 1, 0), for example, defines all planes parallel to one which intersects the x-axis at one half, the y-axis at one arbitrary unit, and is parallel to the z-axis. Table X gives for various crystals the spacings between atomic planes parallel to the plane indicated, and also the expansion coefficient which takes into account the change of the spacings with temperature. The value for rock salt (a cubic crystal) is defined for the face parallel planes as 0.281400 mμ and is used as a primary standard for crystallographic measurements.

Table X. Grating Spacings of Various Crystals

(From X-rays in Theory and Experiment, A. H. Compton and S. K. Allison)

Crystal	Parallel to to Plane	Grating Spacing in Angstroms	Linear Expansion Coefficient (perpendicular to crystal plane)
Calcite	Cleavage	3.029	1.02×10^{-5} per deg cent
Gypsum	Cleavage	7.579	3.78×10^{-5} " " "
Mica	Cleavage	9.928	1.53×10^{-6} " " "
Quartz	Prism	4.245	1.04×10^{-5} " " "
Rock salt	(1, 0, 0)	2.814	4.0×10^{-5} " " "
Sugar	(1, 0, 0)	10.57	

X-ray Analysis of Materials. The Laue pattern and its variation as the Debye-Scherrer pattern for pulverized crystals are used in industry for testing and checking of materials including the study of temperature influences, elasticity, hardening, melting points, and so on. *Radiography* refers to the industrial applications of x-ray photography and fluoroscopy for detecting flaws, inhomogeneities, yielding points in structural parts; to the investigation of materials under operating conditions; and to other uses. In art, the use of x-ray photographs permits the identification of true antiques, old paintings, and the like.

X-ray Spectroscopy. If x-rays fall upon a solid substance, a characteristic secondary radiation is observed which has for each chemical element a definite energy spectrum, although being similar in form for all elements. The spectral distribution of the secondary radiation can be investigated by utilizing Bragg's law (equation 7) if a crystal of known grating d is employed as analyzer. The intensity of the radiation can be measured either with the ionization chamber or by photography. Two types of spectra are discernible, a characteristic line spectrum and a continuous spectrum. The line spectrum is due to electrons in the inner orbits which by collision with the incident x-ray photons are raised to outer orbits and in returning emit radiation of a particular frequency. The continuous spectrum is due to the absorption by atoms of x-radiation of insufficient amounts to raise their electrons to higher orbits. There is for any hardness of incident x-rays a definite critical shortest wavelength at which the continuous spectrum abruptly ends. This wavelength limit constitutes the converse to the photoelectric effect, and the continuous spectrum is often referred to as the *inverse photoelectric effect.* From the line spectra, *energy level diagrams* can be deduced in the same way as in light spectroscopy (see Art. 10). The results of x-ray spectroscopy were instrumental in building up the nuclear models of atoms.

PHYSIOLOGY OF RADIATION

By Ernst Weber

15. VISION

The Eye. Radiation enters the eye through the cornea or outer coating, penetrates the anterior chamber (filled with aqueous humour), the lens, the posterior chamber (filled with a gelatinous, vitreous humour), and is received on the retina, a network of fine fibers which transmit in some way the sensory impressions through the optical nerve to the brain where they are transformed into perceptions. The range of radiation leading to visual perception is from approximately 380 to 780 mμ. The most sensitive point of the retina is called the yellow spot, and has a depression, the fovea centralis, where vision is most distinct. To bring objects into such relative position to the eye that they will be received at the fovea centralis requires a delicate adjustment apparatus which is provided by the muscle fibers holding the eye. Being a multirefracting medium, the eye suffers from both spherical and chromatic aberration (see Art. 5).

Fechner's Law. The sensation of light as produced by the eye varies logarithmically with the intensity of the stimulus. This law, found by Fechner to hold true for most sensory perceptions, is an excellent illustration of natural economy.

Spectral Visibility. The visual sensation of the eye varies greatly with the wavelength of light, reaching a maximum at about 556 mμ (yellow). If white light is used as a standard to be compared with the spectral monochromatic radiations, the relative intensity of white light causing the same sensation as the spectral light is called the *relative visibility.* The spectral distribution of relative visibility is shown in Fig. 1, assuming the visibility of yellow-green light, $\lambda = 556$ mμ, as 100 per cent. The visibility falls off very sharply from this maximum and shows that essentially only the wavelengths between 480 and 640 mμ constitute the easily visible spectrum.

Color Vision. The retina is composed of nervous fibers known as rods and cones, of which only the cones seem to be responsive to colors; the cones are, at the same time, fairly insensitive so that, at low intensities of light, colors cannot be distinguished (twilight vision). The rods are more sensitive; they contain a light-sensitive substance, the visual purple, but apparently they cannot transmit color sensation. Perception of color is not instantaneous; of all the spectral colors the blue sensations are most active, whereas the green sensations are most sluggish.

Purkinje Effect. At low intensities, before twilight vision is reached, there is a distinct shift of the maximum in the visibility curve (Fig. 1) towards a shorter wavelength; this is known as the Purkinje effect. This shift of the spectral visibility curve tends to make color sensations variable quantities, and color photometry very difficult.

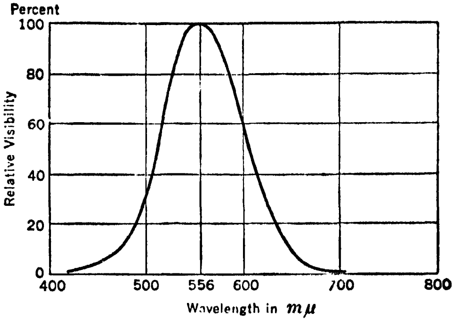

Fig. 1. Spectral Distribution of Relative Human Visibility

Theories of Color Vision. Two types of theories have been advanced to explain the facts of normal and abnormal color sensitiveness of the eye. The first type of theory is due to Young and Helmholtz, and proposes the existence of three distinct modes of response of the eye corresponding to the three fundamental color sensations: red, green, and blue. Each of these partial responses represents a definite spectral distribution, the perception of color being the superposition of the three partial responses; Fig. 2 indicates the partial responses for each wavelength. This theory is capable of accounting very readily for the specific types of color-blindness known as red and green color-blindness. The second type of theory initiated by Hering is based upon antagonistic colors and associates chemical building-up and breaking-down processes with the sensation of complementary colors; from this hypothesis it follows that complementary colors cannot be seen at the same point at the same time. This theory readily accounts for afterimages and contrast colors. It seems difficult to accept any one theory exclusively.

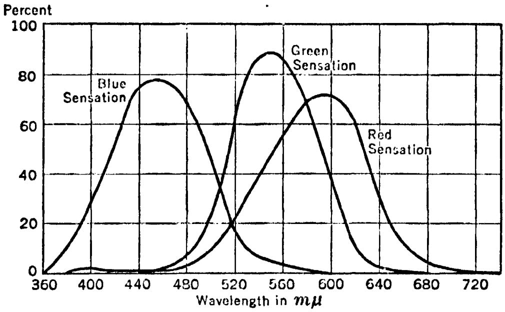

Fig. 2. Relative Excitation of the Three Primary Sensations by Monochromatic Light of Different Wave Lengths

Saturation of a color is its degree of freedom from admixture with white light. Monochromatic radiation can be said to have a saturation of 100 per cent, and white light is of zero saturation.

Hue is that property of color by which the various spectral regions are characteristically distinguished. It is most easily determined by comparison with the spectral colors as blue, yellowish, and so on. Equal hues can still differ in saturation. Complementary hues produce white light when mixed. White can be said to have no hue.

Brightness of a color is closely related to its diffuse reflection factor, and can be classified accordingly. It is customary for artistic purposes to distinguish the values of colors by their relative brightnesses. Table I gives the values of colors as suggested by Luckiesh.

Table I. Scale of Color Values

(From Light and Shade and Their Application, M. Luckiesh)

Artist's Scale		Suggested Scale Reflection factors in percentage	Artist's Scale		Suggested Scale Reflection factors in percentage
Symbols	Values		Symbols	Values	
B	Black	0–10	LL	Low light	50–60
LD	Low dark	10–20	L	Light	60–70
D	Dark	20–30	HL	High light	70–80
HD	High dark	30–40	W	White	80–90
M	Medium	40–50			

Tints are unsaturated colors of definitely recognizable hue.

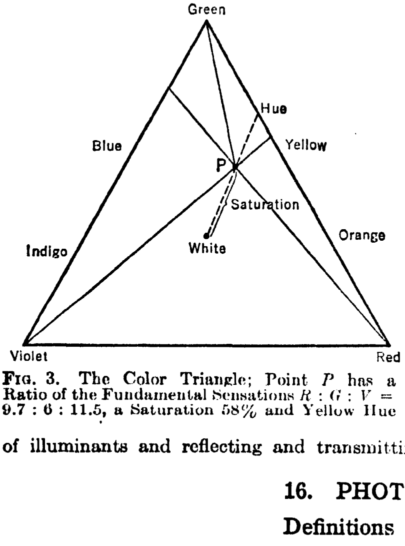

FIG. 3. The Color Triangle; Point P has a Ratio of the Fundamental Sensations $R : G : V = 9.7 : 6 : 11.5$, a Saturation 58% and Yellow Hue

The Color Triangle (Fig. 3). The laws of color mixtures and relative intensities can most readily be visualized in the so-called color triangle. Any point within the triangle indicates by its relative distance from the three fundamental colors in the apices the relative amounts of these fundamental colors. The resultant color, or hue, can be determined by drawing a line from the center (white) through the color point; where it intersects the triangle, the equivalent monochromatic wavelength can be read. The relative distance of the point on this line from the center gives the saturation in percentage.

Analysis of Colors. An objective means to determine the spectral energy distribution of light is provided by the spectral photometer (Art. 16). Automatic methods have been developed which are particularly useful in color matching and mixing, and in determining the characteristics of illuminants and reflecting and transmitting media.

16. PHOTOMETRY

Definitions and Units

Photometry deals with the measurement of light and in particular with the capacity of light to affect the eye. All photometric methods and definitions therefore must take into consideration light sensations as produced in the eye. The following definitions are based upon the standards of the United States Illuminating Engineering Society (IES).

Luminous Flux, F, is the rate of flow of radiant energy evaluated with reference to visual sensation. Although defined as a rate of flow of energy, it may be regarded for photometric purposes as an entity. The *lumen* is the unit of luminous flux and is equal to the flux emitted in a unit solid angle by a source whose average candlepower (see below) throughout the unit solid angle is 1 candle. A source having a uniform candlepower in all directions of 1 candle would emit 4π lumens.

Luminous Intensity, I, of a source of light in a given direction is the solid angular intensity of the luminous flux emitted by the source in the direction considered when the flux involved acts, as far as computations and measurements are concerned, as if it came from a point; mathematically it can be defined as $I = dF/d\omega$, where $d\omega$ is the elemental solid angle. The unit of luminous intensity is the *candle*, and the term candlepower is the luminous intensity expressed in candles. The *international candle* as accepted by France, England, and United States is defined with reference to the standard English sperm candle which under specified conditions is said to have a luminous intensity of exactly 1 international candle. The hefner is the standard used in Germany; it is defined with reference to a standard lamp of specified dimensions, burning amyl acetate or banana oil, and was invented in 1884 by Hefner-Alteneck. The value of the hefner is 0.9 international candle. The Bureau of Standards uses as a primary standard a pentane lamp of specified dimensions which gives an intensity of 10 international candles. Other standards have been proposed, but none seems reliable enough to warrant replacement of the pentane or Hefner-Alteneck lamps.

Mean Horizontal Candlepower of a source is the average intensity in a horizontal plane normal to the axis of the source. The *mean spherical candlepower* of a source is the average intensity over all directions; if the luminous flux is known, the mean spherical candlepower can be computed by dividing the flux by 4π.

Mechanical Equivalent of Light.* The luminous equivalent of radiation at maximum visibility (at $\lambda = 556$ mμ) is defined by

$$1 \text{ lumen} = 0.001496 \text{ watt}$$
$$1 \text{ watt} = 668 \text{ lumens.}$$

Illumination at a given point of a surface is the luminous flux incident on the surface at this point; mathematically it can be defined as $E = dF/dS$, where dS is the surface element receiving the flux element dF. A point source, giving a uniform luminous intensity I in a certain direction, sets up through the small surface dS perpendicular to this direction and at a distance R from the source the elemental flux $dF = I \cdot d\omega$; since the surface element is $dS = R^2 \cdot d\omega$, it follows that $E = I/R^2$ (inverse square law). The units of illumination depend on the reference area chosen and are called *lux* for 1 lumen per square meter, *foot-candle* for 1 lumen per square foot, and *phot* for 1 lumen per square centimeter. The interrelations of the various units are shown in Table II.

Table II. Interrelations between the Units of Illumination

1 Unit is equal to	Lux	Foot-candle	Phot	Milliphot
1 lux	1	0.0929	10^{-4}	10^{-1}
1 foot-candle	10.76	1	0.001076	1.076
1 phot	10^4	929	1	10^3
1 milliphot	10	0.929	10^{-3}	1

Brightness of a surface element dS is defined as the quotient of the luminous intensity produced by the surface element divided by the area as projected into the direction normal to the line from the observer to the surface element; mathematically it is defined as $b = dI(\theta)/dS \cdot \cos\theta$, where $dI(\theta)$ is the luminous intensity in the direction θ and θ the angle between the normal to dS and the line from dS to the observer. The unit of brightness is the candle per square centimeter. For perfectly diffusing surfaces the *average brightness* or flux brightness is used as a more convenient measure; it is defined as the total diffuse luminous flux emitted by one side of a surface element dS divided by dS, and its unit is the *lambert* which is equal to π candles per square centimeter. A more practical unit is the millilambert. For interrelations of the various units see Table III.

Table III. Interrelations between the Units of Brightness

1 Unit is equal to	Candle per sq cm	Lumen per sq cm per steradian	Candle per sq. in.	Lambert	Milli-lambert
1 candle per sq cm	1	1	6.4516	3.1416	3141.6
1 lumen per sq cm per steradian	1	1	6.4516	3.1416	3141.6
1 candle per sq in	0.1550	0.1550	1	0.4869	486.9
1 lambert	0.3183	0.3183	2.0538	1	1000
1 millilambert	0.3183×10^{-3}	0.3183×10^{-3}	0.0020538	0.001	1

Lambert's Laws. A perfectly diffusing surface receives an illumination or emits a luminous intensity (by reflection or true emission) which varies with the cosine of the angle between the normal to the surface and the direction of the incident or emitted (reflected) ray; for perfectly diffusing surfaces the illumination and brightness are therefore constant under all angles of observation. These cosine laws of incidence and emission are only approximately true for the practical substances so that in measurements of illumination or brightness the angle of observation always should be stated.

Instruments and Methods

Equality and Contrast Methods. Most photometric instruments compare an unknown light source with a known light source either simultaneously (comparison) or, by means of a third light source, alternatively (substitution method). To observe the equivalence of two sources either an equality method can be employed in which the two sources illuminate different parts of the same surface, the adjustment being made for equal brightness, or a *contrast method* can be used in which four fields are observed, two receiving light from one source and the other two from the other source, an absorbing medium decreasing the flux received on one field in each instance, and adjustment being made for equal contrast. The special type of table upon which most photometric measurements are made is called a photometer bench.

---

* H. E. Ives, *Journal Optical Soc. of America*, vol. 12, p. 75, 1926.

Bunsen Photometer. A piece of white paper with a grease or wax spot in its center is held between the two sources of light being compared. The relative distances between paper and sources are adjusted until the paper presents uniform brightness. If the luminous intensities of the two light sources are I_1 (known) and I_2 (unknown), and the distance for observation from one side of the paper r_1 and r_2, from the other side of the paper r'_1 and r'_2, then the unknown intensity follows as

$$I_2 = I_1 \frac{r_2 r'_2}{r_1 r'_1} \qquad (1)$$

The advantages are simplicity and cheapness; the error may, however, be as great as 5 per cent or more.

Lummer and Brodhun Photometer. The most essential part is the cube, a combination of two rectangular prisms so fitted together that the light reflected by mirrors from the two sources can be either compared for equality or adjusted for equal contrast. Calibrated filters may be used to adjust the light intensities. The accuracy is very high, about one-half of one per cent, and is considered the highest obtainable accuracy in photometric work.

Illuminometers. These are small portable photometers, usually employing some form of Lummer and Brodhun cube and having a small built-in electric lamp with either adjustable distance, or filters, or both. On a test screen the light from the known source is compared with either the light incident on a surface (illumination) or the light emitted by a surface (brightness). American designs are the Sharp-Millar and the Macbeth type, based upon the original Weber illuminometer. Care must be taken to shield properly and to avoid errors on account of deviations from the cosine laws.

Ulbricht Sphere. To measure the mean spherical candlepower, the Ulbricht sphere has come into predominant use. It consists of a large hollow sphere, coated with highly reflecting paint on its inner surface and having a window of transparent glass. The brightness of this window, shielded from the direct light of the source at the center of the sphere, is proportional to the mean spherical candlepower of the source and can be determined by an illuminometer.

Color Photometry. Methods have been devised which try to eliminate the influence of color in photometric work. The flicker photometer of Rood is perhaps the most useful means of utilizing the fact that two colored surfaces, if presented in quick alternation, appear colorless and thus permit a comparison of illumination. The most objective method is suggested by spectrophotometry, which, however, does not yield results immediately useful in photometry because the relative visibility of the human eye is not taken into account.

Colorimeters are instruments for the measurement of the hue and the saturation of colors. *Trichromatic* colorimeters mix the three fundamental sensations by means of glass filters in order to match the color to be determined; the hue and saturation can then be computed from the color triangle (see Art. 15). *Monochromatic* colorimeters first determine by comparison with the spectral colors the dominant hue of the unknown color and then mix it with white light until the proper saturation is obtained.

17. ELEMENTS OF ILLUMINATION

Artificial Light Sources

Artificial Light Sources. There are four distinct groups of light sources in common use for artificial lighting: the incandescent electric lamps, almost the exclusive illuminant in cities and wherever electricity is available under economic conditions; the illuminating gas and other flame sources where electricity is not economically available; the arc lamps mainly for special purposes; and the vapor lamps which have recently come into more prominent use for public lighting on account of their higher economy.

Luminescence and Incandescence. Radiation of energy can be produced thermally (incandescence), or by atomic or molecular excitation (luminescence). In the first case (incandescent lamps and flames) a continuous spectrum is usually produced which extends far beyond the visible range and thus seriously influences the efficiency. In the second case (arcs and vapor lamps) characteristic line radiation is produced which has sharply distinct color features; this radiation is particularly applicable for decorative and advertising lighting but has little value for ordinary illumination, except when properly corrected by mixed color radiations.

Luminosity Curves. Fig. 4 gives the spectral energy distribution curves of the common illuminants over the visible range. From the spectral distribution of radiated energy the luminosity curves for the various illuminants can be obtained if for each wavelength the relative energy is multiplied with the respective value at the same wavelength of the relative visibility curve from Fig. 1. The luminosity curve is the most important characteristic of illuminants as it shows graphically the distribution of optically useful energy. Unfortunately no single illuminant is known to give an energy radiation just within the visible range and distributed similarly to the sun's spectral energy distribution, which it is desirable to obtain since the maximum of the energy radiation of the sun almost coincides with the point of maximum visibility at λ = 556 mμ. The deviations of the energy distribution of most ordinary illuminants from the energy distribution of the sun account for their "color defects"; these can be corrected with sacrifices in economy.

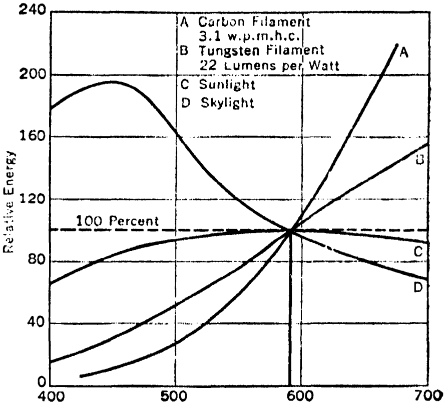

FIG. 4. Spectral Distribution of Radiant Energy in Some Common Illuminants

Luminous Efficiency. A comparison of the luminosity curve with the total radiation energy spectrum reveals the loss of radiation for optical purposes. It is customary to designate the ratio of the total luminous radiation in lumens to the total energy radiation in watts as luminous efficiency. Table IV gives a few selected values of luminous efficiency for the common illuminants and in addition those for the sun and the black body as a matter of comparison. Since the mechanical equivalent of luminous radiation (see Art. 16) is 668 lumens per watt, it is readily seen that the luminous efficiency of all the common light sources is extremely low and even for the sun not comparable with accustomed efficiency values in other fields of engineering.

Brightness of Light Sources. Table IV also gives the values of the brightnesses of various illuminants as compared with those of the sun and the black body.

Table IV. Luminous Efficiencies and Brightnesses of Light Sources

Light Source	Brightness (candles per sq cm)	Luminous Efficiency (lumens per watt)
Sun, outside of earth's atmosphere	200,000	100
at horizon	600	
Clear sky (average)	0.4	
Black body at 6500° K	294,000	90
at 4000° K	24,350	52.2
Electric arcs		
searchlight arc	50,000 to 70,000	
crater of carbon arc	16,000	
mercury-vapor arc (glass)	2.3	14
Incandescent electric lamps		
1000 watts, gas-filled tungsten	1,210	20.0
500 watts, gas-filled tungsten	1,000	18.1
100 watts, gas-filled tungsten	579	12.9
40 watts, vacuum tungsten	203	10.0
tantalum (2 watts per candle)	53.1	5.0
treated carbon (3.1 watts per candle)	70.6	3.4
untreated carbon (4 watts per candle)	54.9	2.6

Characteristics of Electric Incandescent Lamps. The characteristic curves of incandescent lamps give the variation with voltage of the light output in lumens, the efficiency in lumens per watt, the power input in watts, the current in amperes, and the resistance in ohms, taking all the values as 100 per cent at rated voltage which also is considered as

100 per cent. These characteristics can, with a reasonable degree of approximation, be brought into the exponential form

$$\frac{Q_1}{Q_2} = \left(\frac{V_1}{V_2}\right)^{\alpha} \tag{2}$$

where Q_1 and Q_2 are any two values of the characteristic quantities, and V_1 and V_2 the corresponding voltage values. The exponents α vary with the lamps as well as with the characteristic quantities. For ordinary tungsten lamps a 10 per cent voltage variation will cause about 35 per cent variation in light output (lumens), and about 15 per cent variation in the power input (watts). The changes are much larger for carbon lamps which have, however, the advantage of high cold resistance so that there is no initial transient rush of current as in all-metal-filament lamps. The efficiency is highest for tungsten lamps, reaching about 11 lumens per watt for the medium 60-watt lamps at 120 volts as compared with only 3.5 for the treated carbon lamp of equal size. The average life rating of the metal-filament lamps is 600 to 1000 hours, the higher values being for tungsten lamps, as compared with 2000 for carbon-filament lamps.

Principles of Good Lighting

Requirements of Good Lighting. Good lighting must have the following characteristics: it must be adequate, that is, it must provide sufficient illumination at the places needed; it must avoid glare; it must make use of lighting fixtures which properly diffuse and direct the light; it must employ light sources of suitable color and steadiness. Frequencies of 25 cycles per second and less in a-c systems are generally not suitable for good lighting as the constant flicker is very tiring for the eyes.

Glare is the discomforting effect of ill-directed light. It can be caused either by excessive luminous flux entering the eye from a large light source at a relatively small distance, by excessive brightness of a light source in the field of view as unshaded electric lamps or flames, or by excessive contrast in brightness between light source and surroundings as reflections from metals and polished surfaces or dark ceilings and walls. Glare is not only uncomfortable but also injurious to the eye if exposure is prolonged. It is especially important to avoid glare under working conditions. The best means to avoid glare is obviously to eliminate its causes by using indirect lighting, direct lighting from large distances, or properly designed diffusers, and by painting the walls and ceilings in light colors.

Diffusion of Light. Substances which transmit light but in diffused form are called translucent. Diffusely transmitted or reflected light is "softer" than regularly transmitted or reflected light and more comfortable to the eye. Good lighting employs properly diffused light as obtained either by placing diffusing materials in front of clear glass lamps or by using translucent glass bulb lamps of the frosted or white type; the reduction of the intensity of light is approximately between 5 and 15 per cent, the higher reduction being for the white glass bulb.

Directive Reflection of Light. To direct light to the places where it is needed, reflectors of either metallic or enamel type are used. It is convenient for non-commercial lighting to combine reflection and diffusion; for this purpose porcelain enameled steel or mat surfaces of white paint should be used which have a diffuse reflection factor of about 0.6 to 0.8, the higher factors for paints. Metallic coatings on the bowls of lamps are used in indirect lighting to enhance the light flux thrown on the ceiling; silver has the highest reflection factor (0.92) but deteriorates very rapidly, whereas chromium, tin, or aluminum with reflectivities of 0.65 to 0.62 are more durable and therefore to be preferred. To provide economical indirect lighting the ceiling should be of white plaster which has a diffused reflection factor of 0.90 to 0.95 when new, or 0.80 to 0.85 when old. It must be observed that all the energy not reflected by a reflector is absorbed by it and tends to raise its temperature. It is also important to know the angular distribution of the reflected light intensities in order to shape the reflectors properly; this is usually determined by measurement with photometers. Tables and figures can be found in F. E. Cady and H. B. Dates: Illuminating Engineering, John Wiley & Sons, 1928, p. 300 ff.

Reflection from Walls. It is important to consider the wall finish and its influence upon the lighting characteristics of a room. The various colors have different reflectivities, usually higher for the lighter and lower for the darker tones. Surfaces with reflectivities less than 0.50 usually appear agreeable if in mat finish. Table V gives the reflectivities of various colored surfaces (see also Table V, page 9-16, for the diffuse reflectivities of various materials).

Recommended Illuminations for Various Purposes. To have adequate illumination at the point at which the eye is directed most of the time, certain recommendations are made by the various factory codes which can be found in the publications of the American Engineering Standards Committee. It is the generally accepted recommendation to use

Table V. Reflection Factors from Colored Surfaces
(For illumination by Mazda lamps)

Reflection Factor in Per Cent	Colors of Surfaces					
80 to 75	Ivory white					
75 to 70	Ivory					
70 to 65	Bright yellow	Light gray				
65 to 60		Lichen gray	Buff	Latin green		
60 to 55		Silver gray	Tan (Ivory)		Pale azure + white	
55 to 50		Medium gray	Buff stone			Shell pink
50 to 45		French gray		Light green		Pink
45 to 40		Darker gray		Bright sage	Pale azure	
40 to 35			Light brown		Light blue	
35 to 30					Sky blue	
30 to 25			Tan			
25 to 20		Dark gray	Brown	Olive green		
20 to 15		Dark gray	Cocoanut brown	Forest green		Cardinal red

50- and 60-watt lamps in homes and in low-ceiling offices in order to insure adequate illumination for general purposes. Table VI gives a selected list of recommended values for illumination.

Table VI. Recommended Values of Illumination
(Standards set by the various codes sponsored by the American Engineering Standards Committee)

Space	Illumination (foot-candles)	
	Recommended	Minimum
Auditorium	5	3
Cars (railway)	8	5
Club rooms: lounge	5	3
reading room	12	8
Drafting rooms	25	15
Gymnasium: shower and locker rooms	6	4
swimming pool	8	5
exercising floors	12	8
Halls	3	2
Hotels: lobby	8	5
dining room	6	4
writing room	12	8
corridors, stairways	3	2
Libraries: reading room	12	8
stack room	6	4
Offices: close work	15	10
no close work	10	8
file and other rooms	6	4
Schools: auditorium	8	5
corridors	5	3
laboratories	12	8
classrooms, library, study rooms	12	8
drawing rooms	25	15
Walks	0.5	0.1
Factories: roadways, yard thoroughfares		0.02
storage spaces		0.25
where discrimination is not essential		0.5
where slight discrimination is essential		1
where moderate discrimination of detail is essential		2
where close discrimination of detail is essential		3
where discrimination of minute detail is essential*		5

13. THERAPY OF RADIATION

All radiations of the electromagnetic spectrum have been found useful for therapeutic purposes. The physical properties of the radiations are to be found under Physics of Radiation, page 9-15.

Infra-red Radiation

Physiological Action. Infra-red radiation produces heat (Art. 12) when absorbed by organic tissues, which, in general, show more or less selective absorptivity. In the visible range most of the radiation is absorbed by the skin and the superficial layers of flesh; for deep therapy, wavelengths in the range from 700 to 1500 mμ (near infra-red) prove most penetrating, the skin being apparently more transparent for these wavelengths. Beyond 2μ, the longer the wavelength the less penetrating will be the radiation. The heat produced by infra-red radiation has decided thereapeutic effects on arthritis, fractures, and internal injuries and acts stimulatingly on the muscles and tendons.

Sources of Infra-red Radiation. The natural and most efficient source for infra-red therapy is the sun. Next come the gas-filled tungsten lamps glowing at about 3000 deg K which give off very high radiation energies in the near infra-red. Carbon lamps at lower temperatures and other glowing sources and flames have characteristic radiations with band spectral energy distributions of varying widths and locations; they are in general less efficient than tungsten lamps.

Ultraviolet Radiation

Physiological Action. Ultraviolet radiation (Art. 11) is highly stimulating and seems of utmost importance for organic life; the wavelength range from 300 to 400 mμ constituting the shortest-wavelength part of the daylight spectrum and often referred to as "actinic rays" is of particular practical value. Shorter wavelengths also have decided therapeutic effects on human beings; they are, however, easily absorbed by air so that proper care has to be taken to use non-absorbing materials in the path of the rays. Wavelengths at about 280 mμ are supposed to be injurious to organisms and should be avoided in therapeutic uses. In the range from 200 to 300 mμ ultraviolet radiation is highly germicidal and is used practically for the sterilization of food and water supplies. Ultraviolet therapy is entirely superficial, is absorbed by the skin, and produces the tan or sunburn. It is important to time the exposure to ultraviolet radiation and to increase the exposure gradually from very short intervals to not more than about one-half hour depending on the strength of the source and its spectrum.

Photochemical Actions. Industrially the strongly actinic effects of ultraviolet radiation are utilized in chemical processes of bleaching, vulcanizing, and so on. The more recently found food vitamins which are essential for health and the proper performance of biological functions are influenced by ultraviolet radiation, and their production can be stimulated by short-time irradiations. In particular, vitamin D, known to possess antirachitic qualities, is produced industrially in this way.

Sources of Ultraviolet Radiation. Again the most important source is natural sunlight. Artificial sources are provided by the pure carbon arcs; the blue and white burning arcs have slightly different characteristic line radiations in the ultraviolet region. The most important source for therapeutic uses is, however, the high-pressure mercury-arc lamp which produces very strong line radiations in the near ultraviolet—the most active range; high-power mercury arc lamps use water cooling to reduce the heating effects.

X-radiation

Physiological Action. X-radiation is injurious to most organic tissues but can be utilized, if properly directed, to destroy malignant internal growths as well as to cure skin diseases. It is the most widely used weapon in non-surgical medical treatment. The penetrating power of x-rays depends on the voltage of the x-ray tubes; their destroying action, on the voltage and the time of exposure (dosage). Over-exposure causes very severe burns lasting for a disproportionately long time; great care has to be taken to avoid even slight burns.

Sources of X-rays. The Coolidge vacuum x-ray tube with an applied voltage of 10 to 100 kv is the most commonly used source of x-rays; voltages up to 220 kilovolts are used if particularly high penetration power is desired. For production and properties of x-rays see Art. 14.

Dosage of X-rays. The energy of x-rays can be determined by ionization measurements (see Art. 14). A unit of x-ray energy has been defined from ionization measurements, the *international Roentgen*, which is equal to that quantity of x-radiation which produces in a standardized ionization chamber under normal conditions (0 deg cent and 760 mm Hg) an indication of 1 electrostatic unit of charge. Dosage meters are available which give a visual indication of the ionization produced by the x-rays. With the dosemeter, when inserted in the x-ray apparatus, there is often connected an automatic switch which controls the time of exposure so as to make it independent of human action. On account of the danger of burns, x-ray treatment should never be administered except by properly trained persons.

ACOUSTICS

By R. B. Lindsay

19. NATURE OF SOUND

Sound, from the physical point of view, consists of compressional disturbances produced and propagated in solid or fluid media. This includes not only those disturbances which are ultimately (by transmission through the air) audible to the individual but also a large field of disturbances (supersonic, etc.) which are outside the range of audibility and are rendered evident to the senses in other ways, e.g., by touch, etc. The whole field is usually known by the name *acoustics*.

Consider a metal bar which is struck with a hammer. Originally all parts of the bar are at rest with respect to one another; equilibrium exists. The impact of the hammer upsets the equilibrium and squeezes a portion of the bar by producing a relative displacement. (Note that if the bar were rigid it would have to move as a whole—but no material medium is rigid.) The motion of the "squeeze" along the rod constitutes what is called a *compressional wave*. If the rod is in air some of the motion is communicated to the air in its neighborhood and a compressional wave in air results.

The study of acoustics is concerned with the production of such disturbances, their propagation, and their absorption. It must be remembered that the displacements from equilibrium involved here are usually very small. In particular in the case of harmonic or sinusoidal sound waves in air the maximum fractional change in density due to the passage of the waves having the intensity of conversational speech is of the order of 10^{-7} and the maximum corresponding change in pressure (the so-called excess pressure) is about 1 dyne per sq cm. A compressional wave of the same intensity in a metal like platinum at ordinary temperature will correspond to a maximum change in stress of about 370 dynes per sq cm but the corresponding fractional change in density is only of the order of 10^{-10}. The solid is of course much less compressible than the gas. The displacement velocities involved in such displacements are also ordinarily very small, varying from 10^{-2} cm per sec for plane waves in gases to about 10^{-5} cm per sec for similar waves in solids. This velocity, however, must not be confused with the velocity of propagation of the sound wave itself, which may be very large (see Art. 20).

General Properties of Sound Waves. For practical purposes the most important type of wave is the simple harmonic or sinusoidal. A snap-shot picture of a plane wave of this character progressing in the x direction is symbolized in Fig. 1 where a part of such a wave is shown. The ordinate measures the displacement ξ which is being propagated. The maximum ordinate, A, is called the *amplitude* of the wave. A positive maximum is said to correspond to a *crest*, a negative one to a *hollow*. The distance between two successive maxima is the *wavelength*, designated by λ. The wave propagation corresponds to the motion of the whole figure to the right along the x axis with a velocity c. Mathematically such a situation can be symbolized by

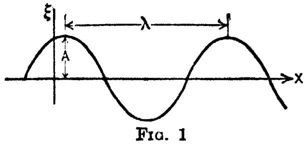

Fig. 1

$$\xi = A \sin \frac{2\pi}{\lambda}(ct - x) \tag{1}$$

It may be noted that either the sine or the cosine may be used. The number of complete wavelengths which pass a given point per second is the *frequency* of the wave, usually denoted by ν and referred to in cycles or cycles per second. The relation

$$\lambda = \frac{c}{\nu} \tag{2}$$

is fundamental in the theory of harmonic waves. Written in terms of frequency

$$\xi = A \sin (\omega t - kx) \tag{3}$$

in which $\omega = 2\pi\nu$ and $k = \omega/c = 2\pi/\lambda$. This form is often preferred because of its greater simplicity. The quantity $\frac{2\pi}{\lambda}(ct - x) = \omega t - kx$ is called the *phase* of the wave.

Types of Waves. The wave symbolized by equation (1) is called a plane wave because the displacement at a given time and value of x is the same over the whole plane through this point perpendicular to the x axis, or, as is sometimes said, all points in this plane are in the same phase. Using still another common phraseology the *wave front* of the wave is a plane. Another type of wave of great value in acoustics is the *spherical* wave in which the wave fronts are spheres. Such a wave results when a disturbance takes place at a point in a homogeneous medium and spreads in all directions from this point as center with the same velocity. Far away from the source a small portion of the wave front may be considered a plane.

Although sound waves have been considered as compressional waves in a material medium, it is quite possible for other types of elastic waves in solids to give rise to acoustic waves in air. Thus the transverse waves in strings, membranes, plates, and rods are of importance in sound. These will be mentioned later in Art. 26.

The progress of a sound wave in air can be made visible by a method due to Foley. (*Physical Review*, vol. 35, 373, 1912.) The wave sent out by a spark discharge is photographed in the light of another suitably timed spark, the excess density produced by the passage of the wave providing enough change in the refractive index of the air to register on the photographic plate. This method is valuable in the picturization of the reflection, refraction, and diffraction of sound.

20. VELOCITY OF SOUND

The general expression for the velocity of a compressional wave in a deformable medium is

$$c = \sqrt{\frac{dp}{d\rho}} \tag{4}$$

where dp is the change in *pressure* accompanying the change $d\rho$ in *density*. Since the compressions and rarefactions accompanying the propagation of sound through a gas are adiabatic, the relation between pressure p and volume V is the well-known one

pV^{γ} = constant (γ being the ratio (c_p/c_v) of specific heat at constant pressure to that at constant volume), and equation (4) becomes for a gas

$$c = \sqrt{\frac{\gamma p}{\rho}} \tag{5}$$

In the case of air, for example, for $p = 1$ atmosphere $= 1.01 \times 10^6$ dynes per sq cm and $\rho = 0.001205$ gram per cu cm at 20 deg cent and 76 cm of Hg and $\gamma = 1.403$, $c = 344$ meters per sec in good agreement with the experimental value.

The Velocity of Sound in a Perfect Gas is independent of the pressure. This is practically true of all real gases, although a slight increase is observed with pressure of the order of 50-100 atmospheres (see International Critical Tables, Vol. VI). The temperature dependence is obtained from equation 5 by the use of the general gas equation, which for a perfect gas is $pV = RT$, T being the absolute temperature and R the gas constant. Thus the velocity at any temperature t degrees centigrade in terms of the velocity at 0 deg cent is given by the formula

$$c_t = c_0\sqrt{1 + t/273} \tag{6}$$

For air in the neighborhood of 0 deg cent and room temperature the increase in c is about 0.61 meter per sec per degree centigrade. The velocity of sound for gases is always lowered slightly by confinement in a tube.

The Velocity of Sound in Air depends slightly on the presence of water vapor. Thus for saturated air at 20 deg cent and standard pressure, c is about 0.40 per cent greater than for dry air at the same temperature and pressure.

For velocity of sound in a *liquid* equation (4) takes the form

$$c = \sqrt{\frac{E}{\rho}} = \sqrt{\frac{1}{K\rho}} \tag{7}$$

where E is the bulk modulus or coefficient of volume elasticity, and in the alternative form K is the compressibility. Both E and ρ depend on the temperature and pressure, but since the equation of state of liquids is not known in general form the precise temperature and pressure dependence of c in this case can be described only by empirical formulas relating to specific substances. The velocity of sound in liquids is almost uniformly greater by a factor of several times than the velocity in gases, the one notable exception being hydrogen where c at 0 deg cent is 1270 meters per sec. In general, aqueous solutions have higher c than water.

The Velocity of Sound in Solids is given by the formula

$$c = \sqrt{\frac{E + 4\mu/3}{\rho}} \tag{8}$$

in which μ is the *shear* modulus or *rigidity* of the solid. For the case of compressional waves in long narrow rods equation (8) must be replaced by

$$c = \sqrt{\frac{Y}{\rho}} \tag{9}$$

Y being Young's modulus. For a large number of solids the former velocity is greater than the latter by roughly 10 per cent. It is interesting to note that the velocity of transverse waves (i.e., flexural or torsional) in a solid is given by $c = \sqrt{\mu/\rho}$, which is less than the value from equation 8 for any given solid under the same conditions. In general the velocity in metallic solids exceeds that in non-metallic solids, although glass, marble, and some varieties of wood are decided exceptions. In the latter case the velocity naturally depends considerably on the relation of the direction of the sound propagation with respect to the grain of the wood. Few data are available on the direct measurement of the velocity of sound in crystals, metallic or otherwise.

Change of Velocity with Frequency. Equation (4) would indicate that the velocity of sound is independent of the frequency. This is found to be approximately true for sound in gases. Pierce * found, however, that the velocity of sound in air at 0 deg cent varies from 332.45 m per sec at 41,009 cycles per sec to 331.64 m per sec at 1,479,900 cycles per sec. This is for entirely unconfined air. The velocity of sound in liquids is slightly dependent on the frequency but the change is small, that in water being a decrease of only 5 per cent as the frequency ranges from 40,000 cycles to 600,000 cycles. The variation with frequency of sound velocity in solids has not yet been studied thoroughly enough to state conclusive results.

---

* *Proc. Am. Acad. Arts and Sci.*, vol. 60, p. 271, 1925.

When gases and liquids are confined in tubes the decrease in velocity due to viscosity may be considerable. This is also a function of the frequency, the change here growing smaller as the frequency increases (see Art. 24).

Since a sound wave is propagated through a material medium, the sound velocity depends on the large-scale motion of the medium. Hence in the free atmosphere the velocity is considerably affected by wind currents.

Wave Length of Sound Waves. A harmonic wave with frequency 256 cycles per sec has a wavelength in air at 20 deg cent of 1.34 meters. In water at the same temperature the wavelength is 5.70 meters, and in a brass *rod,* 13.7 meters. The influence of the change in velocity with the nature of the medium is evident.

FIG. 2

Doppler Effect. When a source of sound moves relatively to an observer, a phenomenon occurs which is known as the *Doppler effect.* Consider a stationary observer at B, Fig. 2 (i.e., stationary with respect to the air), with the sound source at A emitting waves of frequency ν moving towards him with velocity v which is assumed less than c, the velocity of sound in a stationary medium. Since the frequency of the source is ν, this is the number of waves sent out in 1 sec while the source is moving from A to C. These waves will strike the ear of the observer within $1 - v/c$ seconds. Consequently the frequency of the sound as he will observe it is not ν, but

$$\nu' = \frac{\nu}{1 - v/c} \tag{10}$$

Otherwise expressed, there is an apparent increase in the pitch. This is easily observed when a train with whistle blowing approaches one, and is even more commonly noted with approaching automobiles.

When the source recedes from the observer, fewer waves are received per second and the apparent frequency, ν'', is lower than the true frequency. Then

$$\nu'' = \frac{\nu}{1 + v/c} \tag{11}$$

The situation is similar though not identical when a moving observer approaches or recedes from a stationary source. Here the observer, so to speak, goes to meet or runs away from the waves, respectively. Analysis shows the relations between apparent and true frequencies, for approach and recession, respectively, to be:

$$\nu' = \nu(1 + v/c) \tag{12}$$

$$\nu'' = \nu(1 - v/c) \tag{13}$$

The velocity v may be larger than c, resulting in the " bow " wave, characteristic, for example, of the flight of a rifle bullet through the air.

21. REFLECTION AND REFRACTION

The concept of an acoustic wave traveling forward steadily in one direction or spreading outward from a single source is a highly idealized one. Actually all acoustic waves move in bounded media and wherever boundaries are encountered the phenomena of reflection and refraction occur resulting in more or less complicated wave patterns.

Reflection. As a simple illustration, suppose that a plane wave of sound progressing to the right meets a rigid wall parallel to the wave front. Reflection takes place, i.e., the space to the left of the wall is now occupied by a wave moving toward the left as well as the original wave moving toward the right. Symbolically the disturbance may be represented by

$$\xi = A \sin(\omega t - kx) + B \sin(\omega t + kx + \varepsilon) \tag{14}$$

where the term with the plus sign before the kx represents the reflected wave, A and B are the amplitudes of the two waves respectively, and ε is the phase change that accompanies reflection. ε can be shown to be zero when a plane wave of sound is reflected in going from an acoustically rare to an acoustically dense medium, from air to a rigid wall, for example. When the sound is reflected in going from a dense to a rare medium, e.g., water to air, the change of phase is π. It is to be understood in this result that the positive direction of particle displacement is always in the direction in which the wave is being propagated.

The Acoustic Density is measured by the product of the ordinary density and the velocity of sound in the medium. This quantity is called in technical acoustics the *specific acoustic resistance* * for a plane wave (see Arts. 23 and 33).

---

* See bibliography, page 9-54, references 8, 10, and 13.

Echo. When sound in air is reflected from a large wall or barrier the result is known as an *echo*. This will be recognized as a distinct sound if the reflecting surface is sufficiently far away from the observer so that the original sound has died down by the time the reflected wave reaches him.

Reverberation. If a multitude of echoes follow on each other at very short time intervals the result is known as *reverberation*. This is observed in large closed spaces and if the walls and other objects in the room are not sufficiently absorbing can constitute a serious impediment to hearing in halls (see Art. 32).

Reflecting Surfaces and Media. If the surface dimensions are large compared with the wavelength of the sound, the incident plane wave beam will be reflected approximately as such; but if the dimensions are small compared with the wavelength the reflected sound will be scattered in all directions. In the former case the sound that might be scattered outside the beam is nullified by the interference of the reflected waves (i.e., the cancelation of the crest of one wave by the hollow of another) from various parts of the reflector. This interference is no longer materially operative when the reflector is small. It thus turns out that plane reflectors exercise a selective action.

Sound waves can also be reflected in other types of mirrors, e.g., parabolic, in which if a point source of sound is placed at the focus the reflected sound will consist largely of plane waves with wave front normal to the axis of the mirror. Owing to the relatively large wavelength of audible sound in air the focusing of sound in such a mirror is not very precise. The situation is even worse in liquids.

Reflection occurs not only when a sound wave encounters the boundary between two media but also when sound passing down a tube meets an abrupt change in area. The fractional sound energy (see Art. 27) reflected compared with the incident energy can be readily computed * and turns out to be

$$\left(\frac{S_1 - S_2}{S_1 + S_2}\right)^2 \tag{15}$$

where S_1 and S_2 are the two areas of cross-section in question. It is usually assumed for elementary purposes (Art. 26) that when a plane wave of sound passing through a tube is incident on the open end, the reflection is complete. This of course is not entirely true since some radiation takes place.

Oblique Reflection. The discussion of reflection so far has been confined to the case where the incident sound wave front is parallel to the reflecting surface. In unconfined regions, of course, oblique incidence is more common. Reflection then follows the optical law: *the angle of reflection equals the angle of incidence.* The ratio of the sound energy per square centimeter per second reflected to that incident is *

$$\left(\frac{\rho_2/\rho_1 - \cot\theta_2/\cot\theta_1}{\rho_2/\rho_1 + \cot\theta_2/\cot\theta_1}\right)^2 \tag{16}$$

where ρ_1 and ρ_2 are the mean densities of the two media respectively at the boundary of which the reflection takes place, and θ_1 and θ_2 are the angles of incidence and refraction respectively.

Refraction. With oblique incidence there also occurs transmission into the second medium accompanied by bending of the wave front, i.e., *refraction.* The law of refraction is the same as that of Snell in optics, namely,

$$\frac{\sin\theta_1}{\sin\theta_2} = \frac{c_1}{c_2} \tag{17}$$

Very good illustrations of the refraction of sound are provided by transmission through the atmosphere in which a temperature gradient and winds exist. A wave traveling from a region of high temperature to one of low temperature has its front bent toward the normal. Actually there are usually no sharp boundaries and the bending is a more or less continuous process. The increased range of sound in still air when the temperature gradient is negative, i.e., cold air near the ground and warmer air higher up, is to a considerable extent accounted for by this refraction. Acoustic mirages have the same source. Refraction also takes place when sound passes through a region where the wind velocity is changing from place to place. This is called convective refraction, and it is well to note that the wave front is then no longer normal to the *ray* as it is in a stationary medium.

Reflection and refraction play a considerable rôle in the scattering of sound in the atmosphere, which is found in general to be greater for high frequencies than for low.

*** See bibliography, page 9-54, reference 13.**

22. DIFFRACTION

Effect of Rigid Obstacles. When sound in passing through a medium encounters a more or less rigid obstacle in addition to reflection and refraction there results *diffraction*, i.e., the *bending* of the sound waves around the obstacle. Here the situation is precisely analogous to the behavior of light waves in passing the edge of an obstacle. Acoustical diffraction accounts for our ability to hear sound around a corner and at the same time for the difficulty of producing sharp acoustic shadows with ordinary audible sounds; the sound waves with their greater length are able to bend more than the very much shorter light waves. The reception of sound by the individual auditor is largely conditioned by the diffraction caused by the human head. A careful study has been made of this, for the effect both on speech and on hearing. It is found,* for example, that for a point source on a rigid sphere there are two directions of maximum intensity, one directly in front of the source and the other directly behind the sphere, the latter intensity being naturally the smaller of the two. The intensity falls to a minimum in a direction approximately at right angles to that of maximum intensity. The angle increases with increasing frequency of sound and the magnitude of the minimum intensity decreases as the frequency increases, i.e., short-wavelength sounds do not so readily bend around the spherical obstacle. For a given frequency the variation in intensity around the obstacle is greater near than far from the sphere.

A similar discussion can be given for a sphere having two sound receivers on the opposite ends of a diameter (e.g., the head with the two ears). It turns out that the intensity of an outside source of sound at the sphere is greatest when the line joining the two receivers is directed toward the source and least when the line is perpendicular to the source direction. Here again for given source distance the difference is more marked for short waves than for long and for a given wavelength more marked at short distances than long.

These results have an immediate application in respect to the human head and to sound-receiving instruments like microphones for mapping the distribution of sound intensity in a room. The diffraction of sound due to the presence of such instruments can thus be compensated for theoretically.

Scattering. The special phenomenon of diffraction by an obstacle of dimensions much smaller than the wavelength is known as *Rayleigh scattering*. Here the sound is scattered in all directions and its intensity varies inversely as the fourth power of the wavelength, analogously to light scattering. "Harmonic" echoes are due to this type of scattering. When a compound musical note is sounded near a group of obstacles like a grove of trees the intensity of the octave is raised above that of the fundamental by the scattering.

When sound emerges from an opening, diffraction produces in general a scattering in all directions. If the frequency is very high this effect is much reduced and a more or less sharp beam of sound results. This suggests the use of supersonic waves in signaling (see Art. 29).

Diffraction is also important in the use of baffle plates in some loud speakers. The actual calculation of the diffracting effect of such plates is extremely complicated.

23. INTENSITY OF SOUND

Definition. The propagation of sound waves involves the transfer of energy, and it is this idea which is expressed in the concept of acoustic intensity, which is the *average* rate of flow of energy per unit area normal to the direction of propagation. Care must be taken to distinguish between intensity and loudness. The former is a purely physical quantity, whereas the latter is a physico-psychological one. We shall discuss it further below. At the moment consider merely the intensity. It can be shown that the intensity I of a plane or spherical wave (the two predominant types) is given most simply by the formula

$$I = \frac{1}{2}\frac{p^2_{\max}}{\rho_0 c} \qquad (18)$$

where $p_{\max}$ = maximum excess pressure, ρ_0 = average density, and c = velocity of the wave. The quantity $\rho_0 c$ is the *specific acoustic resistance* of a plane wave. For a given $p_{\max}$, a large acoustic resistance means a small intensity, and vice versa. This has considerable bearing on all acoustic transmission problems, e.g., sound proofing and reduction of noise (see Art. 33).

For a sound wave in air at 20 deg cent and 76 cm of Hg the intensity of ordinary conversational speech (with $p_{\max}$ = 1 dyne per cm^2) is approximately 1.21×10^{-9} watt per

---

* See bibliography, page 9-54, reference 13.

$cm^2 = 1.21 \times 10^{-3}$ microwatt per cm^2. Interestingly enough it develops that the ear is sensitive to sounds of intensity as low as 4×10^{-10} microwatt per cm^2. It should be noted that the frequency does not enter (18) explicitly. On the other hand, if the intensity is expressed in terms of displacement amplitude instead of pressure, the frequency ν is necessarily involved, equation (18) being replaced by

$$I = {}^1/_2\, \rho_0\, c\omega^2\, \xi^2_{\max} \tag{19}$$

with $\xi_{\max}$ = maximum displacement and $\omega = 2\pi\nu$. For constant amplitude the intensity thus varies as the square of the frequency. Hence for supersonic waves of reasonable amplitude the intensity can become relatively very large; e.g., for ν = 500,000 cycles per sec in air and $\xi_{\max} = 10^{-4}$ cm, $I = 2.07 \times 10^5$ microwatts per cm^2. For acoustic instruments which record pressure changes, equation (18) is the more useful one. For others, equation (19) is employed.

The Measurement of Intensity in absolute units is now largely replaced by the logarithmic unit, the *bel*, which is of particular advantage in denoting the relative levels of intensity of several sounds. The difference in intensity of two sounds whose absolute intensities are I_1 and I_2 respectively is α bels, where

$$\alpha = \log_{10} I_2/I_1 \tag{20}$$

More commonly the *decibel* (*db*), which is one-tenth of a bel, is used. To illustrate, if one calls an average excess pressure of 1 dyne per cm^2 (strictly this is the root-mean-square value which $= 0.707\, p_{\max}$) the normal level for ordinary speech, the threshold of audibility has a minimum lying about 70 db below this level, and the threshold of feeling (i.e., where hearing is painful) has a maximum lying about 70 db above this level. We may think of audible sound therefore as lying in a maximum range of some 140 db.*

24. INFLUENCE OF THE MEDIUM ON THE PROPAGATION OF SOUND

Spherical Waves. From a point source, sound spreads in a perfectly homogeneous medium in the form of a spherical wave, the mathematical expression for the displacement in a harmonic wave of this kind being

$$\xi = \frac{A}{r} \sin\,(\omega t - kr) \tag{21}$$

From equation (19) it is seen that the intensity of such a wave is given by the expression

$$I_s = {}^1/_2\, \rho_0\, c\omega^2\, A^2/r^2 \tag{22}$$

i.e., the intensity falls off inversely as the square of the distance from the source. This is in contrast to a plane wave (see equation 3), for which the intensity is independent of distance. The diminution of intensity of a spherical wave is a purely geometrical phenomenon—as the wave spreads in all directions, the same amount of energy at any instant flows across spheres of larger radii, whose surfaces increase as the square of the radii. In addition to this geometrical decrease in intensity with distance all material media act to dissipate acoustic energy and so decrease intensity by absorption.

Causes of Sound Absorption in Fluid Media

Viscosity acts to retard the relative motion of adjacent layers of the medium, and so adds a damping force to the elastic restoring force normally present. The effect is to produce an exponential decrease in displacement amplitude with distance; i.e., the amplitude A must be multiplied by $e^{-\alpha r}$ where e is the Naperian base (= 2.71828. . .) and $\alpha = {}^2/_3\, \mu\omega^2/\rho_0\, c^3$. μ, the coefficient of viscosity for air at 20 deg cent, is approximately 18×10^{-5} gram per cm per sec and for water at 20 deg cent is 10^{-2} gram per cm per sec. It will be observed that the damping coefficient increases with the square of the frequency. For $\omega = 1000$ in air, $\alpha = 0.24 \times 10^{-8}$; i.e., a wave in air could proceed a distance of about 4000 km without having its amplitude reduced to more than $1/e$ as far as viscosity is concerned. This is a very slight effect and hardly observable except at high frequencies. The effect is much more marked when the medium is confined as in a tube, for here the fluid tends to stick to the walls. For a tube whose diameter is large compared with $\sqrt{8\pi^2\, \mu/\rho_0\, \omega}$ the theory † again indicates exponential damping with $\alpha = \dfrac{1}{ac}\sqrt{\dfrac{\omega\mu}{2\rho_0}}$, where a = radius of the tube. For a tube of radius 1 cm and $\omega = 1000$, $\alpha = 2.5 \times 10^{-4}$ for air at 20 deg cent. Associated with the absorption is a decrease in the velocity of sound which in the instance just cited is theoretically 0.86 per cent. Actually both the absorption and the decrease in velocity depend on the material of the confining tube and are greater in practice than the theory predicts.

---

* See bibliography, page 9-54, reference 19.

† See bibliography, page 9-54, references 9 and 13.

For capillary tubes, i.e., where $a << \sqrt{8\pi^2\ \mu/\rho_0\, \omega}$, the viscous absorption is naturally very much greater, the value of α being $\frac{2}{a}\sqrt{\frac{\omega\mu}{p_0}}$, where p_0 is the average value of the fluid pressure in the tube. Here the waves are very rapidly damped out, with α having, for moderate frequencies, values in the neighborhood of 10 to 100. This accounts for the large absorption of sound in carpets and other materials with small interstices.*

The effect of viscosity is enhanced by the conduction by the vibrating gas or liquid of the heat produced during the compressions accompanying the passage of the wave. The order of magnitude here is the same as that involved in viscosity damping.

Changes in Physical Properties. In the actual propagation of sound through such media as the atmosphere and the sea the numerous changes in the physical properties of the medium due to temperature, etc., produce by reflection, refraction, and diffraction a damping of a directed beam which is much more pronounced than that due to either of the causes just mentioned.

Recently it has been found by Knudsen † that the absorption of sound in air depends on temperature and humidity in a characteristic manner. Thus the absorption coefficient per centimeter (α) for air at 20 deg cent and for a frequency of 1500 cycles per sec has a maximum value of 10^{-4} at a relative humidity of 10 per cent. For a frequency of 10,000 cycles per sec the maximum is about 6.5×10^{-4} and occurs at a relative humidity of about 18 per cent. These figures are of course much larger than those theoretically predicted on the basis of viscosity absorption. It has been established that this absorption is due almost entirely to the energy transfers between the oxygen molecules of the air. This opens up a new field for the study of sound absorption.

25. VIBRATING SYSTEMS AS SOURCES OF SOUND

Free Oscillations. Most vibrating systems do not oscillate as a whole but are the seat of more or less complicated wave patterns. For the sake of simplicity, however, it is often convenient to think of such bodies as if they moved as a whole. Thus a membrane in which the amplitude at the center is greater than that elsewhere may often conveniently be assumed to oscillate like a piston moving to and fro. The same is true of the air in the opening of a Helmholtz resonator.

The vibration of a body conceived from this point of view is governed by what may be called its "elements," viz., its *inertia* (measured by *mass*), *stiffness* (elastic restoring factor), and *dissipative resistance* (damping factor). The *stiffness* is defined analytically as the restoring force per unit displacement; the *resistance* is the damping force per unit velocity. These are the analogs of inductance, capacitance (strictly reciprocal of capacitance), and resistance, respectively, in an oscillating electric circuit. A knowledge of these elements is sufficient to describe completely the behavior of the system if disturbed from equilibrium and thereafter left to itself. Under such circumstances the system is said to be *free*.

Let m denote the mass, f the stiffness, and R the damping factor of the system. It turns out that a disturbance from equilibrium will lead to oscillations if and only if ‡

$$R^2/4m^2 < f/m \tag{23}$$

and the frequency of the oscillation is

$$\nu_f = \frac{1}{2\pi}\sqrt{\frac{f}{m} - \frac{R^2}{4m^2}} \tag{24}$$

If the damping factor is small enough so that the left side of the inequality (23) is very much smaller than the right, the free or natural frequency is approximately

$$\frac{1}{2\pi}\sqrt{\frac{f}{m}} \tag{25}$$

As an illustration consider a membrane (e.g., a telephone diaphragm) which when replaced by an equivalent piston has

$$m = 0.50 \text{ gram}, \qquad f = 2.5 \times 10^7 \text{ dynes per cm}$$
$$\mathrm{R} = 250 \text{ dyne sec per cm}$$

Then $R^2/4m^2 = 6.25 \times 10^4\ \text{sec}^{-2}$, while $f/m = 5 \times 10^7\ \text{sec}^{-2}$, so that in equation (24)

---

* See bibliography, page 9-54, references 9 and 13.

† *J. Acous. Soc. Am.*, vol. 6, p. 199, 1935; *Science*, vol. 81, p. 578, 1935.

‡ See bibliography, page 9-54, references 7, 9, and 11.

ν_f 1124.6 vibrations per sec whereas equation 25 gives 1125.4 vibrations per sec, the difference being negligible for most practical purposes.

Although the effect of the damping on the frequency is very small, the amplitude of the harmonic oscillation dies away exponentially; i.e., the displacement ξ may be written

$$\xi = Ae^{-(R/2m)\cdot t} \cos (2\pi\nu_f t + B) \tag{26}$$

where A = initial amplitude and B = initial phase. The amplitude decreases to A/e = 0.37 A in the time $t' = 2m/R$, which in the above illustration is 1/250 sec. All free physical oscillations are damped, the damping arising from a variety of factors, such as internal viscosity of the vibrator, viscosity of the medium, or energy communicated to the medium by the vibrator and carried away in the form of radiation.

Forced Oscillations. More interesting and important than free oscillations are those imposed on the system by an external harmonic force, e.g., the fluctuating magnetic field in the telephone diaphragm. If the frequency of the force is $\nu = \omega/2\pi$ and its amplitude is F_0, the displacement is *

$$\xi = F_0/\omega Z \cdot \cos (\omega t - \alpha) \tag{27}$$

where $Z = \sqrt{(m\omega - f/\omega)^2 + R^2}$, and is defined as the *mechanical impedance* of the system (cf. analogy to electrical impedance). The quantity α is the phase difference between the force and displacement and equals $\tan^{-1} \dfrac{R}{m\omega - f/\omega}$. The displacement velocity is usually more important. Denoting this by $\dot{\xi}$ we have

$$\dot{\xi} = F_0/Z \cdot \cos (\omega t - \beta) \tag{28}$$

where $\beta = \tan^{-1} \dfrac{m\omega - f/\omega}{R}$ = phase difference between force and velocity ($\alpha + \beta = 90°$). It is seen that the magnitude of both ξ and $\dot{\xi}$ depends on the impedance; a large impedance, other things being equal, corresponds to a small displacement, and vice versa (cf. the alternating-current analogy: current = emf ÷ impedance).

The impedance is a minimum for $\nu = \dfrac{\omega}{2\pi} = \dfrac{1}{2\pi}\sqrt{\dfrac{f}{m}}$. This is called the *resonance frequency*. For systems with small damping it coincides effectively with the free oscillation frequency. Physically this means that a system will vibrate most vigorously if subjected to a harmonic force with frequency equal to its own natural frequency. At resonance the force contributes energy to the system at maximum average rate and the system itself dissipates energy at an equal rate: if a vibrating tuning-fork is held over the open end of an air column in resonance with the fork, the air in the tube vibrates vigorously and the note is much reinforced; at the same time the fork more rapidly uses up its original store of energy and comes to rest sooner than it otherwise would. Examples of resonance are at hand throughout acoustical phenomena, as well as in vibration phenomena in general.

The damping exercises an important influence on resonance; if the damping factor is small the response of the system at resonance is great but the tuning is sharp; that is, the response drops rapidly as the frequency of the force is altered from the resonance frequency. On the other hand, large damping leads to a smaller resonance response but a broader peak and more diffuse tuning. The same effect is well known in electrical oscillating circuits.

A good illustration of such a vibrating system as we have been considering is a Helmholtz resonator which consists of an enclosure usually but not necessarily spherical in shape communicating with the outside by means of a small orifice. The mass of the system is the mass of the air in the opening which vibrates under external influence against the air cushion provided by the air in the enclosure or resonator chamber, the latter supplying the stiffness of the system. The damping comes mainly from the radiation of sound into the surrounding medium. The resonance frequency is †

$$\nu = \frac{1}{2\pi} c \sqrt{\frac{c_0}{V}} \tag{29}$$

in which c = velocity of sound in air, V = volume of the resonator chamber, and c_0 = a quantity with dimensions of length called the conductivity of the opening. It is rather difficult to compute but is of the order of magnitude of the diameter of the orifice.

Resonators have many practical uses, among them being the construction of sensitive sound detectors and instruments for the measurement of sound intensity (see Art. 34).

26. SPECIAL VIBRATING SYSTEMS

Vibration of Strings. If a string with line density (mass per unit length) ρ and stretched with tension τ is pulled aside from its equilibrium position and let go, a *transverse* wave travels along the string with velocity *

$$v = \sqrt{\frac{\tau}{\rho}} \tag{30}$$

If the string is of finite length l and is fastened at both ends so that no motion is possible there, it turns out that the string is the seat of waves in both directions which combine to form standing waves of only certain frequencies, viz.,

$$\nu = \frac{n}{2l}\sqrt{\frac{\tau}{\rho}} \tag{31}$$

where n is *any* integer. These allowed values of ν are the *characteristic* or *natural* frequencies of the stretched string. $n = 1$ corresponds to the fundamental, and $n = 2, 3, 4$ . . . to the successive harmonics or overtones. By the imposition of a harmonic force the string can, of course, be forced to vibrate with any frequency, but *resonance* (Art. 25) ensues when the frequency of the force coincides with one of the set (equation 31). When a string vibrates with one of its characteristic frequencies, it is said to be in a characteristic mode of oscillation. Each mode is also characterized by the presence of certain points where no motion ever takes place: these are the so-called nodal points or *nodes* in distinction to the places of maximum disturbance or *loops*. Fig. 3 indicates the first three characteristic modes of vibration of a stretched string. The full line in each sketch represents the undisturbed position of the string; the dotted and dashed lines represent the extreme positions assumed by the string. Nodes and loops are indicated by N and L respectively Of course the ends are, strictly speaking, nodes by virtue of the fastening. Obviously the distance between successive nodes is one-half wavelength (see equation 2 in connection with equation 31).

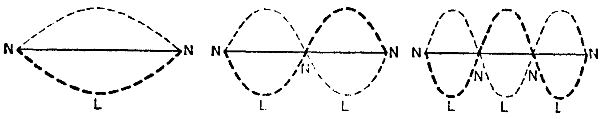

FIG. 3

String Instruments. The most important acoustical application of the vibration of strings occurs in musical instruments. Here strings may be vibrated by plucking (harp), by bowing (violin), or by striking with a hammer (piano). If a string is plucked at one of its possible nodes, the corresponding harmonic or harmonics will be absent. This is known as Young's law: thus plucking at the center removes all harmonics of even order. In any event the higher harmonics are relatively weak in the plucked string. The theory of the struck string has not been completely worked out. Much depends on the precise manner and duration of the blow. But Young's law is again true and is utilized to minimize the harmonics above the sixth. The same is true of the bowing of the violin string. No matter how a string is excited, much of the effect depends on the presence of resonating surfaces and air spaces.

The Vibrations of Air Columns (e.g., organ pipes) are mathematically quite analogous to those of strings. Here, to be sure, the characteristic frequencies depend on whether both ends of the tube are open or only one. If both ends are open the natural frequencies * are $\frac{nc}{2l}$ (c = velocity of sound in air); if only one end is open they are $\frac{(2n+1)c}{4l}$. The difference comes from the fact that the wave pattern must have a node at the closed end of the tube while it has a loop at the open end. The values cited are not quite correct, for radiation from the open end has been neglected. To take account of this the length, l, in the formula must be slightly increased.

Quality. It is the combination of harmonics in the vibration which gives the sound radiation from such a system its characteristic *quality* (see Art. 31 on the analysis of musical sounds); it is this which distinguishes sounds of essentially the same frequency or pitch produced by different systems (e.g., violin and flute).

Membranes and Diaphragms. For the practical production of sound, circular membranes and diaphragms are of the utmost importance. A membrane is supposed to be perfectly flexible, i.e., to possess no rigidity, and many of the diaphragms used in sound generators more nearly approximate plates. The mathematical details in either instance are too difficult to give here. A circular membrane of radius a clamped around the periphery has a very complicated set of characteristic frequencies. The simplest of these correspond to vibrations symmetrical about the center and have frequencies given approximately by

$$0.77\frac{c}{2a},\quad 1.76\frac{c}{2a},\quad 2.76\frac{c}{2a} \tag{32}$$

where c = velocity of flexural waves in the membrane $= \sqrt{\tau/\rho}$, in which τ = superficial tension or force per unit length in the membrane and ρ = mass per unit area. It will be noted that the harmonics bear no integral multiple relationship to one another, differing thus from the harmonics of the string and air column. Corresponding to the nodal points of these systems, the membrane has a set of nodal lines which in symmetrical vibrations are concentric circles. In the higher modes of vibration there also exist nodal diameters. The situation for vibrating plates is even more involved and the wave patterns more complicated, although the characteristic frequencies have been computed in special instances. As has been intimated in Art. 25, the tendency in practical work is to operate with the equivalent piston vibrator.

Energy Radiation. In practical acoustics an important feature of vibrating systems is the rate of energy radiation into the surrounding medium, and in particular the efficiency of the system as a radiator, viz., the ratio of the radiation output to the input. It can be shown that the average rate of radiation of frequency $\omega/2\pi$ from one side of a diaphragm into a semi-infinite medium of density ρ is

$$\frac{1}{4}\pi\rho\frac{\omega^2}{c}a^4\dot{\xi}_0^2 \tag{33}$$

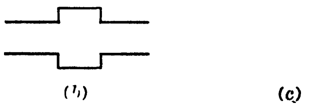
where a is the radius of the *equivalent piston* and $\dot{\xi}_0$ is the maximum displacement velocity. Here c is the velocity of sound in the medium. The efficiency of telephone diaphragms is rather low except at the resonance frequencies. The Fessenden oscillator * for under-water sound signaling has, however, an efficiency as high as 50 per cent at an output of 500 watts. The output of all sources is very largely conditioned by the type of acoustic coupling used: a diaphragm placed in the throat of a horn will have a larger output for the characteristic frequencies of the horn, since the resonance principle comes into play.

27. TRANSMISSION THROUGH TUBES

Many important acoustic problems involve the transmission of sound through tubes; for example, speaking tubes, horns for the production and amplification of sound as well as for its reception, stethoscopes, special types of acoustic filters, and apparatus for the measurement of acoustical intensity and impedance.

Effect of Length. If a plane sound wave produced by a diaphragm or other source is led into a cylindrical tube, the wave form will depend in the first place on the length of the tube. If the tube is short, the reflected wave from the end of the tube away from the source will combine with the direct wave to form a more or less complicated pattern; if the tube is very long the reflected wave may be largely damped out and a wave traveling effectively in one direction results.

Change in Cross-section. Consider a wave traveling in one direction and note what happens to it when the size of the tube is altered.* At A, in Fig. 4a, the wave coming



(b) (c)

FIG. 4

from the left encounters an abrupt increase in cross-section. In Art. 21 it was noted that reflection ensues so that to the left of A there are waves in both directions. The wave that goes across A is therefore weakened in intensity and indeed by an amount which depends on the ratio of the cross-sections (formula 15). The ratio of the total energy flow (watts) in the transmitted wave to the right of the boundary to that in the incident wave may be called the power transmission ratio and will be denoted by P_r. There is no change in phase of the transmitted wave. Incidentally P_r is the same in either direction.

---

* See bibliography, page 9-54, reference 13.

The loss in intensity can be very much mitigated by the use of a connector joining the two tubes so as to make the change in dimensions less abrupt; the longer the connector the greater is P_r.

In Fig. 4*b*, again, a plane wave coming from the left meets an expansion of finite length which joins the main line. In Fig. 4*c* the analogous case of a constriction is illustrated. Calculation and experiment indicate that P_r in both examples is a function of the frequency, being fairly close to unity for low frequencies but becoming very small for a considerable range of high frequencies, then rising and falling again in a series of alternate peaks and hollows, as in Fig. 5. Such a structure is said to be *selective*. Change in phase of the transmitted wave is also involved. This has important application to the pinching of a sound tube in order to control intensity.

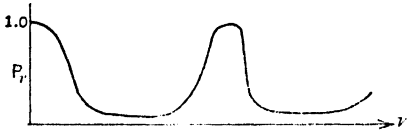


FIG. 5

Orifices or Side Openings. Another important case of transmission is that through a tube containing one or more orifices in the side. The physical effect of the openings is to cut down the transmission by producing reflection due to the inertia of the air in the orifices; each one is a boundary between the confined air in the tube and the much larger mass of unconfined air outside. Of course there is some actual radiation of sound from the openings, but contrary to what might at first be supposed this is less than the inertia effect. Viscous damping in the openings also plays an insignificant rôle unless they are very narrow. Calculation and experiment indicate that P_r is small for low frequencies and rises as the frequency increases. If more than one hole is used, as their number (they are assumed to be evenly spaced) increases, P_r for low frequency decreases until finally no sound passes through the tube up to a certain frequency: it acts as a high-frequency-pass acoustic filter (see the schematic diagram in Fig. 6*a*.*)

(*a*) High-pass Filter (*b*) Low-pass Filter

FIG. 6

It is seen that all the transmission problems discussed so far in this section involve acoustic filtration to a certain extent. The same is true of a Helmholtz resonator placed over an orifice in the side of a tube. Here, as might be expected, P_r is reduced materially only in the neighborhood of the resonance frequency of the resonator. If, however, one attaches a whole series of resonators to evenly spaced openings (Fig. 6*b*), the resulting structure is found to act as a low-pass filter: i.e., P_r is different from zero up to a certain frequency dependent on the dimensions of the various parts; it then falls to zero and stays so for a considerable frequency interval. It then rises again and transmission and attenuation bands succeed each other in a way which can be predicted theoretically. The use of more elaborate side branch attachments permits the construction of filters having transmission bands at any desired frequency and of any desired frequency range.

The Stethoscope. Another important instrument which is essentially an acoustic filter is one form of the stethoscope (see Fig. 7) consisting of a thin air chamber with a broad base of hard rubber or other solid substance.† Sound is incident on A from the left; some of it passes through the base (which may vibrate as a whole if it is thin, or act as a genuine transmitting medium if it is thick) and then through the air chamber to B where more reflection takes place and a final transmitted wave progresses up the narrow tube. The theory is too complicated for presentation here. An illustration will suffice. Consider the stethoscope immersed in water. Assume that the ratio of the area of cross-section at A to that at $B = 225$ and that the thickness of the chamber is 0.3 mm; then at $\nu = 750$ cycles per sec $P_r = 0.13$. This contrasts with $P_r = 0.0012$ for the ordinary power transmission ratio going directly from water to air without change in tube cross-section. It must be emphasized that this type of stethoscope is highly selective. For medical purposes, small conical horns are now being used extensively (see Art. 28).

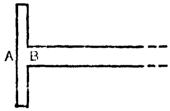

FIG. 7

---

* See bibliography, page 9-54, references 8, 10, and 13.
† See bibliography, page 9-54, reference 13.

28. HORNS

The horn occupies a significant place in the discussion of acoustic transmission.* Strictly speaking, any tube of finite length may be a horn. However, it is usual to restrict the term to tubes of varying cross-section.

The Principal Types are shown diagrammatically in Fig. 8, where (*a*) represents a *conical* horn in which the area of cross-section $S = S_0 x^2$ (x denoting the coordinate distance along the horn axis from some chosen origin and S_0 the cross-sectional area for unit x); (*b*) represents an *exponential* horn with $S = S_0 e^{mx}$, where m is a parameter governing the flare (this horn has the property that the area S is the geometric mean of the areas at the same distance on either side of S); (*c*) represents a *parabolic* horn in which $S = S_0 x$. There are other types of flaring horns but their properties are very similar to the exponential variety.

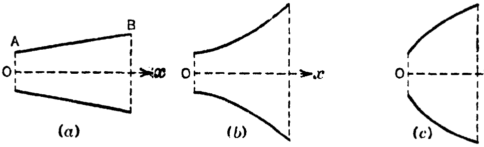

Fig. 8

The Horn as a Receiver of Sound. If the horn were not there, little difference in the intensity of the sound would be noted at the points A and B. However, with the horn in place, and sound directed toward the large end, there is considerable increase in the intensity at the throat (i.e., the small end) over the intensity at B with no horn present. The ratio of these intensities is the *intensity amplification* (I.A.) of the horn and a measure of the horn's utility as a receiver. The mathematical theory by which this quantity is computed is complicated, and it must be made clear that the qualitative idea of the horn's "concentrating" the sound by reflection from the walls, etc., is quite inadequate except at high frequencies. The action of a horn like that of any air column is mainly dependent on *resonance* characteristics. This is clearly shown in the fact that when I.A. for a conical horn, for example, is plotted as a function of frequency, it shows a number of peaks and hollows, the peaks corresponding to the resonance frequencies of the horn considered as a vibrating air column.

This selectivity is most marked in the conical horn. The parabolic horn gives a much more uniform response and is being widely used in connection with sound-motion pictures. The exponential horn, other things being equal, gives the largest I.A. and is often used in loud-speaker units for public-address systems.

The Horn as a Transmitter. A good receiving horn is a good transmitting horn. Naturally the behavior always depends on the acoustical attachments. In general, however, the resistance component of the impedance (Arts. 23 and 25) of the horn at the throat is the best criterion of the horn's action. This is greater for flaring horns than for conical horns of similar dimensions.

The use of horns in musical instruments is well known. Recently large exponential horns have proved valuable in the acoustic detection of aircraft.

29. SUPERSONICS

Considerable interest has been displayed during the past two decades in the use of high-frequency, inaudible sound in under-water signaling, for supersonic waves are not so easily diffracted as audible waves and hence can be directed more or less in a beam. Moreover, high-frequency sound oscillators have a much higher radiation efficiency than low-frequency ones; i.e., much more of the energy of the oscillator actually goes into radiation. For signaling, frequencies of 50,000 to 100,000 have been employed. The effective damping increases with the frequency and hence precludes the use of much higher frequencies.

Sources. A widely used source of supersonic radiation is the *quartz* oscillator (first used for signaling purposes by Langevin in France during the Great War). Quartz like some other asymmetric crystals (notably Rochelle salt) when subjected to stress becomes electrically polarized. Thus if a slab of quartz cut parallel to the optic axis is inserted between two metal plates connected to an a-c circuit, the slab will oscillate with the impressed alternating emf, the oscillations being particularly vigorous at resonance.

Another source of supersonic waves is the *magnetostriction oscillator* developed by Pierce.† When a rod of magnetic material is magnetized it changes its length; when placed in an oscillating magnetic field mechanical vibrations are thus set up with the frequency of the field.

---

* See bibliography, page 9-54, references 8, 10, and 13.

† *Proc. Am. Acad. Arts and Sci.*, vol. 63, p. 1, 1928.

Other Uses. In addition to their use for signaling, supersonic waves have been studied for their physical, chemical, and biological effects. Wood and Loomis * have produced sound waves of frequency about 300,000 cycles and with very high intensity, in some cases reaching a radiation pressure of 3000 dynes per cm^2. When the vibrations are communicated to liquids stable emulsions are often formed, e.g., mercury in water. These waves have also been used in the measurement of the velocity of sound in liquids (see Art. 20).

30. PHYSIOLOGICAL ACOUSTICS

Physiological acoustics comprises all the acoustical phenomena associated with the reception of sound by the ear and the production of speech sounds.

The Human Ear consists of the auricles or pinnae, the canal with the eardrum at the end of it, the middle ear with the three little bones or ossicles, and the inner ear with the liquid-filled cochlea containing the basilar membrane which is presumably the seat of the auditory process. Sound passing through the canal is communicated to the inner ear via the drum and ossicles. The actual mechanism of audition is still a subject of much investigation, and there are several theories of hearing, the chief of which is still that of Helmholtz which assigns resonance characteristics to the fibers in the basilar membrane.†

Intensity and Loudness. As explained in Art. 23, the ear is sensitive to sounds of intensity as low as 4×10^{-10} microwatt per cm^2 and the threshold of feeling as well as that of audibility are both functions of frequency or pitch (the physiological interpretation of frequency). For most normal persons the frequency range of audibility runs from about 20 to 16,000 cycles per sec. A few people can hear up to 20,000. The work of Fletcher should be consulted for details. The connection between intensity and loudness is a matter of some interest: the former is a purely physical quantity (Art. 23); the latter is physiological. The general law connecting the two is a special case of the so-called Weber-Fechner psychophysical law that equal increments of sensation correspond to equal increments in the *logarithm* of the stimulus. This makes it particularly convenient to use the decibel notation (Art. 23) for loudness. Thus the difference in the loudness level of two sounds of physical intensity I_1 and $I_2 (I_2 > I_1)$ respectively is

$$L = 10 \log I_2/I_1 \tag{34}$$

in decibels. The relation is complicated by differences associated with pitch. We cannot go into the discussion of the loudness of complex tones.

Frequency. To every frequency corresponds a minimum perceptible intensity difference; e.g., for a sound or sensation level of 50 db above the audible threshold, $\Delta I/I = 0.10$. There exists a similar minimum perceptible pitch difference, which varies from 0.5 cycle per sec at 50 cycles to 9 cycles per sec at 3000 cycles per sec. For further details, the work of Knudsen should be consulted.

Beats. The presentation simultaneously to the ear of two sounds of definite frequencies ν_1 and ν_2 leads, when the two sounds are of approximately the same intensity and ν_1 and ν_2 do not differ too much, to the well-known phenomenon of beats. Even when the sounds differ widely, a "difference" tone of frequency $\nu_2 - \nu_1$ is heard, and what at first seems more remarkable, a summation tone of frequency $\nu_1 + \nu_2$ together with various linear combinations of these frequencies. The explanation has been sought in the fact that the eardrum is an asymmetrical vibrator, i.e., that the displacement for given excess pressure is not the same in the positive as in the negative direction.

Sound Direction. One of the most striking aspects of hearing is the localization of the direction of a source of sound. The listening individual tends to turn so that this direction is the perpendicular bisector of the line joining the two ears. Presumably two distinct effects are involved: the *binaural intensity* and the *binaural phase* effects respectively.‡ If the phase is the same at both ears a variation in intensity about the head will produce an angular displacement of the apparent source of sound. However, this is very uncertain and for many observers the effect fails to exist at all in frequency regions where localizability still persists. On the other hand, if the intensity is maintained constant and the phase is varied, the apparent shift about the head persists for all frequencies for which tests have been made, although observers differ considerably on the upper limit (about 1300 for most people).

The Origin of Speech is found in the currents of air which are forced by the lungs to pass through the vocal passages exciting to vibration the so-called vocal cords in the larynx and then passing through the cavities of nose and throat. The functions of tongue and lips in the formation of sounds must not be forgotten, of course. The whole mechanism is too involved for description here, and reference should be made to Fletcher's very complete discussion.

† See bibliography, page 9-54, references 16, 19, 27, and 41.

‡ See bibliography, page 9-54, references 13, 16, 19, and 27.

The Flow of Energy in Speech varies greatly from one individual to another and in a given individual from one sound to another. Thus for a single speaker the *average* intensity involved in a certain syllable may be of the order of 100 microwatts per cm^2 while the *peak* intensity in the same syllable may be as high as 2000 microwatts per cm^2. Naturally, these figures depend on the point in front of the mouth where measurements are made, since the intensity falls off with distance. It has been found that the average intensity in normal speech is about 7 microwatts per cm^2 at a point 9 cm from the mouth. Among speech sounds the vowels rank highest in energy content, the semi vowels next, and consonants lowest.

The work of D. C. Miller has made it clear that the peculiar quality of vowel sounds depends on certain frequency regions regardless of the fundamental pitch used. Thus the quality of the vowel *u* (the vowel sound in "pool") depends essentially on a low-frequency component in the neighborhood of 400 cycles per sec and a high-frequency around 800 cycles per sec. Corresponding figures for long *e* (the vowel sound in "team") are 375 and 2400. Complete tables are given in Fletcher's book.

Articulation. By the use of electric and acoustic filters, certain frequency ranges can be eliminated from speech and the effect on articulation studied. By articulation is understood the percentage of intelligible syllables in a selected list. The results may be summarized as follows: (*a*) frequencies above 1550 cycles per sec are just as important for articulation as those below; specifically by using only frequencies above or only frequencies below this value an articulation of 65 per cent results; (*b*) the elimination of all frequencies below 1000 cycles per sec results in an articulation of 86 per cent; (*c*) the elimination of all above 1000 cycles per sec, an articulation of 40 per cent; (*d*) the elimination of all frequencies below 1000 yields the same articulation as the elimination of all frequencies above 3000. With music the elimination of the low frequencies renders it thin and metallic, and cutting out the high frequencies makes it fuller and, so to speak, thicker (H. Fletcher, Speech and Hearing).

31. MUSICAL SOUNDS

A Musical Sound may be defined as a single sustained sound of definite pitch or a composite of such sounds having frequencies related to each other by simple integral ratios. The frequencies used cover practically the whole audible range (Art. 30). The intensity of musical sounds is in general much greater than that involved in speech. For principal sources of musical sounds, viz., strings, organ pipes, membranes, and horns, see Art. 26.

Characteristics Which Distinguish Music from Other Sound. Musical sounds are seldom simple; they usually are composites of several sounds, viz., the fundamental or note of lowest frequency and the overtones or harmonics with frequencies which are integral multiples of the fundamental. This implies that any complex tone can be analyzed into a set of harmonic components (often called partials): *Ohm's acoustical law.* The *quality* of a complex tone depends on the number and relative strength of the various harmonics or partials and does not depend on their differences in phase. The early work on the analysis of complex sounds was due to Miller * using the phonodeik and mechanical analyzers. More detailed studies have recently been made at the Bell Telephone Laboratories, and complete acoustic spectra of many instruments have been obtained using electrical analyzers and filters.†

The Basis of Musical Scales is found in the fact that the ear recognizes as pleasing combinations of simple tones whose frequencies are in the ratio of *small* whole numbers. These are the so-called consonant intervals ‡ (a musical interval is the ratio of the two frequencies concerned), and the principal ones are: octave, 1 : 2; fifth, 2 : 3; fourth, 3 : 4; major third, 4 : 5; minor third 5 : 6; major sixth, 3 : 5, minor sixth, 5 : 8. As the numbers become larger, dissonance results; the interval 7 : 8 is recognized as dissonant. It is probable, however, that the range of accepted consonance can be increased by custom and education.

The Ideal Musical Scale would consist of a set of simple notes in approximately equal steps and including only consonant intervals. This has never been achieved exactly in practice. The two most important scales, the consonant diatonic and the equally tempered scales, are indicated in the accompanying table.

---

* See bibliography, page 9-54, reference 23.
† See bibliography, page 9-54, reference 19.
‡ See bibliography, page 9-54, reference 3.

Table I. Musical Scales

Note	C	D	E	F	G	A	B	C′
Frequency on diatonic scale........	256	288	320	341 1/3	384	426 2/3	480	512
Interval with C..................	1	9:8	5:4	4:3	3:2	5:3	15:8	2:1
Frequency on equally tempered scale	256	287.4	322.6	341.8	383.7	430.5	483.2	512

Most of the notes on the scale form consonant intervals with each other, but the steps are decidedly unequal, so that in using it one cannot play in any key at will; i.e., the frequencies bearing the same relation to D as those in the scale bear to C are not all found in the list, and hence to play in the key of D would involve introducing extra frequencies. This complicates matters considerably, hence in the piano the equally tempered scale is used. This has 12 intervals in the octave: the individual notes are C, C♯, D, D♯, E, F, F♯, G, G♯, A, A♯, B, C. (Not all these are listed in the table.) The interval between each successive pair of notes is $2^{1/12} = 1.05946$, and therefore music can be played in any key with this scale. There are *no* exactly consonant intervals, but apparently the defects are too slight to be observed by most people.

Musical Pitch Specification has been very variable, and various standards have been used within the history of modern music. The classical pitch of Handel and Mozart assigned a frequency of 422 cycles per sec to A whereas the modern " American concert pitch " uses 440 for the same note. The modern " international pitch " assigns 435 cycles per sec to A. In the equally tempered scale this gives middle C a frequency of 258.65 cycles per sec.

32. ARCHITECTURAL ACOUSTICS

The first important experiments on the acoustical properties of rooms were carried out by W. C. Sabine in Cambridge, Massachusetts, in the last decade of the nineteenth century. He was apparently the first to realize the importance of reverberation in its relation to the amount of absorbing material present.

Sound Absorption and Reverberation. When a sound is produced in a closed space, if the walls were perfect reflectors there would be no diminution in the intensity and if the production of sound continued the total energy would therefore increase indefinitely. Actually, however, the sound is absorbed not only by the air but also and primarily by the walls and other furnishings, so that a given amount of energy is dissipated in a certain time. Technically the reverberation time is that which elapses after the stopping of a sustained note having one million times the minimum audible intensity and the resulting reverberant sound has dropped to the audible threshold. The relation between this time, T, in seconds and the dimensions of the room is given approximately for moderate-sized and not too greatly absorbing halls by the formula*

$$T = 0.049\ V/a \tag{35}$$

in which V = volume of the room in cubic feet, and a = total absorbing power of the walls and materials in the room. This latter quantity represents the average fraction of the incident sound energy per unit area which is not thrown back into the room (i.e., average absorption coefficient) multiplied by the total surface area exposed. It is calculated by multiplying the absorption coefficient for each particular article by its area and summing over the whole area. Thus, denoting by α_i the absorption coefficient for a certain group of similar articles with area S_i, the total absorbing power is

$$a = \Sigma \alpha_i S_i = \bar{\alpha} S$$

where the sum is taken over all the absorbing material. The quantity α is called the average absorption coefficient, and S is the total surface.

Sabine's experimental measurements of T for most of the auditoriums which he tested were in rather good agreement with equation (35). In particular the precise shape of the room (barring such things as deep recesses, etc.) does not seem to affect T. Sabine's experimental method was simply to start and stop an organ pipe and measure the time for the decaying sound to become inaudible.

Recent work on reverberation indicates that Sabine's formula (equation 35) is unsatisfactory for very large halls or rooms where the absorption is very great, i.e., where $\bar{\alpha}$ is greater than 0.5. Eyring † has recently derived a more general formula, viz.,

$$T = -\frac{0.05\ V}{S \log (1 - \bar{\alpha})} \tag{36}$$

---

* See bibliography, page 9-54, reference 33.

† *J. Acous. Soc. Am.* vol. 1, p. 217, 1930.

This agrees with Sabine's quite closely for $\bar{\alpha}$ small but departs from it considerably when $\bar{\alpha}$ is larger than 0.5. Eyring's formula checks rather well with experimental determinations for "dead" rooms. Other methods of averaging lead to still different though analogous formulas. The whole question is at present somewhat unsettled. For example, the above formula does not take into account the absorption of sound in the air of the room, which further reduces T.

It is clear that, if sufficient intensity of sound is secured, the most important single factor in the satisfactory acoustical use of a room is the reverberation time.* If it is too great, any given sound like a spoken syllable or musical note will take so long to build up and decay that speech becomes inarticulate and music blurred. A short reverberation time greatly increases articulation. Of course too short a time gives the impression of acoustic "deadness," particularly with music. In general a larger value of T can be tolerated for music than for speech; hence it is easier to set an optimum value in the latter case. Knudsen has made the most complete tests of this matter. He has found, for example, that the optimum T for rooms with volume about 300,000 cu ft (without audience) is about 2.75 sec. In general, for a given T, the articulation is greater for vowels than for consonants. The figures depend on the size of the room. For smaller halls of volume up to 40,000 cu ft to be used for both speech and music, a period of about 1 sec is indicated.

Absorption Coefficients. For a room of given size the control of T rests with the absorption. The unit commonly used is 1 sq ft of open window, which is effectively a perfect absorber. The absorption coefficient α_i for any particular material is then defined as the ratio of the absorbing power of 1 sq ft of the substance to that of 1 sq ft of open windows. The measurement of absorption has been carried out by a number of methods. The following table gives some typical values.† It is of interest to note that some substances show highly selective absorption, in particular the high absorbers.

Table II. Sound-absorption Coefficients

Material	Sound-Absorption Coefficients Frequencies 128	512	2048	Weight	Composition	Thicknesses	Stock Sizes
Acousti - Celotex, Single B, 5/8 in.	0.11	0.45	0.68	13 oz per sq ft	Cane fiber tile perforated with 441 holes per sq ft	5/8 in. 13/16 in. 1 1/4 in.	6 in. by 12 in. 12 in. by 12 in. 12 in. by 24 in.
Acoustic Flexfelt	0.27	0.56	0.68		Rock wool felted between metal netting and stucco lath	Required thickness	4 ft by 4 ft 4 ft by 8 ft
Acoustone 1/2 in.		0.48	0.59	1 1/4 lb. per sq ft	Artificial stone filaments bonded together in tile form in a large variety of shapes and colors	1/2 in. 3/4 in. 1 in.	6 in. by 6 in. 6 in. by 12 in. 12 in. by 12 in. 9 in. by 18 in. Special sizes up to 24 in. by 36 in. available
Akoustolith Plaster 1/2 in.	0.21	0.29	0.37		Light-weight plastic material	Applied 1/2 in. in thickness over usual ground coats	
Akoustolith A, Tile, 1 in.	0.14	0.48	0.83	About 4 lb per sq ft	Artificial stone	1 in. 1 1/2 in. 2 in.	3 in. by 16 in. 4 in. by 8 in. 5 in. by 10 in. 12 in. by 12 in. 8 in. by 16 in. for 1-in. thickness

Sound Proofing has become a significant branch of architectural acoustics. When sound strikes a wall, part is reflected and part is absorbed in the true sense of being ultimately dissipated into heat. Another part passes through the wall in the form of compressional waves. Finally some of the incident sound energy causes the wall to vibrate as a whole, and it is indeed in this way that most of the sound energy gets across the wall into the room space on the other side. This suggests that to prevent sound transmission from air to air through walls they should be made as rigid as possible. On the other hand, rigidity facilitates wave transmission through the walls and flooring of sounds originating there, so that the problem of complete sound proofing is somewhat complicated. The use of double walls with a fairly wide air space is of considerable help, as is also the use of inner floors floating on insulating material resting in turn on the main structural floor.

33. NOISE AND ITS PREVENTION

Noise. Previously the scientific definition of noise was any sound or set of sounds having no definite pitch or pitch components. At the present time it would be perhaps fairer to consider as noise any *disturbing* sound, regular or otherwise. For some people, a large amount of radio " music " is quite definitely noise. The endeavor is now under way to study very thoroughly the effect of noise in all forms on the individual, particularly with respect to fatigue and the lowering of mental and motor efficiency. No safe generalizations are yet at hand, though it is widely believed that city noise is ultimately harmful to man (A. H. Davis, Modern Acoustics).

Noise Measurement. In order to study noise it is necessary to measure its intensity (e.g., by means of a microphone coupled with some kind of amplifier system), its wave form (by oscillographic observation), and the distribution of energy among the various component frequencies. One difficulty encountered is the fact that physical intensity must be translated into physiological loudness, i.e., one must use a noise meter which closely simulates the response of the ear.

In the use of noise meters the usual plan is to vary the intensity of a standard note until it is judged subjectively to be of the same loudness as the noise being measured. The level of the sound in decibels (db) above the audible threshold is then taken as a measure of the noise. The results in all cases depend more or less on the frequency. Thus the average street noise may run from 10 db at 8000 cycles per sec to 35 db at 1000 cycles per sec. At a particularly noisy corner of a busy city, the level may reach 50 db (Fletcher). A boiler factory in operation runs from 95 to 100 db (Davis). In a quiet residence the figure should not be above 15. These last values are averages over a considerable range of frequency. Of course there is fluctuation with time.

For the important effect of noise on speech articulation the work of Fletcher should be consulted.

In the Reduction of Noise from Machinery, which is probably the largest single source of indoor noise and much outdoor noise as well, the general principle is the prevention of the transfer of vibrational energy to surfaces large enough to communicate this energy to the air in the form of acoustical radiation. In general, the amount of sound given to the air directly by the moving parts is negligible compared with that due to the vibration of the supports and foundation. It is therefore desirable as far as possible to insert between moving parts and supports material of very different specific acoustical resistance (see Art. 23) from either. The material should also have as large a damping coefficient as possible.

For a very complete discussion of the possibility of noise prevention in large cities, reference should be made to City Noise, published by the Noise Abatement Commission, Department of Health, New York, 1930.

34. CERTAIN ACOUSTICAL INSTRUMENTS AND MEASUREMENTS

The measurements of leading importance in acoustical work are those of the intensity of sound and acoustic impedance.

The Rayleigh Disk. The classical method for measuring intensity is that employing the Rayleigh disk.* This is a small thin disk of glass about $^1/_2$ cm in diameter suspended by a quartz fiber so that its plane faces are vertical. When such a disk is immersed in a sound beam it tends to set itself so that its plane is normal to the direction of particle displacement. The sound wave thus exerts a torque on the supporting fiber which can be measured by the angular deflection of the disk. Theory indicates that this torque depends on the mean square of the particle velocity in the sound wave. It is therefore a measure of the intensity (Art. 23).

---

* See bibliography, page 9-54, references 8 and 13

Webster's Phonometer is another intensity-measuring instrument consisting of a tunable cylindrical resonator with a diaphragm mounted in its mouth.* This diaphragm is tuned to resonance with the sound whose intensity is to be measured by changing the tension in the wires supporting it. The diaphragm vibrates under the action of the air vibrations produced by the sound in the mouth of the resonator, and the motion of the diaphragm causes rotation of a small concave mirror from which light is reflected. The displacement amplitude of the diaphragm is proportional to the pressure amplitude of the sound at the diaphragm, and hence the intensity can be computed from equation (18).

The Hot-wire Microphone. A fine platinum wire heated to red heat and exposed to a fluctuating current of air in the neck of a resonator suffers a decrease in resistance which is proportional to the mean square particle velocity and hence to the intensity of the sound. This arrangement is called the hot-wire microphone.*

It is of interest to note the important rôle played by the resonator in the last two instruments mentioned.

Of the Electroacoustical Methods of measuring intensity only two can be mentioned: the condenser microphone and the ribbon microphone.† The former consists of a thin stretched circular diaphragm fastened about the periphery and attracted toward a metal plate by means of a static electric charge. When sound waves impinge on the diaphragm they alter the capacity of the system and hence produce a small alternating current in the circuit of which the diaphragm and plate are a part. This current is amplified and used as a measure of intensity on proper calibration. The great advantage of the instrument is its remarkably uniform sensitivity over a wide range of frequencies.

The ribbon microphone consists of a light metallic ribbon suspended in a magnetic field and exposed to air vibrations on both sides. The vibrations of the ribbon produced by an incident sound wave lead to the induction of an emf corresponding to the oscillations in the wave. This instrument has the advantage of possessing directional characteristics, a property not possessed by the condenser microphone and other pressure-operated instruments.

The Measurement of Acoustic Impedance has recently become of importance as a means of estimating the performance of acoustic apparatus such as horns (Art. 28). Reference should be made to the literature.

35. SIGNALS OF UNITED STATES WEATHER BUREAU

Flag Signal for cold wave warning is shown in Fig. 1.

Storm and Hurricane Warnings are given by the flags in Fig. 2.

A red flag with a black center indicates that a storm of marked violence is expected. The pennants displayed with the flags indicate the direction of the wind: red, easterly (from northeast to south); white, westerly (from southwest to north). The pennant above the flag indicates that the wind is expected to blow from the northerly quadrants; below from the southerly quadrants.

Two red flags with black centers, displayed one above the other, indicate the expected approach of a tropical hurricane, or of one of those extremely severe and dangerous storms which occasionally move across the Lakes and northern Atlantic coast.

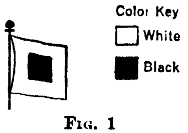

Fig. 1

Wind Pressure on Flags. Tests at the U. S. Navy Yard, Washington, D. C., using the largest flags that could be handled in the wind tunnel, form the basis for an empirical formula for determining the pressure of wind on flags, for use in designing flagpoles. Two sizes of flags were used—one 3 by $5\frac{1}{2}$ ft and the other $2\frac{1}{2}$ by $4\frac{1}{4}$ ft—and velocities varying from 20 to 60 miles per hour were applied. The following formula was

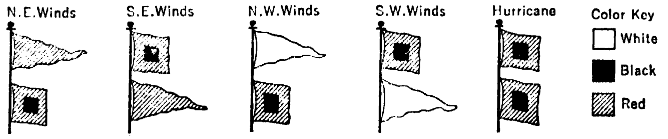

Fig. 2

---

* Articles 35 to 41 by Edgar W. Woolard and R. J. Martin of the U. S. Weather Bureau and Article 43 by H. L. Dryden of the Bureau of Standards; revised from material previously prepared for Merriman's Civil Engineers' Handbook.

found to represent the results, the constant varying but slightly with size of flags, being less for the larger flag:

$$R = 0.0003AV^{1.9}$$

in which R is the resistance in pounds, A is the area of flag in square feet, and V is the velocity of wind in miles per hour. This formula is for steady wind pressure. It was not found practicable to measure the forces produced by wind gusts.

36. LOCAL WEATHER PREDICTIONS

The wind and barometer indications for the United States are generally summarized in Table I (E. B. Garriott, U. S. Dept. Agriculture).

Table I. Wind and Barometer Indications

Wind Direction	Barometer Reduced to Sea Level	Character of Weather Indicated
SW to NW.	30.10 to 30.20 and steady..........	Fair, with slight temperature changes, for 1 to 2 days
SW to NW.	30.10 to 30.20 and rising rapidly	Fair, followed within 2 days by rain
SW to NW.	30.10 to 30.20 and falling slowly	Warmer, with rain within 24 to 36 hours
SW to NW.	30.10 to 30.20 and falling rapidly	Warmer, with rain within 18 to 24 hours
SW to NW.	30.20 and above and stationary	Continued fair, with no decided temperature change
SW to NW.	30.20 and above and falling slowly	Slowing rising temperature and fair for 2 days
S to SE....	30.10 to 30.20 and falling slowly	Rain within 24 hours
S to SE....	30.10 to 30.20 and falling rapidly	Wind increasing in force, with rain within 12 to 24 hours
SE to NE..	30.10 to 30.20 and falling slowly	Rain in 12 to 18 hours
SE to NE	30.10 to 30.20 and falling rapidly	Increasing wind, and rain within 12 hours
E to NE...	30.10 and above and falling slowly	In summer, with light winds, rain may not fall for several days. In winter, rain within 24 hours
E to NE...	30.10 and above and falling rapidly	In summer, rain probable within 12 to 24 hours. In winter, rain or snow, with increasing winds, will often set in when the barometer begins to fall and the wind sets in from the NE
SE to NE..	30.00 or below and falling slowly	Rain will continue 1 to 2 days
SE to NE..	30.00 or below and falling rapidly	Rain, with high winds, followed, within 36 hours, by clearing, and in winter by colder
S to SW....	30.00 or below and rising slowly	Clearing within a few hours, and fair for several days
S to E.....	29.80 or below and falling rapidly...	Severe storm imminent, followed, within 24 hours, by clearing, and in winter by colder
E to N.....	29.80 or below and falling rapidly...	Severe northeast gale and heavy precipitation; in winter, heavy snow, followed by a cold wave
Going to W	29.80 or below and rising rapidly	Clearing and colder

As a rule winds from the east quadrants and falling barometer indicate foul weather; and winds shifting to the west quadrants indicate clearing and fair weather. The rapidity of the storm's approach and its intensity are indicated by the rate and the amount in the fall of the barometer.

The indications afforded by the wind and the barometer are the best guides for determining future weather conditions. As low barometer readings usually attend stormy weather, and high barometer readings are generally associated with clearing or fair weather, it follows that falling barometer indicates precipitation and wind, and rising barometer fair weather or the approach of fair weather. As atmospheric areas of high barometer and areas of low barometer are, by natural laws, caused to assume circular or oval forms, the wind directions with reference to areas of low barometer in the northern hemisphere are spirally and contraclockwise inward toward the region of lowest atmospheric pressure, as indicated by readings of the barometer. The areas of high barometer, on the contrary, show winds flowing spirally clockwise outward from the region of highest barometric pressure in the northern hemisphere.

The wind directions thus produced give rise to, and are responsible for, all local weather signs. The south winds bring warmth; the north winds cold; the east winds, in the middle latitudes, indicate the approach from the westward of a low-barometer, or storm, area; and the west winds show that the storm area has passed to the eastward. The indications of the barometer generally forerun the shifts of the wind. This much is shown by local observations.

During the colder months, when the land temperatures are below the water temperatures of the ocean, precipitation will begin along the seaboards when the wind shifts and blows steadily from the water over the land without regard to the height of the barometer. In such cases the moisture in the warm ocean winds is condensed by the cold of the continental area. During the summer months, on the contrary, the onshore winds are not necessarily rain winds, for the reason that they are cooler than the land surfaces and their capacity for moisture is increased by the warmth that is communicated to them by the land surface. In such cases thunderstorms commonly occur when the ocean winds are intercepted by mountain ranges or peaks. If, however, the easterly winds of summer increase in force, with falling barometer, the approach of an area of low barometric pressure from the west is indicated and rain will follow within a day or two.

From the Mississippi and Missouri valleys to the Atlantic coast, and on the Pacific coast, rain generally begins on a falling barometer, whereas in the Rocky Mountain and Plateau districts, and on the eastern Rocky Mountain slope, precipitation seldom begins until the barometer begins to rise, after a fall.

Table II. Temperature in the United States

Prepared by the Weather Bureau, U. S. Department of Agriculture

States	Stations	Temperature F				States	Stations	Temperature F

37. WEATHER OBSERVATIONS

Mean Temperature. When maximum and minimum readings of temperature are taken, the mean of the two may be taken as the mean temperature of the day. The mean of all the daily means in a month is the mean temperature of the month. When a recording thermometer is used the area between the curve and an axis of abscissas is to be divided by the length of that axis in order to obtain the mean temperature for the elapsed time.

Rainfall. The rain gage used by voluntary observers consists of a cylindrical receiver 8 in. in diameter which has a funnel-shaped bottom that discharges into a tube 2.53 in. in diameter. The cross-section of tube is one-tenth that of the receiver, and hence height of water in tube is ten times as great as actual rainfall. The depth in the tube is measured by a stick which is so graduated as to read the true rainfall in inches. The tube is 20 in. long so that a precipitation of 2 in. or less can be measured without emptying it.

Self-registering rain gages are used at main stations of U. S. Weather Bureau. Snowfall is caught, melted, and then measured; roughly 10 in. of snow make 1 in. of water. A rain gage at the top of a building gives a less rainfall than one on the ground.

Voluntary observers of the Weather Bureau record maximum and minimum temperature, precipitation, wind direction, general character of day, and miscellaneous phenomena such as halos, dates of frost, hail, sleet, auroras, and tornadoes. The general character of the day is recorded " clear " when the sky is 3/10 or less obscured, " partly cloudy " when from 4/10 to 7/10 is obscured, and " cloudy " when more than 7/10 is obscured.

38. RAINFALL AND EVAPORATION

Table III. Evaporation

Place	Position of Pan	Diameter of pan, ft	Annual Evaporation, in.
Salton Sea, Calif.	1500 ft inland	2	164.50
Salton Sea, Calif.	500 ft at sea	4	108.65
Salton Sea, Calif.	7500 ft at sea	4	106.45
Indio, Calif.	15 miles from Salton Sea	6	119.33
Mecca, Calif.	1/2 mile from Salton Sea	6	107.81
Brawley, Calif.	20 miles from Salton Sea	6	103.55
Mammoth, Calif.	40 miles from Salton Sea	6	125.53
North Yakima, Wash.	1/2 mile west of city	4	67.96
Hermiston, Ore.	On raft in reservoir	4	68.05
	On ground	3	97.29
Granite Reef, Ariz.	Floating in Salt River	4	97.74
	On ground	4	115.18
California, Ohio	Floating in reservoir	4	45.99
Birmingham, Ala.	Floating in reservoir	4	51.74
Dutch Flats, Neb.	A few miles from Mitchell	4	65.67
Deer Flat, Idaho	On raft near water edge	4	77.43
	On ground of embankment	3	79.00
Ady, Ore.	Floating in borrow pit	4	53.45
Fallon, Nev.	Floating in canal	4	53.65
Lake Tahoe, Calif.	2 ft above water	4	42.21
Elephant Butte, N. Mex.	Near Rio Grande River	4	86.95
Carlsbad, N. Mex.	In the city	4	107.25
	In an alfalfa field	4	94.35
Lake Avalon, N. Mex.	A few miles from Carlsbad	4	94.51

The evaporation from a pan 2 ft in diameter is about 75 per cent, that from a pan 4 ft in diameter is about 50 per cent, and that from a pan 6 ft in diameter is about 30 per cent greater than the evaporation from a large pond or lake. The above figures may be roughly corrected by using these percentages; thus, at Birmingham, Ala., the true annual evaporation is 34.50 in.

The U. S. Weather Bureau maintains at selected locations hook gage measurements of evaporation losses from cylindrical pans 10 in. deep and 4 ft in diameter, exposed on wood frames, bottom of pans 1 in. above the ground, generally on level ground, and in full sunshine. Detailed description published in *Monthly Weather Review*, December, 1916, or in Circular L, Instrument Division, Weather Bureau, No. 559. From comparisons available, it appears that losses from bodies of water of considerable area are 50 to 60 per cent as great as from pans exposed as above. The records are published in detail in the reports issued by the state section directors of the U. S. Weather Bureau, and in the Annual Reports of the Chief of the Weather Bureau.

Measurements of Evaporation are made by placing water-tight pans at the level of the ground and noting daily the variations in depth, together with the rainfall. On a water surface similar measurements may be made by floating boxes. It is found that the evaporation from large water surfaces is less than that from pans, that it is greater in dry and desert regions than in cultivated ones, that it decreases as the humidity of the air increases, and that it increases with the temperature of the air and the velocity of the wind.

In the North Atlantic states the annual evaporation from land surfaces is, on the average, about 40 per cent, and that from water surfaces is about 60 per cent of the annual rainfall. In low and level localities these percentages are decreased; for high regions and steep slopes they are increased. In some arid localities west of the Rocky Mountains nearly all the rainfall evaporates from land surfaces, and the evaporation from water surfaces may be several times as great as the rainfall.

Experiments made in 1909–10 by the U. S. Department of Agriculture gave the figures listed in Table III for the annual evaporation at twenty places in the United States, the evaporating pan being at or very near the surface of the ground or water.

Table IV. Maximum Intensity of Rainfall

Station	Inches per Hour for			Station	Inches per Hour for		
	5 min	10 min	60 min		5 min	10 min	60 min

This table has been compiled from all the available records at stations of the U. S. Weather Bureau which are equipped with self-registering rain gages.

39. SPEED OF WINDS IN THE UNITED STATES

U. S. Weather Bureau records of the average speed of wind in miles per hour at selected stations, and the highest speeds ever reported for a period of 5 minutes, are given in Table V.

The Beaufort Scale is used by seamen. In Table V the corresponding velocity per hour in statute miles and in nautical miles is added.

Table V. Wind Velocities

Table V. Wind Velocities—*Continued*

Intensity of Force of Wind, Beaufort's Scale	Velocity	
	Statute Miles per Hour	Nautical Miles per Hour
0. Calm. Full-rigged ship, all sail set, no headway..	0 to 3	0 to 2.6
1. Light Air. Just sufficient to give steerageway....	8	6.9
2. Light Breeze. Speed of 1 or 2 knots, " full and by "	13	11.3
3. Gentle Breeze. Speed of 3 or 4 knots, " full and by "	18	15.6
4. Moderate Breeze. Speed of 5 or 6 knots, " full and by "......................................	23	20.0
5. Fresh Breeze. All plain sail, " full and by "......	28	24.3
6. Strong Breeze. Topgallant sails over single-reefed topsails..................................	34	29.5
7. Moderate Gale. Double-reefed topsails..........	40	34.7
8. Fresh Gale. Treble-reefed topsails (or reefed upper topsails and courses)........................	48	41.6
9. Strong Gale. Close-reefed topsails and courses (or lower topsails and courses)..................	56	48.6
10. Whole Gale. Close-reefed main topsail and reefed foresail (or lower main topsail and reefed foresail)	65	56.4
11. Storm. Storm staysails.......................	75	65.1
12. Hurricane. Under bare poles..................	90 and over	78.1 and over

The words " intensity " and " force," used in connection with this scale, have no direct relation to pressure, but refer to speed or velocity.

40. BAROMETRIC OBSERVATIONS

Whenever pressure is specified in terms of the height of a column of mercury, it is always tacitly understood that it is the height the column balancing the pressure would have under "standard conditions," that is, at 0 deg cent, and where g has the standard value $g_0 = 980.665$ cm per sec per sec adopted by the International Committee of Weights and Measures. In all cases where the mercury column (if of average barometric height and at ordinary atmospheric temperature) is to be read closer than 2 or 3 mm (0.1 in.) one or more of the corrections described below must be made or the accuracy of the reading will be imaginary.

Corrections. Let l be the height of the mercury column as read at t degrees centigrade with a scale correct at t_0 degrees centigrade whose coefficient of linear expansion is β. Let ϕ be the latitude and H the elevation in meters above sea level.

(1) Temperature of the Mercury. Subtract $0.000182\ lt$.

(2) Temperature of the Measuring Scale. Add $\beta\ (t - t_0)l$. For brass $\beta = 0.000019$; for glass $\beta = 0.000008$. If, as is usual, the scale is correct at 0 deg cent, the complete correction, (1) and (2), for the expansion of both the mercury and the scale may be made by subtracting from the observed reading $(0.000182 - \beta)\ lt$, which gives

$0.000163\ lt$ for a brass scale, and
$0.000174\ lt$ for a glass scale.

Under ordinary conditions the correction may amount to as much as 4 mm.

(3) Capillary Depression in a Cistern Barometer. Add to the reading of the top of the meniscus the amount given in the table below corresponding to the internal diameter of the tube and the height of the meniscus. This somewhat uncertain correction can be avoided by using a tube at least 25 mm in diameter.

Table VI. Capillary Depression of Mercury

(After Mendeléeff and Gutkowsky. Kohlrausch, 1910)

Diameter	Height of the Meniscus in Millimeters							
	0.4	0.6	0.8	1.0	1.2	1.4	1.6	1.8
mm	mm	mm	mm	mm	mm	mm	mm	mm
4	0.83	1.22	1.54	1.98	2.37	....	....	....
5	0.47	0.65	0.86	1.19	1.45	1.80	....	....
6	0.27	0.41	0.56	0.78	0.98	1.21	1.43	....
7	0.18	0.28	0.40	0.53	0.67	0.82	0.97	1.13
8	....	0.20	0.29	0.38	0.46	0.56	0.65	0.77
9	....	0.15	0.21	0.28	0.33	0.40	0.46	0.52
10	....	....	0.15	0.20	0.25	0.29	0.33	0.37
11	....	....	0.10	0.14	0.18	0.21	0.24	0.27
12	....	....	0.07	0.10	0.13	0.15	0.18	0.19
13	....	....	0.04	0.07	0.10	0.12	0.13	0.14

(4) Pressure of the Mercury Vapor. This causes a slight depression at high temperatures, but is less than 0.01 mm under 40 deg cent.

(5) Variation of weight with Latitude and Elevation. Multiply by $g/g_0 = (1 - 0.0026 \cos 2\phi - 0.000\,000\,2\,H)$, the local height obtained by applying the above corrections to the reading. The correction for elevation is only 0.1 mm at 700 m, but the correction for latitude may amount to as much as 2 mm.

Table VII. Mean Barometer Height *b* at an Elevation of *H* Meters above Sea Level (Kohlrausch)

Air at 10 deg cent (50 deg fahr) $b_0 = 760$ mm.

$H =$	0	100	200	300	400	500	600	700	800	900	1000 m
$b =$	760	751	742	733	724	716	707	699	690	682	674 mm
$H =$	1000	1100	1200	1300	1400	1500	1600	1700	1800	1900	2000 m
$b =$	674	666	658	650	642	635	627	620	612	605	598 mm

The international meterological formula for reducing height b of mercurial barometer at t deg cent and latitude ϕ to height b_0 at 0 deg cent and latitude 45° is

$$\log_e b_0 = \log_e b + \frac{H(1 - {}^3/_8\, e/b)}{(18{,}429 + 67.5\,t + 0.003\,H)(1 + 0.0026 \cos 2\phi)}$$

41. HUMIDITY

There is always present in the atmosphere a greater or less quantity of invisible water vapor, mixed with the other gases. The *absolute humidity* is the mass of water vapor present per unit volume; and the gas pressure which this water vapor is exerting is called the *vapor pressure.* The ratio of the actual absolute humidity to the maximum quantity of water vapor that could be present at the existing temperature is the *relative humidity.* By means of suitable tables, the relative humidity may be computed from the difference between simultaneous readings of an ordinary thermometer and a thermometer with a wetted and amply ventilated bulb. The temperature at which the actual absolute humidity would be the maximum possible—i.e., the temperature at which the existing quantity of water vapor would produce saturation—is called the *dew point.*

42. PROTECTION AGAINST LIGHTNING

The following discussion and rules have been abstracted from a Safety Code for Protection against Lightning which has been prepared for the American Engineering Standards Committee under the sponsorship of the National Bureau of Standards and the American Institute of Electrical Engineers. The material included here is intended to indicate the general principles to be followed. For details as to materials and methods reference should be made to the Code.

Protection of Buildings and Miscellaneous Property

Fundamental Principles of Protection. The fundamental theory of lightning protection for buildings is to provide means by which a discharge may enter or leave the earth without passing through a non-conducting part of the structure, as for example, parts which are made of wood, brick, tile, or concrete. Damage is caused by the heat and mechanical forces generated in such non-conducting portions by the discharge, whereas in metal parts the heat and mechanical forces are known to be of negligible effect if the metal has sufficient cross-sectional area. There is a strong tendency for lightning discharges on structures to travel on those metal parts which extend in the general direction of the discharge. Hence, if metal parts are provided, of proper proportions and distribution, damage can be largely prevented. However, because lightning has such a wide range of characteristics, it is difficult to provide any practicable means which will afford absolute protection under all conditions, although the degree of protection afforded by present practice is high if the installation is properly made.

The required condition that there be a metallic path for the part of the discharge which is intercepted is met most fully by a grounded metal or metal-covered structure which presents what might be thought of as an infinite number of parallel conductors from the uppermost part of the structure to earth. It is substantially met by a steel-framed structure, which, though faced with brick, terra-cotta, or other building material, usually has, or at relatively small cost can be equipped with, a sufficient number of metal terminals or receiving points on the upper portions which connect with the frame to protect it thoroughly.

For a structure which is built wholly or partly of non-conducting materials, one of the best defenses against direct hits by lightning is to surround it with a ring of grounded metallic masts or poles of sufficient height. Or, if the structure is not large, a single mast erected nearby may be sufficient. Experiments have indicated that, under certain assumed test conditions, such a vertical conductor will generally divert to itself all direct hits which might otherwise fall within a cone-shaped space of which the apex is the top of the conductor, and the base a circle of radius two to four times the height of the conductor. This agrees with theoretical deductions. Incidentally, any metallic structure, or adequately protected structure, will function in the same manner as a mast. Thus a tall steel windmill or water-tower or rodded steeple will tend to protect nearby structures of lesser height, although before relying upon such protection care should be taken to see that the structure lies well within the cone-shaped space mentioned above.

Generally, however, on account of architectural considerations, the mast type of protection is not feasible. More suitable protection is provided by the installation of lightning conductors. Here the required conditions of protection are closely approximated by placing air terminals or receiving points on the uppermost parts of the building, with interconnecting and grounding conductors attached to the building itself. By this means a relatively small amount of metal properly proportioned and distributed is made to afford a satisfactory degree of protection and at the same time, if necessary, to afford a minimum of interference with the contour of the structure. It should be stated, however, that this type of protection is to be considered only for structures in which very small induced sparks do not present an appreciable element of danger, as they do in oil tanks, cotton warehouses, and powder-storage houses. These require much more elaborate precautions to insure their safety than do the general run of buildings.

When designing and installing a system of protection of the lightning-rod type the following principles should be followed:

(*a*) The structure should be examined and all points or parts most likely to be struck by lightning should be noted, with the view of erecting air terminals thereon for the reception of the discharge. The object is to intercept the discharge immediately above the parts likely to be struck rather than to attempt to divert it in a direction it is not likely to take. The receiving points should be placed high enough above the structure to obviate danger of fire from the arc; the more inflammable the roof material the higher the points should be placed.

(*b*) Conductors should be installed with the view of offering the least possible obstruction to the passage of a stroke between air terminals and ground. The most direct path is in general the best, and there should be no sharp bends or loops for the lightning to jump across. The obstruction is practically inversely as the number of widely separated paths, so from each air terminal there should be at least two paths to ground and more if practicable. The number of paths is increased and the obstruction lessened by connecting the conductors to form a cage enclosing the building.

(*c*) When a stroke is about to take place to earth the surrounding surface of the ground for a radius of several miles carries an electric charge. As the discharge takes place this surface charge moves radially toward the ground end of the air path, forming an electric current in the ground. Near the point where the discharge enters the ground the current density becomes high, and if the flow takes place through the foundation wall of a building damage may result. Ground connections should therefore be distributed more or less symmetrically about the circumference of a structure rather than grouped on one side. With ground connections properly distributed the current will be collected at the outer extremities and a flow underneath the building minimized. In every case, for the foregoing reason, at least two ground connections should be made at opposite extremities of the structure. Satisfactory ground connections are made in the majority of cases by extending the rod into the earth to a distance of 6 to 10 ft. Driven rods or plates may be used as alternatives. If there is a water pipe nearby connection should be made to it.

(*d*) If a lightning conductor system is placed on a building within or about which are metal objects of considerable size within a few feet of the conductor, there will be a strong tendency for sparks, or sideflashes, to jump from the conductor to the metal at its nearest point. To prevent damage an interconnecting conductor should be provided at all places where sideflashes are likely to occur.

(*e*) Within buildings where metallic objects may be liable to a dangerous rise of potential due to a lightning flash, the metal, if not interconnected with the lightning-rod system, should under some circumstances be independently grounded.

(*f*) Since a lightning conductor system as a general rule is expected to remain in working condition for long periods with little attention, the mechanical construction should be strong and the materials used such as to offer high resistance to corrosion.

(*g*) The minimum permissible weight of copper conductor for all ordinary buildings is 187 1/2 lb per 1000 ft. The foregoing general principles are embodied in the detailed specifications mentioned at the beginning of this article, which correspond to the approval requirements of underwriters' laboratories. An approved lightning conductor, therefore, will meet the requirements of the Safety Code.

Protection of Structures Containing Inflammable Liquids and Gases from Lightning

Lightning is responsible for a majority of the tank fires of the petroleum industry. In a Report on Records of Oil Tank Fires in the United States, 1915-1925, published by the American Petroleum Institute, it was stated that lightning caused 55 per cent of the fires recorded.

1. Reduction of Damage. Certain types of structures used for the storage of inflammable liquids and gases are essentially self-protecting. Protection, of a greater or less degree, may be secured for others through the installation of various types of protective equipment, such as screens, rods, or protective towers, and by other means.

2. Fundamental Principles of Protection. Protection of structures and their contents from lightning involve the following principles.

(*a*) The storage of inflammable liquids and gases in all-metal structures essentially gas-tight.

(*b*) The use in all necessary breathing vents of efficient flame arresters.

(*c*) The maintenance of containers in good condition, so far as potential hazards from electrical discharges are concerned.

(*d*) The avoidance, so far as possible, of the accumulation of explosive mixtures, in and about such structures.

(*e*) The avoidance of spark gaps in metallic conductors or between metallic conductors at points where there may be an accumulation of explosive mixtures or an escape of inflammable vapors or gases to the air.

(*f*) In connection with structures not inherently self-protecting, the establishment of cones of protection through the use of grounded screens, rods, or towers, or the equivalent.

(*g*) The location of structures containing inflammable liquids and gases not inherently self-protecting, in positions of lesser exposure with regard to lightning. Thus elevated positions should be avoided.

43. WIND PRESSURE ON STRUCTURES

Windstorm Damage. According to the statistics of one of the large insurance companies * well over one-half of the total windstorm damage is caused by the high winds that accompany ordinary storms and thunder-storms. Much of the loss is directly attributable to the omission of anchorage of buildings to foundations, of roofs to the walls, to inadequate fastening of tiles and other roof coverings, and to similar neglect of good practice in construction details. It is not customary to design such details for definite wind loads, and aside from exceptional cases any reasonable provision gives ample strength.

Protection against very severe storms can be accomplished only by adequate engineering design of the whole structure.

Wind Velocity Measurement. When it is desired to design a structure to withstand high winds, great difficulty is experienced in determining the maximum wind velocity to which the structure will be exposed. The records of the Weather Bureau give the maximum average velocity indicated for a 5-min period, known as the *maximum*, and the velocity of the fastest mile, known as the *extreme*. At 100 miles per hour average velocity the *extreme* velocity is really the average over a period of 36 sec. The maximum gust velocities are known to be much greater. What then shall be the speed for which the design is to be made?

When the records at any one place are examined, it is found that the high velocities occur very infrequently. Therefore for such structures as telephone or power lines an attempt is made to balance the cost of replacement against the cost of insurance. In other words, it is cheaper to rebuild occasionally than to build the structure strong enough initially to withstand the maximum wind speeds. In buildings and other structures the element of human safety enters and the considerations of cost are not the only ones. Yet so far as tornadoes are concerned, it is usually felt to be impracticable to build strong enough to withstand the maximum speeds. The cost of insurance is far less than the increased construction costs.

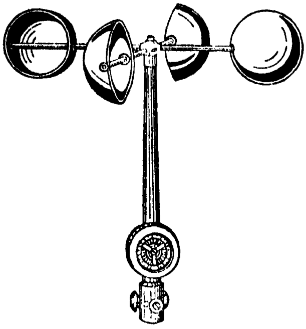

FIG. 3

Robinson Anemometers. Prior to January 1, 1928, the official Weather Bureau instrument was a Robinson-type cup anemometer with a 4-cup driving unit (Fig. 3). The readings of this instrument were usually published without correction. Because of the large errors of that instrument at high speeds a change was made on January 1, 1928, to a 3-cup unit which had smaller errors. Beginning January 1, 1932, corrections for instrumental errors were applied to the data before publication, and no single type of instrument was considered as standard. At the present time an extensive investigation of anemometer design is in progress to develop a type of instrument having small errors.

Table IX. Indicated Wind Speeds by Robinson Cup Anemometers

True Speed, miles per hour	Indicated Speed, Old 4-cup Standard	Indicated Speed, 1928 3-cup Standard	True Speed, miles per hour	Indicated Speed, Old 4-cup Standard	Indicated Speed, 1928 3-cup Standard
5	5	5	60	78	63
10	11	10	65	85	68
15	17	15	70	91	73
20	23	20	75	98	79
25	30	25	80	105	84
30	37	31	85	112	89
35	44	36	90	118	95
40	50	41	95	125	100
45	57	47	100	132	105
50	64	52	105	138	111
55	71	57	110	145	116

Note. Values above a true speed of 75 miles per hour are extrapolated, but are probably correct to the precision given, namely, 1 mile per hour.

Pitot Tubes. The standard instrument adopted by the National Bureau of Standards, National Physical Laboratory, and other scientific organizations for the measurement of air velocities is a Pitot-static tube of proper design. The instrument consists of an open tube facing into the wind and a concentric tube closed to the air stream except for several small holes drilled radially and sufficiently far from the nose that the air flows by smoothly when the tube is in line with the wind direction. A pressure gage is used to measure the difference in the pressure between the two tubes. The second tube gives the static pressure, i.e., the pressure that would be shown by a gage moving with the air. The first gives the static pressure plus the increased pressure produced by reducing the velocity to zero at the mouth of the tube. The differential pressure is $^1/_2\, dV^2$, where d is the density of the air and V the wind speed, and is known as the velocity pressure. Pitot-static tubes of poor design usually indicate a higher pressure because of a failure to give the true static pressure. Values of the velocity pressure at various wind speeds are given in Table X above for an air density of 0.07651 lb per sq ft corresponding to 15 deg cent, 760 mm Hg. The dimensions of several standard Pitot tubes, which may be used without calibration if the supporting bracket is at least 20 diameters behind the static holes, are given in the figure.

Table X. Wind-velocity Pressures

True Wind Speed, miles per hour	Velocity Pressure, lb per sq ft	True Wind Speed, miles per hour	Velocity Pressure, lb per sq ft	True Wind Speed, miles per hour	Velocity Pressure, lb per sq ft	True Wind Speed, miles per hour	Velocity Pressure, lb per sq ft
5	0.06	35	3.13	65	10.80	95	23.08
10	0.26	40	4.09	70	12.53	100	25.57
15	0.58	45	5.18	75	14.38	105	28.19
20	1.02	50	6.39	80	16.36	110	30.94
25	1.60	55	7.73	85	18.47	115	33.82
30	2.30	60	9.21	90	20.71	120	36.82

Note. The formula becomes $\frac{1}{2g}\, dV^2$ if the pressure is measured in pounds per square foot and the density in pounds per cubic foot.

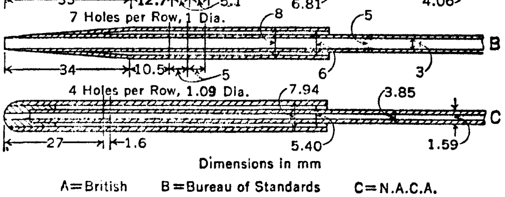

Fig. 4

Dines Tube Anemometer. The laboratory standard Pitot tubes are not suitable for use in field measurements of wind velocity but an instrument of this general type is in occasional use, namely, the Dines tube anemometer. In this instrument, the impact tube is kept pointed into the wind by means of a weather vane while the static tube is vertical. Because of this arrangement of the static tube a calibration factor is necessary and it has recently been shown that the factor depends to some extent on the wind direction and on the exact constructional details of the instrument.*

The pressures developed are transmitted to a float or diaphragm whose motion is recorded by a pen on a chart. Gusts are shown in the records, and average velocities over comparatively short intervals of time can be estimated by a consideration of the inertia effects.

Electrical Anemometers. Recently several instruments giving an indication and record of wind velocity have been developed. They consist of an electric generator driven by either a 4-cup or 3-cup Robinson anemometer wheel. The voltage is indicated or recorded, the scale being graduated in terms of wind velocity. Gust velocities are indicated and can be evaluated for comparatively short time intervals by a consideration of the inertia effects.

Bridled Cup Anemometer. Still another type of instrument for field indication of wind velocity is the bridled cup anemometer, available in an instrument developed by Julien P. Friez. A multiblade turbine wheel is rotated against a spring system to a position of equilibrium such that the spring torque balances the wind torque on the wheel. The spring system is arranged to give a uniform wind velocity scale on the indicating dial.

Interpretation of Records. The only records available in sufficient quantity to be of any service to the engineer are those of the Weather Bureau for the maximum velocity over a 5-min period and the velocity of the fastest mile. The use and interpretation of these records in connection with any particular engineering project must be left to the judgment of the engineer in charge. If it is desired to build so strong that the structure will not fail under any possible circumstances, it is believed that the design should be made for a wind speed of 150 miles per hour.

It is commonly believed that the natural gusty wind imposes severe racking stresses which are greater than those imposed by a steady wind of the same speed. This is probably true only in rare instances, for most of the puzzling effects of high winds in lifting roofs, causing walls to fail outwards, etc., are readily explained by the nature of the pressure distribution in a steady wind.

Design Practice. The current practice of most structural engineers is to consider neither the shape of the structure, the nature of the exposure, nor the probable maximum wind velocity. All these variable factors are lumped together in a design wind load of usually 20 to 30 lb per sq ft. In addition, the usual factors of safety for the material are often waived, and the allowable working stresses increased 25, 50, or even 100 per cent—a procedure described by Fleming † as giving an intellectual assent to the theories of the textbook and ignoring them in actual practice. It would seem to be more logical to retain the same working stresses and to design for a properly selected wind velocity. To that end we attempt to give experimental data known to apply with sufficient accuracy for design purposes on the wind pressures on various engineering structures. From these data the wind load actually encountered at a selected wind velocity may be computed.

Method of Giving Wind Pressure Data. ‡ The nature of the reaction between the wind and an obstacle to its progress is extremely complicated. Two characteristics should be emphasized. First, the reaction consists of a surface distribution of pressure, and the representation of the action by a single resultant force or by an average wind pressure is only a convenient device useful for certain purposes. Second, when there is no wind there is a distribution of pressure over the surface due to the normal atmospheric pressure of approximately 14.7 lb per sq in. The effect of the wind is a modification of this normal pressure, at some points an increase, at others a decrease, in pressure. The magnitude of these changes is only a small percentage of the normal atmospheric pressure, and the words " suction " or " vacuum " as commonly used in this connection do not imply any large change in density or pressure. The changes are usually less than 2 per cent of the normal atmospheric pressure (0.3 lb per sq in. or 42 lb per sq ft).

The maximum increase in pressure produced by the wind is equal to $^1/_2\, dV^2$, where d is the density of the air and V the wind speed. This pressure, usually termed the velocity pressure or impact pressure, is indicated by a Pitot-static tube of standard design. Values have already been given in a preceding table.

It is found convenient to express all observed pressure differences including the average wind pressure as ratios to the velocity pressure. Although the maximum increase in pressure is equal to the velocity pressure, pressure decreases of greater amount often occur and the force resulting from the surface distribution over a structure is frequently greater than the velocity pressure times the projected area. We may regard the ratio, or coefficient as it is sometimes called, as a shape factor. Thus if the shape factor is 1.5, we may readily find the average pressure at any wind speed by multiplying by 1.5 the velocity pressure taken from the table.

† Wind Pressure on Structures. Robin Fleming (Engineering News Co., 1915).

‡ From Sci. Paper 523, Bureau of Standards.

The shape factor for a thin square flat plate normal to the wind is 1.12, and therefore the wind force on such a plate is 1.12 times the velocity pressure times the area. On an infinitely long thin rectangular plate the shape factor is 2.0. Other values are given later.

In the above examples the shape factor is very nearly independent of size or wind speed. In general, the shape factor depends to some degree on the size and speed, the variations being said to be due to scale effect. For bodies with flat surfaces and sharp edges, the scale effect is in general so small as to be negligible for the present purpose. For spheres and cylinders the variation is great, and critical regions of speed and size occur where the shape factor decreases very rapidly. In these cases it is difficult to predict the average pressure on a full-scale structure from model tests. The important practical structure of this type is the tall chimney.

It should be especially emphasized that no single value of the wind pressure is applicable to all types of structures for a given wind velocity. The variations in shape factor are sufficiently large to demand individual treatment.

Flat Plates, Signs, etc. The shape factor for a thin flat plate depends on the ratio of length to breadth. With the wind normal to the plate, the shape factor varies from 1.12 for a square or round plate to 1.33 for a rectangular plate of length-breadth ratio equal to 6. The wind force also varies with the angle of the plate to the wind. The direction of the resultant force is very nearly at right angles to the plate, and if the force is expressed as an average pressure over the area of the plate (*not* projected normal to the wind), the maximum shape coefficients observed are 1.75 for a square plate, 1.00 for a rectangular plate of length-breadth ratio equal to 3 and 1.34 for a rectangular plate of length-breadth ratio equal to 6. The detailed values for several angles to the wind are given in International Critical Tables, Vol. 1, p. 406. For approximately square signs, a shape factor of 1.75 should be used. For rectangular signs, the factor may be reduced as indicated by the above values.

Structural Shapes, Bridge Trusses. The shape factor for a very long thin flat plate is 2. In attempting to apply this value to built-up structures such as bridge trusses or radio towers difficulty is experienced owing to shielding. Experiments on built-up members have been published in *Ergebnisse der aerodynamischen Versuchsanstalt zu Göttingen*, Vol. III, 1927; and experiments are in progress at the National Physical Laboratory of Great Britain. Reference should be made to the original publication for details as to the variation of the shape factors with angle.

On simple structural steel shapes such as angles, I beams, and built-up columns, the wind pressure is referred to the product of the length of the section by the greater dimension of the cross-section. The resultant force is resolved parallel to this dimension and perpendicular to it, and two shape factors are given. We consider here only the shape factor for the component perpendicular to the greater dimension of the cross-section; i.e., the component giving the highest stress. The maximum values observed ranged from 1.6 to 2.2., usually being about 2 and occurring when the wind was normal to the face of greater area. We may therefore conclude that a safe value for isolated structural steel shapes is 2.

A number of model bridge trusses were tested. When used singly, the shape factors were from 1.4 to 1.6 referred to the projected area of the truss. When two trusses were placed one behind the other with wind normal to the plane of the truss, the shape factor for the front truss was from 1.4 to 1.6 for all positions of the rear truss, and for all models, whereas that for the rear truss varied, with the distance apart from 0.0 to 1.2, depending on the ratio of open to closed area.

Further experiments were made on one model at a given spacing (2.75 times the vertical dimension of truss) by varying the wind direction in both horizontal and vertical directions. Variation in the vertical plane is most important, the shielding effect disappearing at an angle of 15 deg.

A further experiment was made on a model consisting of two trusses spaced a distance equal to the maximum vertical dimension of the truss with floor between. In this case the shape factor referred to the area of *one* truss reached the value 1.85, and at varying angles in the vertical plane a large lifting force was found. Bridges across deep canyons or in other locations where variations of the wind direction in a vertical direction are possible may need some provision to take care of possible lifting forces.

The most recent and authoritative data on the wind pressure on open frameworks are contained in the paper Winddruck auf vollwandige Bauwerke und Gitterfachwerke, by O. Flachsbart, published in the first volume of *Mémoires de l'association internationale des ponts et charpentes*, Zurich, 1932. The shape coefficient of a single truss of a given perimeter was found to be a function of the solidity ratio, i.e., the projected area of the individual truss members divided by the total projected area within the perimeter of the framework.

The coefficient is approximately independent of the distribution of the individual members. Flachsbart proposed for design purposes a coefficient of 2.0 for solidity ratios between 0 and 0.2, 1.8 for those between 0.2 and 0.3, 1.6 for those between 0.3 and 0.9, and 2.0 for those between 0.9 and 1.0.

For two frameworks, one behind the other, at distances of the order of the width of the framework, the shape coefficient to be applied to the area of *one* truss is as follows:

Solidity Ratio	Shape Coefficient
0.1	3.6
.2	2.7
.3	2.4
.4	2.2
.5	2.0

In any large project where wind forces are an important item, wind-tunnel tests of a model will more than pay their cost.

Buildings, Skyscrapers. For tall buildings of usual proportions it appears that a shape factor in the neighborhood of 1.5 is required.* For slender towers the factor probably approaches 2.0 as for a long prism. For buildings of approximately cubical form, the factor is from 0.8 to 1.0. As is true for bridge structures, model tests are justified in important projects. Otherwise an estimate should be made from the known shape factors given in the table below:

Cube	0.8
Thin square flat plate	1.1
Prism 1 by 1 by 3	1.5
Very long prism	2.0

Frequently questions arise as to the strength of individual walls. Here the load depends on the pressure in the interior of the building which in turn depends on the number, size, and location of openings. It seems probable that in many cases the average pressure on a wall may equal twice the velocity pressure. The average pressure over small areas may reach three times the velocity pressure. It should especially be noted that the force may be in either direction depending on the pressure within the building, and the outward collapse of walls in high winds is readily explained without the necessity of assuming a very low barometric pressure.

Roofs. The force on a roof also depends on the pressure within the building, which is somewhat indeterminate. The distribution on the outer surface is such as to give ordinarily a lifting force provided the pitch of the roof does not exceed 30 deg. There seems to be no occasion for providing for a wind load acting downward on the roof under these conditions. There is every reason to provide for substantial lifting forces which are present even when the wind does not penetrate beneath the roof covering. If the interior is not subject to the full velocity pressure through broken windows or otherwise, the upward loading is of the order of 0.7 to 1 times the velocity pressure. Under special circumstances, such as in a factory-type building with windows broken on the windward side, the loading may reach twice the velocity pressure. The roof should accordingly be securely anchored to the walls and the walls in turn to the foundations.

When the pitch of the roof exceeds 30 deg, regions of increased pressure appear as shown by the experiments of T. E. Stanton (*Proc. Inst. C. E.*, London, 156, 1903–04, p. 78).

A large number of measurements of wind pressure on roofs and buildings were published in *Jahrbuch der deutschen Gesellschaft für Bauingenieurwesen*, 1927, p. 87.

Volume 97 of *Engineering News-Record* contains analyses of the effects of the Florida hurricane of 1926 which show that pressures of 55 to 65 lb per sq ft were attained. The wind velocity was independently estimated as 132 miles per hour, which would give the observed pressures on structures having a shape factor of 1.5.

Additional model experiments on an approximately cubical structure are given in Volume 100, No. 13, p. 508, by Professor Dawley of the Kansas State Agricultural College. These give shape factors from 0.7 to 0.85, depending on the presentation of the model to the wind and the presence or absence of windows and doors.

Chimneys, Standpipes, Gas-holders, Flag Poles, Transmission Lines. If the product of diameter in feet by wind speed in miles per hour is less than about 40, the shape factor for cylindrical structures may be taken from the Table XI.

The flow about cylinders in this region in a steady wind is very definitely periodic, the frequency in cycles per second being equal to about 0.3 times the ratio of the wind speed in miles per hour to the diameter in feet. Care should be taken that the natural period of vibration of the structure does not correspond to the above eddy frequency at high wind speeds. It is understood that in some cases transmission lines have been observed to

---

* Scientific Paper 523, Bureau of Standards.

vibrate (in segments) with the eddy frequency and under certain conditions cause fatigue failures.

Table XI. Shape Factors for Cylindrical Structures

Ratio of Length to Diameter	Shape Factor	Ratio of Length to Diameter	Shape Factor
1	0.63	10	0.83
2	0.69	20	0.92
3	0.75	40	1.00
5	0.74	Infinite	1.20

When the product of diameter in feet by wind speed in miles per hour exceeds 40, the shape factor is found to decrease to a comparatively low value. Experiments on full-scale cylinders in a natural wind indicate a value as low as 0.3 to 0.4. The flow is no longer definitely periodic but is very irregular and often unsymmetrical. Sufficient information is not available to justify such a radical reduction in the shape factor. Until the flow about large cylinders is fully understood, it is recommended that the same shape factors be used as for small cylinders.

In transmission lines, the problem of shielding again appears since individual wires are near each other. It is common practice to compute the wind force not on the actual wire but on the wire assumed coated with ice 1/2 in. in thickness. The shielding depends on the spacing of the wires, and on the wind speed. With a spacing of about 1 ft, the force on the shielded wires is about 50 per cent of that on the front unshielded wire. The factor for an unshielded wire may be taken from the table above.

If the wind blows at an angle to a single wire, the force remains nearly normal to the wire and the magnitude of the force falls off approximately as the square of the sine of the angle of the wire to the wind.

General Remarks on the Choice of Shape Coefficients. It has been assumed in the foregoing treatment that the winds of high velocity might come from any direction, and only the maximum shape coefficients are given. Under certain special conditions it may be found that high winds are likely to prevail only from certain directions. Some further study than that given here is then necessary.

In any extensive construction where wind loads are an important factor, the shape factor should be determined by wind tunnel experiments on a model.

Air Resistance of Automobiles. The observed shape coefficients found for automobiles of conventional design vary from about 0.75 to 1.35* depending on the exact shape. Special streamline automobiles and racing cars have been designed for which the shape coefficient is as low as 0.2. The area to which the shape coefficients apply is the area of projection on a plane normal to the usual direction of motion.

An average value is of doubtful service since in most cases the resistance of a particular automobile is desired for certain specified conditions of car speed, wind speed, and wind direction. This is most readily found by wind tunnel experiments on a model, since full-scale conditions are not easily controlled.

The effect of natural winds is an important one, especially as the speed of the car approaches or exceeds 100 miles per hour. Lateral forces, lifting forces, and turning moments become of appreciable magnitude. Some experiments described in Research Papers 591 and 749 of the U. S. Bureau of Standards show that a streamline model may maintain its advantage of a lower resistance to motion as compared to conventional model up to relative wind angles of 40 deg. The lateral forces are also less for the streamline model. The vertical lifting forces do not differ much for relative wind angles up to 40 deg. However, the turning moments, which tend to produce skidding, are considerably greater for the streamline model.

Air Resistance of Trains. A few papers have appeared on the determination of the air resistance of trains.† It appears from the experiments of Goss that the shape factor for an isolated car is about 0.5, applied to the area of projection normal to the usual direction of motion. For the first car in a train the factor is about 0.4, second car about 0.036, other intermediate cars about 0.04, last car 0.1.

The French experiments were carried out on a train consisting of locomotive, tender, and two cars, the dimensions of which are not given. The coefficients appear to be of the same order of magnitude as those found by Goss, except for the intermediate car. Those interested should consult the original papers for details as to the shapes of the cars.

No information is available on the effect of angle of the train to the relative wind. It seems probable that as with automobiles a comparatively small side wind will introduce a fairly large side force.

CHEMISTRY

GENERAL CHEMISTRY

1. CHEMICAL ELEMENTS

Atoms. All forms of matter may be decomposed by the proper choice of conditions of treatment to ultimate units upon which the modern science of chemistry is based. These are known as *atoms*. These ultimate units cannot then be further reduced by the conditions of temperature, pressure, electrical voltage, etc., ordinarily available.

Ninety-two kinds of such atoms, variously combined and associated, constitute the building blocks of the material universe.

Elements. A substance composed of a multitude of a single kind of atom is known as an *element*. There are thus ninety-two elements, named and classified in Table I. All the atoms of an element may be considered to be identical with respect to mass and other properties. For convenience the names of these elements have all been abbreviated to *symbols*, as H for hydrogen, O for oxygen, etc.

Table I. The Chemical Elements

In the following table, in every case the atomic number is given as well as the atomic weight. The atomic weights are those of 1934.

Name *	Symbol	Atomic Number	Atomic Weight	Nature
Actinium	Ac	89		
Aluminum	Al	13	26.97	Metal
Antimony (stibium)	Sb	51	121.76	Metal
Argon	A	18	39.944	Inert gas
Arsenic	As	33	74.91	Metalloid
Barium	Ba	56	137.36	Metal
Beryllium (glucinum)	Be	4	9.02	Metal
Bismuth	Bi	83	209.00	Metal
Boron	B	5	10.82	Metalloid
Bromine	Br	35	79.916	Liquid
Cadmium	Cd	48	112.41	Metal
Calcium	Ca	20	40.08	Metal
Carbon	C	6	12.000	Metalloid
Cassiopeium (see Lutecium)	Cp	71		
Celtium (see Hafnium)	Ct	72		
Cerium	Ce	58	140.13	Metal
Cesium	Cs	55	132.91	Metal
Chlorine	Cl	17	35.457	Gas
Chromium	Cr	24	52.01	Metal
Cobalt	Co	27	58.94	Metal
Columbium (niobium)	Cb	41	93.3	Metal
Copper (cuprum)	Cu	29	63.57	Metal
Dysprosium	Dy	66	162.46	Metal
Erbium	Er	68	165.20	Metal
Europium	Eu	63	152.0	Metal

* Names of the more abundant elements are in bold-face type.

Molecules. The reactions of the elements are the result of the reactions of the constituent atoms. Combinations of atoms are known as *molecules*, which are the ultimate units obtained by physical division of *compounds*. Compounds are the products of the combination of two or more elements. The symbol H may be taken to represent either the element hydrogen or a single hydrogen atom. Similarly, O may represent either the element oxygen or a single oxygen atom. The formula H_2O, which represents a molecule of water, indicates that such a molecule consists of two atoms of hydrogen and one of oxygen. Atoms and elements are thus represented by symbols; molecules and compounds, by formulas.

Most of the gaseous elements, at ordinary temperatures, are ***diatomic***, i.e., their molecules consist of two atoms. Thus we have the formulas: H_2, O_2, Cl_2, Br_2, N_2, etc.

Reactions. Formulas, representing compositions, may be combined into *chemical equations* representing *reactions*. Thus $2H_2 + O_2 \rightarrow 2H_2O$. This is an abbreviated statement of the fact that two molecules of hydrogen may, under favorable conditions, react with one of oxygen to yield two molecules of water. The hydrogen and oxygen are called *reactants*; the water is called the *product*. It will be observed that the number of hydrogen and of oxygen atoms in the reactants is equal to the number in the product. The equation is then said to be *balanced*. All true equations must be balanced since matter can neither be created nor destroyed, in accordance with the *Law of Conservation of Matter*.

2. CHEMISTRY OF WATER

A Molecule of Water, corresponding to the formula H_2O, consists of two atoms of hydrogen with an atomic weight of 1.008 and one of oxygen with an atomic weight of 16. The proportion of the constituent elements by weight is therefore approximately one-ninth hydrogen and eight-ninths oxygen.

Water may be formed according to the reaction $2H_2 + O_2 \rightarrow 2H_2O$ by the spontaneous reaction of hydrogen and oxygen in a gaseous mixture. The combination occurs with explosive violence upon the application of a small spark or flame. Decomposition of water into its constituents can be accomplished only by the application of considerable energy by the passage of an electric current through the liquid. Pure hydrogen is then liberated at the cathode or negative electrode, while pure oxygen gas is liberated at the anode or positive electrode. This is the reverse reaction of that of combination, in which rôles of reactants and products are interchanged.

Decomposition. Certain very active metallic elements displace one of the two hydrogen atoms in the water molecule.

$$\left.\begin{aligned} 2Na + 2H_2O &\rightarrow 2NaOH + H_2 \\ 2K + 2H_2O &\rightarrow 2KOH + H_2 \end{aligned}\right\} \qquad (1)$$

These elements, sodium and potassium, react with water very vigorously to liberate hydrogen. The products other than hydrogen are sodium hydroxide and potassium hydroxide, respectively. These dissolve and remain in solution in the excess of water. Other metallic elements such as barium, calcium, magnesium, etc., displace hydrogen similarly from water, though less vigorously in the order given.

Other, less active, metals such as iron, displace hydrogen from water only when in the form of steam at high temperature.

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2 \qquad (2)$$

In this case, an oxide, magnetic iron oxide, is formed.

Hydroxides. Oxides of some of the metallic elements combine with water with great avidity. The products are *hydroxides*.

$$\left.\begin{aligned} Na_2O + H_2O &\rightarrow 2NaOH \text{ (sodium hydroxide)} \\ K_2O + H_2O &\rightarrow 2KOH \text{ (potassium hydroxide)} \\ CaO + H_2O &\rightarrow Ca(OH)_2 \text{ (calcium hydroxide)} \\ BaO + H_2O &\rightarrow Ba(OH)_2 \text{ (barium hydroxide)} \end{aligned}\right. \qquad (3)$$

Hydrates. Many salts combine with water to form hydrated compounds. Thus

$$\left.\begin{aligned} CuSO_4 + 5H_2O &\rightarrow CuSO_4 \cdot 5H_2O \\ Al_2(SO_4)_3 + 18H_2O &\rightarrow Al_2(SO_4)_3 \cdot 18H_2O \\ CaCl_2 + 6H_2O &\rightarrow CaCl_2 \cdot 6H_2O \end{aligned}\right\} \qquad (4)$$

Such compounds are called *hydrates*. The special method of writing their formulas is to be noted. It indicates that the water they contain is loosely bound and may be readily removed by the application of heat. Often the number of molecules of water which a hydrate contains depends upon the temperature of its formation and the availability of the water. At sufficiently high temperatures all are reduced to the anhydrous condition.

Oxides of aluminum, iron, and the heavy metals are more stable and combine with water much less readily.

Acids. Oxides of non-metallic elements also combine readily with water. The products are *acids*.

$$\left.\begin{aligned} N_2O_5 + H_2O &\rightarrow 2HNO_3 \text{ (nitric acid)} \\ P_2O_5 + 3H_2O &\rightarrow 2H_3PO_4 \text{ (phosphoric acid)} \\ SO_3 + H_2O &\rightarrow H_2SO_4 \text{ (sulfuric acid)} \end{aligned}\right\} \qquad (5)$$

3. VALENCE, IONIC DISSOCIATION, AND ATOMIC DISINTEGRATION

Atomic Forces. Modern theory recognizes that the forces which bind atoms into molecules are electrical in character, and are the forces of attraction of unlike charges.

Positive and Negative Valence. Atoms, or groups of atoms, which have a tendency to gain electrons are said to be acidic in character; atoms, or groups of atoms, which tend to lose electrons are said to be basic. The non-metals are acidic, the metals basic. The number of electrons which a non-metal may gain is called its *negative valence*; the number of electrons which a metallic atom may lose is called its *positive valence.*

Oxygen with a negative valence of two may combine with two atoms of hydrogen with a positive valence of one to form H_2O. The rule is that the sum of the positive valences in a stable inorganic substance must equal the sum of the negative valences to give molecules which are electrically neutral. Thus in potassium dichromate, $K_2Cr_2O_7$, potassium has a positive valence of one, chromium a positive valence of six, and oxygen a negative valence of two. The sum of the positive valences is $2 \times 1 + 2 \times 6 = 14$; the sum of the negative valences is $7 \times 2 = 14$. In sulfuric acid, H_2SO_4, hydrogen has a positive valence of one, sulfur a positive valence of six, and oxygen a negative valence of two. The sum of the positive valences is $2 \times 1 + 1 \times 6 = 8$, and the sum of the negative valences is $4 \times 2 = 8$. In this way a knowledge of valence may be very helpful in the writing of formulas.

Ions. Many inorganic compounds dissociate in aqueous solutions into positive elements or groups of elements and an equal number of negative elements or groups of elements. The ultimate units of these dissociation products differ from ordinary atoms or groups of atoms in that they carry units of positive or of negative electricity; they are called ions. Such solutions are capable of conducting an electric current and show a number of other electrical manifestations which will be treated in the section on Electrochemistry. The subject of ionic dissociation is very important for the reason that the properties of these solutions are equivalent to the summation of the properties of the constituent ions, which serves to simplify their treatment very considerably.

Isotopes. Modern theory assumes that atoms consist merely of configurations of positive and negative electric charges and that their properties, and thus the properties of the elements, depend upon these configurations. The simplest of these is that of the hydrogen atom, while all the heavier atoms are supposed to consist merely of multiples of this fundamental atomic unit. This is confirmed by the observation that the atomic weights of most of the elements are approximately integers. Those which appear to deviate from this rule have, in many cases, been shown to be mixtures of two or more so-called isotopes whose atomic weights are, in fact, integers. *Isotopes* are simply variations of an element, identical in every property except in those depending upon their atomic weights.

Many isotopes are known, and more are constantly being discovered and isolated. Those of greatest present interest are of the element hydrogen, which has been found to contain three. Inasmuch as the atomic weights of isotopes differ by integral values, and since the atomic weight of the simplest and most abundant isotope of hydrogen has an atomic weight of approximately one, the second isotope is twice as heavy, so that here the difference in behavior between isotopes is greatly accentuated. It is for this reason that so much interest has been devoted to this subject. The second hydrogen isotope is found in comparatively minute amounts accompanying the first; its concentration entails such a great amount of effort that it is, at present, very expensive. The third hydrogen isotope has not as yet been isolated but is known to exist on the basis of evidence obtained from the so-called mass spectroscope. Efforts to effect its concentration have already met with considerable success.

Heavy Water. The second hydrogen isotope combines with oxygen to form water having a molecular weight of 20—so-called *heavy water*—as compared with 18 for ordinary water. This " heavy water " is actually present in small concentrations in natural waters and may be concentrated by selective decomposition such as may be produced by electrolytic decomposition, a method which has been the subject of numerous refinements.

Table II. Formula for Different Waters

	Atomic Weight of Hydrogen	Formula	Atomic Weight of Water
Ordinary water	1	H_2O	18
Heavy water	2	D_2O	20

Radioactivity and Atomic Disintegration. Although the elements are ordinarily stable against decomposition, certain of the heavier ones change spontaneously. Thus the element radium changes gradually into lead accompanied by the *emission of rays* which are common to all radioactive substances. The so-called *alpha-rays* are known to be doubly charged atoms of helium, the *beta-rays* electrons, and the *gamma-rays* are radiations similar to light but of much shorter wavelength. The alpha-rays are positively charged while the beta-rays are negative, an observation which indicates that matter is fundamentally electrical in nature.

The alpha- and beta-rays consist of material particles at high velocities. Similar rays have been artificially induced by purely electrical means. By the impact of such particles on otherwise stable atoms, elements have been transmuted, a feat which was long deemed impossible.

4. ACIDS, BASES, AND SALTS

Acids

The Simplest Acids, and those which typify in many respects the properties of acids in general, are those of the halogen elements: fluorine, chlorine, bromine, and iodine in simple combination with hydrogen, represented by the formulas H_2F_2, HCl, HBr, and HI. The most common of these is HCl, known as hydrogen chloride or hydrochloric acid. This substance may be produced from its constituent elements by introducing a flame into a gaseous mixture of hydrogen and chlorine or by exposing the mixture to light.

Hydrochloric Acid is very soluble in water, in which it undergoes ionic dissociation according to the following equation:

$$HCl \rightarrow H^+ + Cl^- \qquad (6)$$

the positive and negative signs indicating electric charges. This reaction goes practically to completion, for which reason hydrochloric acid is known as a strong acid.

The Acid Character of a Solution is due solely to the presence of hydrogen ions, H^+. Perhaps the most characteristic and distinguishing property of solutions of acids is the sour taste which may be regarded as the taste of hydrogen ion. Hydrosulfuric acid, or hydrogen sulfide, H_2S, is an example of a very weak acid which dissociates only very slightly, and which manifests the properties of acids very sparingly. Other acids which are even weaker, and a great number of intermediate strength, are known.

Sulfuric Acid is an example of an acid which may dissociate to furnish two hydrogen ions for each molecule.

$$H_2SO_4 \rightarrow 2H^+ + SO_4^{--} \qquad (7)$$

The SO_4 group which furnishes the SO_4^{--} ion (doubly charged) is called a *radical*, and is bivalent. A *radical* is a group of atoms which is found in a series of compounds and which gives them a characteristic property common to them all. Phosphoric acid, H_3PO_4, may furnish three hydrogen ions, and contains the trivalent radical PO_4.

Bases

Sodium Hydroxide, together with other hydroxides, are called bases. They dissolve in water to yield alkalis, or alkaline solutions, ionizing as follows:

$$NaOH \rightarrow Na^+ + OH^- \qquad (8)$$

The monovalent radical OH thus yields the OH^- ion which is as characteristic of alkalis as H^+ is of acids and which gives alkaline solutions a soapy feel and an alkaline, or caustic taste.

Calcium Hydroxide, $Ca(OH)_2$, is an example of a base which may furnish two hydroxyl ions per molecule. Trivalent and higher bases are generally very insoluble, and are therefore only weakly alkaline.

Neutralization

If an acid solution, containing hydrogen ions, is mixed with an alkaline solution, containing hydroxyl ions, the two react with considerable evolution of heat. For the case of sodium hydroxide and hydrochloric acid, the following series of equations indicates the reaction:

$$\begin{array}{rcl} NaOH \rightleftarrows Na^+ + & OH^- & \\ & + & \\ HCl \rightleftarrows Cl^- + & H^+ & \qquad (9) \\ & \downarrow\uparrow & \\ & H_2O & \end{array}$$

Thus the hydrogen and hydroxyl ions react to form water which is identical with the solvent. The solution thus contains only sodium, Na^+, and chloride, Cl^-, ions if the acid and base are in equivalent proportions. Upon evaporating the solution, these ions combine to form solid, crystalline sodium chloride.

$$Na^+ + Cl^- \rightarrow NaCl \quad \text{(common salt)} \tag{10}$$

If only the initial reactants and the final product are considered, omitting the ionic intermediates, we have

$$NaOH + HCl \rightarrow NaCl + H_2O \tag{11}$$

This molecular equation is the more concise, and is generally used for that reason. The ionic equations, however, indicate the true course of the reaction.

This process is called *neutralization* for the reason that the acid and basic properties truly neutralize one another unless there is an excess of one or another of the reactants, in which cases the neutralization is only partial. The acid and the base owe their properties to hydrogen and to hydroxyl ions, neither of which are present in the resulting salt typified by sodium chloride. A large number of salts are known, some of which will be discussed below.

Calcium hydroxide, $Ca(OH)_2$, each molecule of which is capable of neutralizing two of HCl, is known as a diacid base. Similarly aluminum hydroxide, $Al(OH)_3$, is a triacid base, etc. Sulfuric acid, H_2SO_4, is a dibasic acid, while phosphoric acid, H_3PO_4, is a tribasic acid.

Reversibility

Many reactions of chemistry are reversible, i.e., the products may become reactants so that the process moves backwards. Equilibrium will be attained when the forward and backward reactions progress at the same rate so that the proportions of the substances involved do not change with time. In the ionization of hydrogen sulfide to hydrogen and hydrosulfide ions.

$$H_2S \leftrightarrows H^+ + HS^- \tag{12}$$

the double arrow indicates the reversibility. The tendency to react in the forward direction will be proportional to the concentration of H_2S; the tendency to move backwards will be proportional to the concentration of H^+ and also proportional to the concentration of HS^-. Thus we have:

$$\text{Forward tendency} = K_1\,(H_2S) \tag{12a}$$

$$\text{Backward tendency} = K_2\,(H^+)(HS^-) \tag{12b}$$

where the parentheses indicate numerical concentration of the substances included therein in any convenient units. For convenience in calculations of this sort the unit generally employed is the mol per liter. The mol is simply the molecular weight expressed in grams. For example, a mol of hydrogen (H_2) gas would be 2 grams; a mol of oxygen (O_2) gas 32 grams. A mol of any substance contains 6.06×10^{23} molecules, so that it is a practical unit proportional to the number of molecules.

At equilibrium the forward and backward tendencies in the above equation must be equated.

$$\left.\begin{aligned} K_1\,(H_2S) &= K_2\,(H^+)(HS)^- \\ \text{or} \qquad \frac{(H^+)(HS^-)}{(H_2S)} &= \frac{K_1}{K_2} = K \end{aligned}\right\} \tag{13}$$

where K is a constant known as the *dissociation constant*. If this constant is determined experimentally we have a mathematical equation from which we may determine the concentrations of reactants or products under any given conditions. This is an example of the so-called *Law of Mass Action.*

The second stage in the ionization involves the reaction:

$$HS^- \leftrightarrows H^+ + S^= \tag{14}$$

from which the equilibrium equation 15, may be derived:

$$\frac{(H^+)(S^=)}{(HS^-)} = K' \tag{15}$$

By multiplying equation 13 by equation 15

$$\frac{(H^+)^2(S^=)}{(H_2S)} = KK' = K'' \tag{16}$$

which is the equation for the complete ionization

$$H_2S \leftrightarrows 2H^+ + S^= \tag{17}$$

Thus it is seen that the factors which affect, and the equations which represent, a chemical equilibrium are independent of other intermediate equilibria. Equation 16 indicates, among other things, that the ionization of a typical weak acid, hydrogen sulfide, is repressed by increasing (H^+) through introduction of a strong acid such as HCl.

Hydrolysis

An important application of these principles is in the *hydrolysis* of certain salt solutions. To illustrate, a solution of sodium sulfide, Na_2S, will ionize to $2Na^+ + S^{--}$. Water also dissociates very slightly into hydrogen and hydroxyl ions.

$$H_2O \leftrightarrows H^+ + OH^- \qquad (18)$$

The equation which describes this dissociation quantitatively is similar in form to that of the dissociation of hydrogen sulfide.

$$\frac{(H^+)(OH^-)}{(H_2O)} = K_{H_2O} \qquad (19)$$

In fairly dilute solutions the concentration of the water (H_2O) does not change appreciably in percentage with small variations in the concentrations of dissolved substances so that it is usual to assume that it is a constant. The above then becomes

$$(H^+)(OH^-) = K'_{H_2O} = 10^{-14} \text{ numerically} \qquad (19a)$$

The hydrogen ions formed by the dissociation of the water may combine with the sulfide ions of the sodium sulfide to form hydrosulfide ions described above. The equation for the equilibrium which may thus be established is

$$\frac{(H^+)(S^{--})}{(HS^-)} = K'_{HS^-} = 1.2 \times 10^{-15} \qquad (20)$$

Combining the two equations we have

$$\frac{(OH^-)(HS^-)}{(S^{--})} = \frac{K_{H_2O}}{K'_{HS^-}} = 8.3 \qquad (21)$$

which is the dissociation equation for the reaction

$$S^{--} + H_2O \leftrightarrows HS^- + OH^- \qquad (22)$$

or as a molecular equation

$$Na_2S + H_2O \leftrightarrows NaHS + NaOH$$

This reaction is the reverse of neutralization, and is called *hydrolysis*. It represents the dissociation of a salt to an acid (or acid salt) and a base. Only salts formed from a weak acid, or a weak base, or both, hydrolyze appreciably. A salt of a weak acid and a strong base hydrolyzes to an alkaline solution; a salt of a strong acid and a weak base hydrolyzes to an acid solution.

*p*H and Acidity

The equation for the dissociation of water

$$(H^+)(OH^-) = K_{\text{Ion}} = 10^{-14} \qquad (23)$$

expresses the interdependence of hydrogen- and hydroxyl-ion concentrations in aqueous solutions. These vary over such a wide range that their logarithms rather than their absolute values are employed. Taking logarithms of both sides.

$$-\log (H^+) - \log (OH^-) = 14 \qquad (24)$$

The negative logarithm of hydrogen-ion concentration, $-\log (H^+)$, is called the *p*H and is a measure of acidity. The lower the *p*H the higher is the acidity or the lower the alkalinity. If the *p*H is 7 the hydrogen- and hydroxyl-ion concentrations are equal and the solution is neutral. This is the case in pure water or in solutions of neutral salts which do not hydrolyze appreciably. Solutions having a *p*H lower than 7 are acid; those having a *p*H higher than 7 are alkaline. As an example, a hydrogen-ion concentration of 10^{-5} mol per liter corresponds to a *p*H of 5. The *p*H of a solution may be measured by certain organic indicators which change in color according to the acidity or alkalinity; also by means of certain electrode potential methods and others of lesser importance.

5. SOLUTIONS AND RULES FOR SOLUBILITY

Solubility and Saturation

The above treatment is valid only for weak acids. Similar equations will now be derived which are quantitatively valid only for difficultly soluble salts.

Calcium sulfate, ($CaSO_4$), in contact with water will dissolve according to the following equation:

$$\text{Solid } CaSO_4 \leftrightarrows Ca^{++} + SO_4^{--} \qquad (25)$$

The reversibility of the reaction indicates that the dissolved salt tends to precipitate back to the solid phase. At equilibrium the two tendencies will be equal and the solution will then be said to be *saturated* with respect to the salt.

Table III. Solubilities of Certain Salts in Water at 18° (Professor Alexander Smith)*

* Previously published in Mining Engineers' Handbook, by Robert Peele.

The upper figure of each pair is the number of grams of the anhydrous salt held in solution by 100 cc of water; the lower is the molar solubility, i.e., the number of mols (molecular weight expressed as grams) contained in 1 liter of saturated solution. The numbers for small solubilities have been abbreviated; thus $0.0_{6}4$ = 0.0000004.

Solubility Product

It may be assumed that the tendency of solid calcium sulfate to pass into solution as calcium and sulfate ions is constant since it depends only upon the character of the solid salt. The reverse tendency to precipitate solid calcium sulfate from the solution may be assumed to be proportional to the concentrations of the ions taking part in the reaction. Thus

$$CaSO_4 \rightarrow Ca^{++} + SO_4^{--} \quad \text{Forward tendency} = K_1 \text{ a constant}$$

$$Ca^{++} + SO_4^{--} \rightarrow CaSO_4 \quad \text{Backward tendency} = K_2\,(Ca^{++})(SO_4^{--}) \qquad (26)$$

When the solution is saturated with calcium sulfate the reaction is in a state of equilibrium, and we may equate the two, obtaining

$$K_1 = K_2\,(Ca^{++})(SO_4^{--}) \qquad (27)$$

or

$$(Ca^{++})(SO_4^{--}) = K_1/K_2 = K_{sol} = 2.25 \times 10^{-4}$$

where K_{sol} is called the solubility product constant.

The constancy of the product of the two ion concentrations at equilibrium would indicate, for example, that calcium sulfate would be considerably less soluble in sodium sulfate solution than in pure water since an increase in (SO_4^{--}) must be accompanied by a decrease in (Ca^{++}).

For the case of the solubility of calcium sulfate in pure water it will be noted that each molecule of salt that dissolves yields an ion of calcium and an ion of sulfate. Hence the calcium-ion concentration expressed in mols per liter (Ca^{++}) must be equal to the solubility of the salt in mols per liter. The same applies to the sulfate-ion concentration. The solubility-product constant is therefore equal to the square of the solubility in mols per liter for the simple type of salt exemplified by calcium sulfate.

Solubilities are generally expressed in grams per liter or grams per 100 grams of water. For purposes of calculations of complex solubility relations these should always be converted to molal units as will be explained in greater detail under the title Chemical Calculations. (See p. 10–10.)

Precipitation

If a solution contains ions of a salt and the product of their concentrations in mols per liter exceeds the solubility product as calculated, precipitation must occur until finally the product of the concentrations of the ions which remain equals the computed constant. It has been shown that the solubility product of calcium sulfate

$$(\mathrm{Ca}^{++})(\mathrm{SO}_4^{--}) = K_{\mathrm{sol}} = 2.25 \times 10^{-4} \tag{28}$$

We now ask what will be the amount of calcium sulfate precipitated per liter of solution upon the addition of sulfuric acid sufficient to produce a concentration of 0.1 M (0.1 mol per liter).

Since the quantity of sulfuric acid is large compared with the small amount of calcium sulfate present, we may assume that the sulfate-ion concentration is 0.1 (SO_4^{--}). Substituting this value in the above equation we find that the concentration of calcium ion after precipitation is $2.25 \times 10^{-4}/0.1$, or 2.25×10^{-5} mol per liter. The amount present in a saturated solution in pure water is 1.5×10^{-2} mol per liter, as shown in Table III. The amount precipitated is therefore the difference of the two, or $0.015 - 0.0000225$, which is equal to 0.0149775, so that all but a very small quantity of the salt is precipitated by the sulfuric acid.

It sometimes happens that, owing to complex ion formation, the true ion concentrations are difficult to compute. Another difficulty may arise in the application of the principle to very soluble salts, in which case it may not be truly valid. Finally it is to be observed that in some cases a precipitate may be formed in a colloidal state so that it may not be observed, the solution remaining clear. These difficulties do not, however, destroy the usefulness of the method, which may constitute an important tool in the calculation of solubilities of salts in solutions of specified composition.

6. CHEMICAL CALCULATIONS

Percentage Composition by Weight. In Table IV the molecular weight of calcium phosphate, $\mathrm{Ca_3(PO_4)_2}$, is given as 310.28. With the atomic weights given in Table I, the percentage composition of the compound may be calculated as follows:

Ca .... $3 \times 40.08 \div 310.28 = 38.7\%$
P .... $2 \times 31.02 \div 310.28 = 20.0\%$
O .... $2 \times 4 \times 16 \div 310.28 = 41.3\%$

100.0%

To Determine the Formula from Analysis, divide the percentage of each element by its atomic weight and determine the lowest integer ratios between the quotients. Thus, in the above example,

$$\frac{38.7}{40.08} : \frac{20.0}{31.02} : \frac{41.3}{16} = 3 : 2 : 8$$

Computations from analysis will not always work out with mathematical precision. Elements, however, always combine in simple proportions represented by whole numbers.

To Determine the Weight of a Substance Consumed or Produced in a Reaction. The unit of mass used in chemical calculations is the mol. If the data of the problem are specified in grams, the gram-mol is the proper unit. This is equal to the molecular weight in grams. Given g grams of a substance, this will be equivalent to g/M gram-mols, where M is the molecular weight.

Example. A high-grade phosphate rock containing phosphate equivalent to 85 per cent of "bone phosphate," $\mathrm{Ca_3(PO_4)_2}$, is treated with an excess of sulfuric acid which converts 95 per cent of the phosphate to phosphoric acid. How much phosphoric acid would be produced from 100 grams of rock? The reaction (for purposes of calculation) is

$$\mathrm{Ca_3(PO_4)_2 + 3H_2SO_4 \rightarrow 2H_3PO_4 + 3CaSO_4}$$

The balanced equation shows that one mol of calcium phosphate may be converted to two mols of phosphoric acid. One hundred grams of rock contain $100 \times 0.85 \times 0.95 = 80.75$ grams of converted $\mathrm{Ca_3(PO_4)_2}$.

Molecular weight of $\mathrm{Ca_3(PO_4)_2}$ is 310.28.

$80.75/310.28 = 0.260$ mol of $\mathrm{Ca_3(PO_4)_2}$ yielding $0.260 \times 2 = 0.52$ mol of $\mathrm{H_3PO_4}$ of molecular weight 98.06, which is equivalent to $0.520 \times 98.06 = 51.0$ grams of phosphoric acid.

Thus 100 grams of rock will be converted to 51.0 grams of phosphoric acid. The units used are immaterial. Thus 100 lb of rock would yield 51 0 lb of acid, and 100 tons would yield 51.0 tons. For convenience in industrial calculations, the pound-mol or molecular weight in pounds is often used instead of the gram-mol The principles involved are the same.

Gas Calculations. (See also Art. 16, Chemistry of Gases.) The weight of a unit

volume of a perfect gas varies directly as the pressure and inversely as the absolute temperature.

$$\frac{w_1}{w_2} = \frac{P_1}{P_2} \times \frac{T_2}{T_1} \tag{29}$$

Table IV. Composition, etc., of More Important Industrial Compounds*

Name	Formula	Mol wt	Sp gr	Name	Formula	Mol wt	Sp gr

Table V. Weights of Common Gases

Name	Chemical Symbol	Relative Weight Air = 1	At 760 mm Hg, 0° C; kg per cu m	At 29.92 in. Hg, 32° F; lb per cu ft
Air	O + 4 N	1.00000	1.2932	0.08072
Oxygen	O	1.1056	1.4298	0.0893
Hydrogen	H	0.06926	0.08957	0.005592
Nitrogen	N	0.97137	1.25615	0.07841
Carbon monoxide	CO	0.9569	1.2344	0.07706
Carbon dioxide	CO_2	1.52901	1.9774	0.1234
Methane	CH_4	0.559	0.727	0.04539
Sulfuretted hydrogen	H_2S	1.177	1.522	0.09501
Ammonia	NH_3	0.5967	0.7697	0.04805

The volume of a given weight of gas varies inversely as the pressure and directly as the absolute temperature in accordance with the law.

$$pV = nRT \tag{30}$$

where p is the pressure, V is the volume, n is the number of mols, R is the gas law constant and T is the absolute temperature.

Example. If 1000 cu ft of air at 25 deg cent and 14.7 lb per sq in. of pressure are compressed to 50 lb per sq in. and heated to 350 deg cent, what will be the volume occupied?

For use in gas calculations, the temperatures must be converted to the absolute scale by addition of 273.2. Thus 25 deg cent is equivalent to 298.2 deg abs, while 350 deg cent is equivalent to 623.2 deg abs. From equation 30,

$$V_2 = \frac{nRT_2}{nRT_1} \times \frac{p_1}{p_2} \times V_1 = \frac{623.2}{298.2} \times \frac{14.7}{50} \times 1000 = 614.4 \text{ cu ft}$$

INDUSTRIAL CHEMISTRY

It is useful, in discussing the compounds of the elements, to make a systematic classification into certain families the members of which show many similarities. The following groups of elements will be discussed (hydrogen and oxygen have already been considered):

1. The alkali metals, sodium, potassium, lithium, cesium, and rubidium.
2. The alkali earth metals, calcium, strontium, and barium.
3. Magnesium, zinc, cadmium, and mercury.
4. Copper, silver, and gold.
5. Rhodium, rhuthenium, platinum, palladium, osmium, and iridium.
6. Aluminum.
7. Iron, nickel, and cobalt.
8. Chromium and manganese.
9. Lead, tin, and titanium.
10. Nitrogen, phosphorus, arsenic, antimony, and bismuth.
11. The halogens: chlorine, bromine, iodine, and fluorine.
12. Sulfur, selenium, and tellurium.
13. Carbon, boron, and silicon.

Only those substances and reactions which are of industrial importance, or which throw a useful light on industrial processes, are treated. The formulas for the various salts are included. These formulas show the water of hydration contained in the materials as they are usually shipped and marketed. The formulas of minerals are the nominal formulas generally accepted and do not indicate small quantities of elements considered "impurities."

7. THE ALKALI METALS

Sodium

The most abundant of the alkali metals is sodium, which is found as the chloride, sulfate, nitrate, and carbonate in commercial deposits.

Sodium Chloride ($NaCl$), or common salt, is obtained as the mineral halite or as a constituent of natural brines. It is, directly or indirectly, the starting material for almost all industrial chemicals which contain sodium or chlorine.

Sodium Sulfate (Na_2SO_4) is obtained from the minerals mirabilite and glauberite, but chiefly as a by-product from the manufacture of hydrochloric acid. By heating concentrated sulfuric acid with sodium chloride a reaction takes place in two stages.

$$H_2SO_4 + NaCl \rightarrow NaHSO_4 + HCl \tag{1}$$

The sodium bisulfate thus formed then reacts with additional sodium chloride to produce more hydrochloric acid and sodium sulfate.

$$NaHSO_4 + NaCl \rightarrow Na_2SO_4 + HCl \tag{2}$$

Sodium Bisulfate ($NaHSO_4$) is an intermediate product in the formation of sulfuric acid. Commercially, the most important source is from the manufacture of nitric acid from soda niter, which is treated with sulfuric acid and heated to distil the nitric acid which is formed.

$$NaNO_3 + H_2SO_4 \rightarrow NaHSO_4 + HNO_3 \tag{3}$$

Unlike the reaction for the manufacture of hydrochloric acid, this reaction stops at the bisulfate stage so that large quantities of sodium bisulfate, called niter cake, are produced as a by-product, and may be used to manufacture hydrochloric acid from sodium chloride.

Sodium bisulfate is an example of an *acid salt* which may be formed from a polybasic acid by partial neutralization so that the metallic element replaces only a part of the available hydrogen.

Sodium Bicarbonate ($NaHCO_3$) along with sodium carbonate occurs in soil and in certain lakes. It is made industrially by the Solvay process, in which a solution of sodium chloride is saturated with ammonia and carbon dioxide gases. The ammonia and carbon dioxide form ammonium bicarbonate which ionizes.

$$\left.\begin{array}{r} NH_3 + CO_2 + H_2O \rightarrow NH_4^+ + HCO_3^- \\ NaCl \rightarrow Na^+ + Cl^- \end{array}\right\} \rightarrow NaHCO_3 + NH_4Cl \qquad (4)$$

We have thus a solution containing four ions. On cooling, sodium bicarbonate, which is the least soluble salt which might be formed, precipitates out. Ammonium chloride, NH_4Cl, may then be obtained by evaporation of the solution and sold as sal ammoniac.

Sodium Carbonate (Na_2CO_3) is obtained by heating the bicarbonate.

$$2NaHCO_3 \rightarrow Na_2CO_3 + CO_2 + H_2O \qquad (5)$$

Sodium carbonate is the salt of a strong base and a weak acid, so that its solutions are moderately strongly alkaline and it is useful wherever a cheap, moderately strong alkali is needed. Solutions of the bicarbonate are weakly alkaline.

Disodium Phosphate ($Na_2HPO_4 \cdot 12H_2O$) is manufactured in a way which will exemplify this use of sodium carbonate. A solution of phosphoric acid is partially neutralized to form an acid salt.

$$H_3PO_4 + Na_2CO_3 \rightarrow Na_2HPO_4 + CO_2 + H_2O \qquad (6)$$

Disodium Phosphate hydrolyzes to some extent in solution and is slightly alkaline. It is used extensively in the textile industry.

Trisodium Phosphate ($Na_3PO_4 \cdot 12H_2O$) is strongly alkaline and can be formed only by the action of a strong alkali, caustic soda, on a solution of disodium phosphate.

$$Na_2HPO_4 + NaOH \rightarrow Na_3PO_4 + H_2O \qquad (7)$$

Sodium Hydroxide (NaOH), or caustic soda, is made commercially by suspending slaked lime in a solution of sodium carbonate.

$$Na_2CO_3 + Ca(OH)_2 \rightarrow CaCO_3 + 2NaOH \qquad (8)$$

The calcium carbonate is less soluble than the lime so that the reaction goes almost to completion. The precipitate is filtered, and the solution evaporated to give solid sodium hydroxide. The electrolytic process for making caustic soda will be discussed under Electrochemistry.

Sodium Nitrate ($NaNO_3$), called soda niter or saltpeter, is found in deposits in Chile. It is used for the manufacture of nitric acid and niter.

Sodium salts, as well as the salts of the other alkali metals, are strongly ionized in solution. The metal ions of this family are colorless and very stable in aqueous solutions so that the properties of these solutions are primarily those of the non-metallic ion or ions. These metals show a valence of unity in all their compounds.

The metals themselves are of very low density and have a brilliant metallic luster when a fresh surface is cut. They form compounds with all the non-metals and react with most of the elements spontaneously as well as with many compounds. They oxidize readily in the air to form the oxides Na_2O, K_2O, etc., and must therefore be kept under mineral oils. They ignite in the atmosphere to form peroxides such as Na_2O_2. This peroxide appears to violate the rules of valence, but it is believed to have a structure Na—O—O—Na, the oxygen atoms being joined, and thus canceling two of their available valences. Compounds of this kind are not generally very stable, except organic compounds, which belong to another realm of chemistry.

Potassium

Potassium is widely distributed in nature, particularly in the form of silicates, orthoclase, muscovite (mica), and leucite, and the products of their decomposition such as the clays.

Commercial deposits are comparatively few. In certain localities such as Stassfurt, Germany, there has been a deposition from sea water together with sodium and magnesium, in the minerals carnallite, kainite, and sylvite. Limited deposits of niter are found in Chile and elsewhere. Other sources are alunite and certain brines.

Potassium Chloride (KCl) is obtained from sylvite (KCl), carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$), and kainite ($KCl \cdot MgSO_4 \cdot 3H_2O$). It is used as a source of other potassium compounds.

Potassium Nitrate (KNO_3) is manufactured from the chloride by reaction with sodium nitrate. The two salts are dissolved to saturation, and the solution cooled. Under the conditions, potassium nitrate is the least soluble combination of the four ions, and crystallizes out.

It is an important constituent of fertilizers, supplying both the potassium and the nitrate which are important plant foods. It is also used as a constituent of gunpowder.

Potassium Carbonate (KCO_3) is similar to sodium carbonate, and is made by the leaching of the ash residues of plants such as kelp.

Potassium Hydroxide (KOH) is made by a process similar to that of the manufacture of sodium carbonate. It is similar in its properties to sodium hydroxide and is seldom used because of its greater cost.

Potassium Sulfate (K_2SO_4) is obtained from the minerals kalinite ($KAl(SO_4)_2 \cdot H_2O$), and alunite $\{K[Al(OH_2)]_3(SO_4)_2 \cdot 3H_2O\}$. It is useful as a constituent of fertilizers.

Lithium, Cesium, and Rubidium

The Other Alkali Metals are found only in very limited deposits and are of minor importance.

8. THE ALKALI EARTH METALS—CALCIUM, STRONTIUM, AND BARIUM

Calcium

Calcium salts are widely distributed in nature. The most important source is limestone, which is composed chiefly of the mineral calcite.

Calcium Oxide (CaO), or quicklime, is produced by heating limestone ($CaCO_3$) in vertical kilns.

$$CaCO_3 \leftrightarrows CaO + CO_2 \qquad (9)$$

It is a white, amorphous solid which reacts vigorously with water to form **calcium hydroxide** [$Ca(OH)_2$], or slaked lime. Thus

$$CaO + H_2O \rightarrow Ca(OH)_2 \qquad (10)$$

This reaction is used in the making of *mortar*. In the setting of mortar there is an evaporation of water and a reaction with the carbon dioxide of the air.

$$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O \qquad (11)$$

The calcium carbonate sets to a solid mass.

Calcium hydroxide is soluble in water to a very limited extent. More concentrated mixes are prepared by mechanically suspending excess lime in a saturated solution. Such a preparation is called milk of lime. This is the cheapest alkali and one that finds considerable application.

Calcium Sulfate ($CaSO_4 \cdot 2H_2O$) is widely distributed in nature as the mineral gypsum. When gypsum is heated at 150 deg cent it is converted to *plaster of paris.*

$$2CaSO_4 \cdot 2H_2O \leftrightarrows (CaSO_4)_2 \cdot H_2O + 3H_2O \qquad (12)$$

When water is added to plaster of paris, gypsum is formed by hydration, a reversal of the above reaction, while the paste dries and expands slightly, thus filling in the details of casts as it sets to a hard mass.

Calcium Hypochlorite ($CaOCl_2$), or chloride of lime, is prepared by passing chlorine gas over slaked lime.

$$Ca(OH)_2 + Cl_2 \leftrightarrows CaOCl_2 + H_2O \qquad (13)$$

The reaction is reversible so that chloride of lime, otherwise known as *bleaching powder*, is used as source of free chlorine, which is an active bleaching agent.

Calcium Bicarbonate [$Ca(HCO_3)_2$] is formed by treating a suspension of the highly insoluble carbonate in water with carbon dioxide. The bicarbonate is very soluble, and the above reaction explains its presence in natural waters which flow over limestone deposits.

$$CaCO_3 + CO_2 + H_2O \leftrightarrows Ca(HCO_3)_2 \qquad (14)$$

When a solution of the bicarbonate is boiled, carbon dioxide is driven off and the above reaction is reversed.

Temporary Hardness in water is due to the presence of considerable amounts of calcium and magnesium bicarbonates. These react with soaps, which are the sodium and potassium salts of certain organic acids, to give insoluble calcium and magnesium salts which will not produce the desired suds nor have the desired cleansing properties. Temporary hardness may be removed, as has been noted, by simple boiling which precipitates the insoluble carbonates (hence temporary) or, more conveniently, by treating the water with an alkaline substance such as lime or caustic soda,

$$\left.\begin{aligned} &Ca(HCO_3)_2 + Ca(OH)_2 \rightarrow 2CaCO_3 + 2H_2O \\ &Ca(HCO_3)_2 + 2NaOH \rightarrow CaCO_3 + Na_2CO_3 + 2H_2O \end{aligned}\right\} \qquad (15)$$

with similar reactions for the magnesium. It will be observed that, if lime is used, it should not be added in excess since soluble calcium hydroxide will produce additional hardness.

Permanent Hardness is hardness in water that cannot be removed by boiling. It is due to the presence of small amounts of calcium sulfate, which is slightly soluble, or magnesium sulfate. Permanent hardness may be removed by treatment with sodium carbonate.

$$CaSO_4 + Na_2CO_3 \rightarrow CaCO_3 + Na_2SO_4 \qquad (16)$$

Magnesium sulfate reacts similarly.

Ordinarily water contains both permanent and temporary hardness, in which case sodium hydroxide may be used to produce sodium carbonate by reaction with the bicarbonates, and this in turn may precipitate the permanent hardness. An alternative would be to use a combination of lime and sodium carbonate in the proper proportions.

Water-softening compounds which are sold are, in general, to be avoided since each water requires a specific treatment which must be determined from its analysis.

Certain minerals and artificial insoluble substances called *permutits* have the property of removing calcium and magnesium ions from solution, and replacing them with harmless sodium ions. Both temporary and permanent hardness may be removed in this way. The permutit may afterwards be reactivated by treatment with sodium chloride brine which reverses the process.

Calcium Carbonate ($CaCO_3$), besides being the chief constituent of limestone, is the basic material of marble, alabaster, pearl, coral, shells of marine animals, and chalk. The last is used both as the natural and as the artificially precipitated calcium carbonate in the pigment *whiting* which finds uses in the paint and paper industries.

Strontium

Strontium is similar in its properties to calcium. It is found in the minerals strontianite ($SrCO_3$) and celestite ($SrSO_4$). The chief application of strontium is in the sugar industry, in which its salts are used to precipitate the sugar from molasses, and in medicinal preparations.

Barium

Barium is mined in considerable quantity, particularly for the pigment industry.

Barium Carbonate ($BaCO_3$) is found as the mineral witherite.

Barium Sulfate ($BaSO_4$) is found as barite which is ground to produce a cheap white pigment. Precipitated barium sulfate is much finer and therefore more useful for this purpose.

Barium Sulfide (BaS) is made by heating barite with coke (carbon).

$$BaSO_4 + 4C \rightarrow BaS + 4CO \qquad (17)$$

A solution of the sulfide, together with one of zinc sulfate, precipitates a mixture of barium sulfate and zinc sulfide, called *lithopone*, a white composite pigment.

$$BaS + ZnSO_4 \rightarrow ZnS + BaSO_4 \quad \text{(lithopone)} \qquad (18)$$

Barium sulfate is also used in mixtures with titanium dioxide in pigments sold as Titanox B.

The pure alkali earth metals are similar in appearance to the alkali metals, and are only slightly less reactive. They are bivalent in all their compounds and give colorless ions.

§9. MAGNESIUM, ZINC, CADMIUM, AND MERCURY

Magnesium

Magnesium is obtained chiefly from salt brines containing magnesium chloride. It also occurs in dolomitic rock, which contains the mineral magnesite ($MgCO_3 \cdot CaCO_3$), and in many silicate rock formations.

Magnesium metal is very active at elevated temperatures or when in a finely divided condition. In the massive state and near room temperatures, however, the metal is so stable that it forms the basis of an important series of structural alloys.

Magnesium Oxide (MgO), or magnesia, is obtained similarly to calcium oxide by calcination of the carbonate. It is used as an insulating material and in some cements.

Magnesium Sulfate ($MgSO_4 \cdot 7H_2O$), or Epsom salt, is soluble salt produced by treating the carbonate with sulfuric acid. Uses are in tanning, dyeing, and soap-making.

$$MgCO_3 + H_2SO_4 \rightarrow MgSO_4 + CO_2 + H_2O \qquad (19)$$

Zinc

The important zinc minerals are sphalerite, smithsonite, willemite, zincite, franklinite, and calamine.

Zinc Sulfide (ZnS) is found as the mineral sphalerite. This ore is generally converted to the oxide by roasting.

$$2ZnS + 3O_2 \rightarrow 2ZnO + 2SO_2 \qquad (20)$$

The sulfur dioxide liberated is converted to sulfuric acid, which is a by-product.

Pure zinc sulfide is white. It is made by treating a solution of zinc sulfate with hydrogen sulfide or an alkaline sulfide.

$$ZnSO_4 + H_2S \leftrightarrows ZnS + H_2SO_4 \qquad (21)$$

The reaction is reversible, so that care must be exercised to prevent the sulfuric acid (or hydrogen ion) from becoming too concentrated. The pure white sulfide is used as a pigment. With barium sulfate it is sold as lithopone, already discussed under barium sulfate.

Zinc Carbonate ($ZnCO_3$) is obtained as smithsonite or calamine. It is converted by heat to the oxide.

$$ZnCO_3 \rightarrow ZnO + CO_2 \qquad (22)$$

Zinc Oxide (ZnO) is obtained as the mineral zincite or by roasting the sulfide or carbonate. When heated with powdered coal it is converted to metallic zinc vapor which is condensed to the molten metal.

$$ZnO + C \rightarrow Zn + CO \qquad (23)$$

If the zinc vapor is suddenly chilled in the absence of air it is precipitated as *zinc dust*, a blue metallic powder which is used as a paint pigment. If the vapor is burned in air, a pure form of white oxide is obtained which is sold for pigmenting paints, enamels, rubber, etc.

$$2Zn + O_2 \rightarrow 2ZnO \qquad (24)$$

Zinc Sulfate ($ZnSO_4 \cdot 7H_2O$) is obtained by treating sphalerite with dilute sulfuric acid.

$$ZnS + H_2SO_4 \leftrightarrows ZnSO_4 + H_2S \qquad (25)$$

The salt may then be crystallized from the solution.

Zinc Hydroxide [$Zn(OH)_2$] is precipitated as an insoluble gelatinous precipitate by treating zinc salts in solution with an alkali.

$$ZnSO_4 + 2NaOH \rightarrow Zn(OH)_2 + Na_2SO_4 \qquad (26)$$

An excess of alkali redissolves the hydroxide, forming a sodium salt—sodium zincate.

Sodium Zincate (Na_2ZnO_2) is thus obtained

$$Zn(OH)_2 + 2NaOH \rightarrow Na_2ZnO_2 + 2H_2O \qquad (27)$$

It will be observed that zinc hydroxide, which generally shows basic characteristics, may under alkaline conditions act as an acid. Hydroxides which have this property are called amphoteric. They include the hydroxides of zinc, aluminum, tin, titanium, and others.

Metallic zinc itself reacts with alkali to form the zincate

$$Zn + 2NaOH \rightarrow Na_2ZnO_2 + H_2 \qquad (28)$$

All the metals which form amphoteric hydroxides are thus attacked by both acids and alkalis.

Cadmium

Cadmium is obtained along with zinc from most of its ores. Its compounds are very similar to those of zinc except that the hydroxide is not amphoteric. It forms the insoluble yellow sulfide (CdS) which finds application as a pigment.

Both zinc and cadmium are bivalent in all their compounds, and form colorless ions in solution.

While both zinc and cadmium metals are quite active, they form coatings of oxides when exposed to the air, which help to resist corrosion under most conditions. Iron coated with zinc is called *galvanized*. Cadmium is even more corrosion-resisting than zinc.

Mercury

The principal source of mercury is cinnabar.

Mercuric Sulfide (HgS) is found as cinnabar. It is obtained in pure form by precipitation from solutions of mercury salts treated with hydrogen sulfide or alkali sulfides. This reaction is similar to the precipitation of zinc and cadmium sulfides.

Metallic Mercury is obtained readily by roasting cinnabar.

$$HgS + O_2 \rightarrow Hg + SO_2 \qquad (29)$$

The mercury is volatilized and condensed as the heavy metallic liquid, quicksilver. It dissolves all the common metals except iron, platinum, and nickel as *amalgams*.

Mercury forms two series of salts corresponding to valences of one and two. The monovalent compounds are called mercurous salts; the bivalent are called mercuric.

Mercurous Nitrate [$Hg(NO_3)\cdot 2H_2O$] and *mercuric nitrate* [$Hg(NO_3)_2$] are formed by treating metallic mercury with hot nitric acid. If an excess of mercury is present the mercurous salt is formed; in the presence of excess nitric acid, the product is mercuric nitrate. Mercurous nitrate may be formed by adding mercury to a solution of mercuric nitrate.

Mercuric Fulminate [$Hg(ONC)_2$] is obtained by the action of mercury with nitric acid and alcohol. It is used as a detonator.

Mercuric Sulfate ($HgSO_4$) is obtained by the reaction of mercury with hot sulfuric acid.

$$Hg + 2H_2SO_4 \rightarrow HgSO_4 + SO_2 + 2H_2O \qquad (30)$$

Mercuric Chloride ($HgCl_2$), or corrosive sublimate, is obtained by the sublimation of mercuric sulfate with salt.

$$HgSO_4 + 2NaCl \rightarrow HgCl_2 + Na_2SO_4 \qquad (31)$$

Mercurous Chloride ($HgCl$), or calomel, is produced by subliming mercuric chloride and mercury.

$$HgCl_2 + Hg \rightarrow 2HgCl \qquad (32)$$

10. COPPER, SILVER, AND GOLD

Copper

Copper is found as native copper, covellite, chalcocite, bornite, chalcopyrite, enargite, tetrahedrite, cuprite, malachite, azurite, and chrysocolla. Copper is similar to mercury in that it forms two series of salts corresponding to valences of one and two. These are termed cuprous and cupric.

Cuprous Sulfide (Cu_2S) and **cupric sulfide** (CuS) are found as chalcocite and covellite respectively. They are roasted to give the oxides,

$$Cu_2S + O_2 \rightarrow Cu_2O + SO_2 \qquad (33)$$

the sulfur dioxide being converted to sulfuric acid. The complex sulfides bornite (Cu_6FeS_4) and chalcopyrite ($CuFeS_2$), and the arsenious and antimonial sulfides enargite (Cu_3AsS_4) and tetrahedrite ($Cu_8Sb_2S_7$), are treated similarly.

Cuprous Oxide (Cu_2O) and **cupric oxide** (CuO) are obtained as cuprite (Cu_2O) and, along with impurities, by the roasting of the sulfide ores. By complex metallurgical operations they are converted to impure, or *blister*, copper which is refined electrolytically. (See Electrochemistry.)

Cupric Sulfate ($CuSO_4\cdot 5H_2O$) is prepared by allowing dilute sulfuric acid to react with pure copper in the presence of air.

$$2Cu + 2H_2SO_4 + O_2 \rightarrow 2CuSO_4 + 2H_2O \qquad (34)$$

It may be crystallized as commercial blue vitriol.

Cupric Hydroxide [$Cu(OH)_2$] is formed by adding an alkali to a solution of a copper salt. It is a blue, gelatinous precipitate.

$$CuSO_4 + 2NaOH \rightarrow Cu(OH)_2 + Na_2SO_4 \qquad (35)$$

Cupric hydroxide is dissolved by ammonium hydroxide, giving a deep blue solution,

$$Cu(OH)_2 + 6NH_4OH \rightarrow Cu(NH_3)_6(OH)_2 + 6H_2O \qquad (36)$$

The cuprammonium hydroxide is practically completely ionized. The blue color is that of cuprammonium ion. Such solutions are used to dissolve cellulose for the manufacture of a kind of artificial fiber.

The above reaction, in which a *complex ion* is formed, differs from the process of solution of the amphoteric hydroxides inasmuch as it is specific for the particular alkali, ammonium hydroxide. Sodium hydroxide, which is a stronger alkali, does not dissolve cupric hydroxide. Other metallic hydroxides, such as cuprous, zinc, iron, nickel, chromium, tin, silver, and titanium, also form complexes with ammonia. Only those of cuprous and silver, however, of the common metals are as stable as that of cuprammonium ion.

We have already described the acid salts sodium bisulfate and disodium phosphate which are formed by partial neutralization of polybasic acids. In a similar way basic salts may be formed by partial neutralization of polyacid bases. Basic carbonates of copper are found as the minerals malachite [$Cu_2(OH)_2CO_3$] and azurite [$Cu_3(OH)_2(CO_3)_2$]. These are leached with dilute sulfuric acid to form solutions of the sulfates.

$$Cu_2(OH)_2CO_3 + 2H_2SO_4 \rightarrow 2CuSO_4 + 3H_2O + CO_2 \qquad (37)$$

The copper is then recovered from the impure solution by electrowinning. (See Electrochemistry.) Copper and other metals which form gelatinous hydroxides tend to form basic salts of such great complexity and of such variety that their compositions appear to be indefinite. The hydroxides themselves, when precipitated from solutions of the sulfates, generally carry considerable sulfate in the precipitate, the amount depending on the conditions which prevail. These precipitates may therefore be considered to be complex basic salts although it is more usual to consider them as hydroxides with "contaminating" or "absorbed" acid radicals.

Cuprous ions are colorless in solution; cupric ions are colored blue.

Silver

Silver occurs as the native metal and as the minerals argentite, hessite, proustite, pyrargyrite, stephanite, and cerargyrite. It is commonly found in association with lead, zinc, copper, nickel, and gold ores and is obtained as a by-product from the smelting and refining of these metals besides being recovered from the high-silver ores.

In the smelting of lead ores, zinc is added to the molten lead and forms an immiscible liquid which floats. The silver, being more soluble in the zinc than in the lead, is extracted into the upper layer which may then be drawn off and the zinc vaporized from the dissolved silver. Silver is also obtained as a sediment in the electrolytic refining of copper and zinc and may be recovered from the "mud." (See Electrochemistry.) Native silver is soluble in mercury, with which it forms an amalgam. Certain ores are treated in this way, the mercury being afterwards removed from the silver by distillation.

Silver Sulfide (Ag_2S) is found as the mineral argentite from which the silver is usually recovered by cyaniding. (See below.) The same applies to the telluride hessite (Ag_2Te), and to the arsenious and antimonial minerals proustite (Ag_3AsS_3), pyrargyrite (Ag_3SbS_3), and stephanite (Ag_6SbS_4).

The pure sulfide, a gelatinous black precipitate, is obtained, as are the sulfides of copper, zinc, mercury, etc., by treating a solution of a silver salt with hydrogen sulfide or an alkaline sulfide.

Silver Nitrate ($AgNO_3$) is obtained by treating silver with hot, strong nitric acid.

$$3Ag + 4HNO_3 \rightarrow 3AgNO_3 + NO + 2H_2O \qquad (38)$$

The nitrate is soluble, and may be crystallized from the solution. Its chief uses are in photography and medicine.

Silver Chloride ($AgCl$), **silver bromide** ($AgBr$), and **silver iodide** (AgI) are highly insoluble salts prepared by treating solutions of silver nitrate with solutions of chlorides, bromides, or iodides. They are precipitated in highly dispersed form in gelatin for use in photographic plates, film, and paper, and for medicinal preparations. The chloride is found as the mineral cerargerite; the other two halides occur in rare deposits.

Silver chloride and silver bromide dissolve in ammonium hydroxide to give the complex ion $Ag(NH_3{}^+)_2{}^-$ similar to the cuprammonium complex. The iodide is so highly insoluble that it does not dissolve. Solutions of thiosulfates and of cyanides, however, dissolve even the iodide and the sulfide, which is not affected by ammonia, to give the complex ions $Ag(S_2O_3)_2{}^-$ and $Ag(CN)_2{}^-$. It is for this reason that sodium thiosulfate, or hypo, is used in photographic fixing baths to dissolve silver salts, while sodium cyanide solutions are used to dissolve sulfide and complex ores of silver in the process of cyaniding.

Silver is monovalent in all its compounds and forms colorless ions. It is a very unreactive metal, and its salts are decomposed to the metal when exposed to light or considerable heat.

Gold

Gold is found chiefly as the native metal but also as the complex gold and silver tellurides, sylvanite and calaverite. It is obtained as a by-product, along with silver, from copper, lead, zinc, and nickel smelters and refineries.

Gold forms two series of compounds corresponding to valences of one and three, but none of the simple salts are stable. It forms the same cyanide complex as does silver, $Au(CN)_2{}^-$, and is recovered from its ores by cyaniding as well as by amalgamation. The metal is even less reactive than silver. It is insoluble in the mineral acids as are the other metals, but dissolves in a mixture of nitric and hydrochloric acids, called *aqua regia*, to form the complex chlorauric ion $AuCl_4{}^-$.

11. RHODIUM, RUTHENIUM, PLATINUM, PALLADIUM, OSMIUM, AND IRIDIUM

These metals are extremely inert toward chemical attack. All except rhodium and iridium, however, are dissolved by aqua regia, a mixture of hydrochloric and nitric acids, forming soluble complex chlorides. Platinum in specially prepared forms is useful as a catalyst in many chemical processes, sulfuric acid manufacture by the contact process being the most important.

12. ALUMINUM

By far the most important source of aluminum is the mineral bauxite. Gibbsite and alunite are also used, while cryolite is chiefly important as a flux for bauxite in the electrochemical manufacture of the metal. Aluminum is an important constituent of clays and many rocks.

Aluminum Oxide (Al_2O_3) is found as the hard mineral corundum used as an abrasive, and in the hydrated form as bauxite.

Aluminum Sulfate [$Al_2(SO_4)_3 \cdot 18H_2O$] is manufactured by the reaction of strong sulfuric acid and bauxite.

$$Al_2O_3 + 3H_2SO_4 \rightarrow Al_2(SO_4)_3 + 3H_2O \qquad (39)$$

It is used in water purification, mordanting, paper-making, and fire-proofing cloth.

Alum [$K_2SO_4 \cdot Al_2(SO_4)_3 \cdot 24H_2O$] is typical of a large group of complex salts called alums. It is readily crystallized from a solution containing potassium and aluminum sulfates. Its importance is due to the fact that, owing to its perfect crystallization, it is readily prepared in a very pure form, whereas the other aluminum salts are usually contaminated and are not completely soluble in water. It is prepared by the addition of potassium sulfate to a solution of aluminum sulfate. It is used in mordanting and for photographic fixing baths as well as in baking powders and other products.

Sodium and ammonium may replace potassium in alum, giving sodium and ammonium alum, respectively.

Aluminum Hydroxide [$Al(OH)_3$], or a basic salt, is formed as a gelatinous white precipitate when aluminum salts are treated with alkali. It is precipitated in drinking water from aluminum sulfate or alum, to coagulate the suspended matter and thus produce a clear liquid. It is amphoteric, forming aluminates which are, in the case of the alkali metals, soluble.

$$Al(OH)_3 + NaOH \leftrightarrows NaAlO_2 + 2H_2O \qquad (40)$$

The aluminates of calcium and magnesium are important constituents of portland cements.

Aluminum metal itself is prepared electrolytically from bauxite. (See Electrochemistry.) It is quite reactive but forms an inert protective coating of aluminum oxide. Aluminum is trivalent in all its compounds and forms colorless ions.

13. IRON, NICKEL, AND COBALT

Iron

Iron occurs in the minerals pyrrhotite, pyrite, marcasite, magnetite, hematite, limonite, and copiapite, besides being present in all silicate rocks.

Iron forms two series of compounds, corresponding to valences two and three, called ferrous and ferric.

Ferrous Oxide (FeO) and **ferric oxide** (Fe_2O_3) result from the rusting (oxidation) of iron. Ferric oxide is found as the mineral hematite; a combination of the two oxides occurs as magnetite ($FeO \cdot Fe_2O_3$). The oxides are heated in a blast furnace with coke to yield metallic iron (pig iron).

$$\left.\begin{array}{l} FeO_3 + 3C \rightarrow 2Fe + 3CO \\ FeO + C \rightarrow Fe + CO \end{array}\right\} \qquad (41)$$

Ferrous Carbonate ($FeCO_3$) is found as the mineral siderite. Under heat it decomposes to ferrous oxide which may be treated with coke to give the metal.

$$FeCO_3 \rightarrow FeO + CO_2 \qquad (42)$$

Sulfides of Iron are found as the minerals pyrrhotite ($Fe_{11}S_{12}$) (composition variable), pyrite (FeS_2), and marcasite (FeS_2). These substances are not true salts and do not conform to the usual rules of valence. They are roasted to give iron oxide and sulfur dioxide which is converted to sulfuric acid.

$$2FeS_2 + 5O_2 \rightarrow 2FeO + 4SO_2 \tag{43}$$

Some ferrous sulfate is also formed inadvertently in the process.

Ferrous Sulfide (FeS) is precipitated as are the sulfides of zinc, copper, etc., by treatment of a solution of a ferrous salt with hydrogen sulfide or a soluble sulfide. In this form it is a black gelatinous substance. It is also formed by direct reaction of its elements under heat.

Ferrous Sulfate ($FeSO_4 \cdot 7H_2O$) is produced as a by-product of many industrial processes such as the pickling of steel and the manufacture of titanium oxide pigments. It is used in water treatment, being cheaper than aluminum sulfate, and as a source of electrolytic iron. Solutions of the salt oxidize slowly in the presence of air to ferric sulfate, provided excess of sulfuric acid is present. Otherwise a basic ferric sulfate is formed.

$$4FeSO_4 + O_2 + 2H_2O \rightarrow 4Fe(OH)SO_4 \tag{44}$$

Ferric Sulfate $Fe_2(SO_4)_3 \cdot 9H_2O$ is reduced to ferrous sulfate by hydrogen sulfide in solution.

$$2Fe^{+++} + H_2S \rightleftarrows 2Fe^{++} + 2H^+ + S \tag{45}$$

If the acid (or hydrogen-ion) concentration is not too high, ferrous sulfide is precipitated, and ferric sulfide can never be obtained. Ferric sulfate is similar to aluminum sulfate in forming alums such as ferric ammonium sulfate $[(NH_4)_2SO_4 \cdot Fe_2(SO_4)_3 \cdot 24H_2O]$. Both ferrous and ferric ions form stable cyanide complexes, the former giving ferrocyanide $Fe(CN)_6^{----}$, the latter ferricyanide $Fe(CN)_6^{---}$.

Potassium Ferrocyanide $[K_4Fe(CN)_6]$ is made by heating scrap iron and potassium carbonate with nitrogenous organic compounds such as slaughter-house wastes. The mass is then leached with water, and the solution evaporated until the potassium ferrocyanide crystallizes out.

Potassium Ferricyanide $[K_3Fe(CN)_6]$ is produced by treating a solution of potassium ferrocyanide with chlorine.

$$2K_4Fe(CN)_6 + Cl_2 \rightarrow 2K_3Fe(CN)_6 + 2KCl \tag{46}$$

Ferric Ferrocyanide $[Fe_4\{Fe(CN)_6\}_3]$ and **ferrous ferricyanide** $[Fe_3\{Fe(CN)_6\}_2]$ are insoluble blue salts which give colloidal, or highly dispersed, suspensions. The former is Prussian blue; the latter Turnbull's blue. Prussian blue is used as a paint pigment. Mixed with the yellow lead chromate it forms a green pigment known as chrome green.

Metallic iron is highly reactive but tends to form an oxide film which is protective under certain conditions. Its properties are markedly affected by impurities and alloying constituents.

Ferrous Hydroxide $[Fe(OH)_2]$ and **ferric hydroxide** $[Fe(OH)_3]$ are formed as gelatinous precipitates by treatment of solutions of iron salts with alkalis. The former is pale green, the latter brown.

Cobalt and Nickel

These metals are found as linnaeite $[(Co \cdot Ni)_3S_4]$, cobaltite ($CoAsS$), smaltite $[(Co \cdot Ni)As_2]$, millerite (NiS), pentlandite $[(Fe \cdot Ni)S]$, niccolite ($NiAs$), and garnierite $[H_2(Ni \cdot Mg)SiO_4 \cdot H_2O]$.

Both cobalt and nickel are similar to iron in forming bivalent and trivalent compounds (cobaltous and cobaltic, nickelous and nickelic). Both also form cyanide complexes.

Both metals behave similarly to metallic iron, and form even more stable protective films. They are obtained electrolytically. (See Electrochemistry.)

14. CHROMIUM AND MANGANESE

Chromium

The chief ore of chromium is chromite ($FeO \cdot Cr_2O_3$), which is very similar to magnetite ($FeO \cdot Fe_2O_3$).

Sodium Chromate ($Na_2CrO_4 \cdot 10H_2O$) is produced by the reaction of chromite with lime and sodium carbonate.

$$4(FeO \cdot Cr_2O_3) + 8Na_2CO_3 + 6O_2 \rightarrow 8Na_2CrO_4 + 4FeO + 8CO_2 \tag{47}$$

The lime keeps the mass porous and forms some calcium chromate. The mass is then leached, and the calcium chromate reacts with the excess of sodium carbonate to form the insoluble calcium carbonate and additional sodium chromate.

Sodium Dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$) is formed when the solution of sodium chromate prepared as described above is acidified with sulfuric acid.

$$2Na_2CrO_4 + H_2SO_4 \rightarrow Na_2Cr_2O_7 + Na_2SO_4 + H_2O \tag{48}$$

By analogy with the salts of other polybasic acids, an acid salt $NaHCrO_4$ might be expected. Such a compound is not stable, however, and decomposes immediately to the dichromate

$$2NaHCrO_4 \rightarrow Na_2Cr_2O_7 + H_2O \tag{49}$$

The dichromate may therefore be considered a dehydrated acid salt of chromic acid. That the dichromates are essentially acid salts may be seen from the fact that a solution of the dichromate is converted by alkali to the neutral chromate.

$$Na_2Cr_2O_7 + 2NaOH \rightarrow 2Na_2CrO_4 + H_2O \tag{50}$$

Sodium dichromate is more readily crystallized from the solution than the chromate, and is formed for that reason.

The tendency of acid salts of chromic acid to dehydrate is further manifested by the behavior of the acid itself which is always obtained as the anhydride.

Chromic Anhydride (CrO_3), usually called chromic acid, is formed by the treatment of sodium dichromate with concentrated sulfuric acid.

$$Na_2Cr_2O_7 + H_2SO_4 \rightarrow Na_2SO_4 + 2CrO_3 + H_2O \tag{51}$$

The anhydride separates in the form of red needles. It is used in chromium plating.

Oxidation and Reduction. Chromium differs from the other metals studied thus far in forming an acid, although it will be remembered that the hydroxides of some of the other metals are amphoteric, sharing acidic and basic qualities.

The essentially metallic, and hence base-forming, character of chromium is shown by the fact that the chromates and dichromates are not very stable but tend to pass to chromic and chromous salts. Thus sulfurous acid, formed by passing sulfur dioxide into water, converts the dichromate to chromic sulfate.

$$Na_2Cr_2O_7 + 3SO_2 + H_2SO_4 \rightarrow Cr_2(SO_4)_3 + Na_2SO_4 + H_2O \tag{52}$$

In this reaction the valence of chromium drops from six to three, while that of the sulfur in the SO_2 passes from four to six. The diminution of positive (or increase of negative) valence of an element is called reduction, and increase of positive (or decrease of negative) valence is called oxidation. The two always occur simultaneously. A substance such as sodium dichromate which tends to oxidize another is called an oxidizing agent; sulfur dioxide which tends to reduce dichromate is called a reducing agent.

In a restricted sense, oxidation is sometimes used to imply the addition of oxygen to a substance, and reduction its removal, The more general case, however, may or may not involve oxygen either as a product or reactant.

A large number of reducing agents are available which may replace the sulfur dioxide in equation 52.

Chromic Sulfate [$Cr_2(SO_4)_3$] is prepared industrially by the reduction of sodium dichromate in solution with reducing agents such as sulfur dioxide, starch, sugar, glucose, and others in the presence of excess sulfuric acid. Although it is quite soluble, it does not crystallize readily in pure form so that it is generally used in solution along with its oxidation products. Such solutions are used in tanning and in the mordanting of textiles.

Chromic salts in which the chromium has a valence of three are very similar to ferric salts. Chromic hydroxide is also very similar to ferric hydroxide although somewhat amphoteric, forming chromites with strong alkalis. Like aluminum and iron, chromium salts form well-crystallized alums.

Chromium Acetate [$Cr(C_2H_3O_2)_3$] is a particularly good mordant formed by reducing sodium dichromate in the presence of acetic acid.

Chromic Oxide (Cr_2O_3) is formed by heating sodium dichromate with coke. It is used as a green pigment, known as chrome oxide green.

Chromium also forms a series of chromous salts similar to the ferrous salts, in which the chromium is bivalent. Chromium forms ammonium and cyanide complexes and highly complex basic salts, particularly with sulfate. Owing to the fact that simple chromic ions are rarely obtained, chromic salts are either green or violet, depending upon the conditions of preparation.

The metal itself is very resistant to corrosion, and is used as a thin protective or decorative coating on plate.

Manganese

Manganese is found as pyrolusite, psilomelane, manganite, rhodocrosite, and rhodonite.

Manganese Dioxide (MnO_2) is found chiefly as the mineral pyrolusite and, more sparingly, as psilomelane, a more impure form. It is important as a source of manganese for steel alloys and for the manufacture of other compounds. A very important direct use is in the manufacture of dry cells. Manganese dioxide has weak acidic properties, forming manganites with strong alkalis. It is a fairly strong oxidizing agent.

Potassium Permanganate ($KMnO_4$) is formed by treating pyrolusite with a boiling solution of potassium hydroxide and potassium chlorate.

$$2MnO_2 + KClO_3 + 2KOH \rightarrow 2KMnO_4 + KCl + H_2O \tag{53}$$

The solution is evaporated and the residue fused. Under these conditions the reaction does not go to completion since some **potassium manganate** (K_2MnO_4) is also formed.

The fusion mass is leached and further oxidized with chlorine. Potassium permanganate crystallizes in metallic crystals which dissolve readily to give a purple solution (color of permanganate ions). Permanganate in solution is similar to dichromate in its strong oxidizing power.

Manganese forms manganous salts in which the element is bivalent, and manganic salts in which it is trivalent. These are similar to ferrous and chromous, and ferric and chromic salts. The manganous compounds are readily oxidized by the air to the more stable manganic forms.

15. LEAD, TIN, AND TITANIUM

Lead

Lead is obtained chiefly from galena, but also from anglesite, pyromorphite, and cerussite.

Lead Sulfide (PbS) is found as galena. It may also be precipitated as a black gelatinous precipitate by treating solutions of lead salts with hydrogen sulfide or soluble sulfides. Galena is roasted under carefully controlled conditions to react as follows:

$$\left.\begin{aligned} 2PbS + 3O_2 &\rightarrow 2PbO + 2SO_2 \\ PbS + 2O_2 &\rightarrow PbSO_4 \\ 2PbO + PbS &\rightarrow 3Pb + SO_2 \\ PbSO_4 + PbS &\rightarrow 2Pb + 2SO_2 \end{aligned}\right\} \tag{54}$$

Molten lead is the final product. The sulfur dioxide is converted to sulfuric acid.

Lead is highly resistant to most types of corrosion and is used for pipes, chemical equipment, etc.

Lead Oxide (PbO), or litharge, is formed by heating lead in a strong blast of air. It is used in glass-making and as a source of lead salts. The corresponding hydroxide [$Pb(OH)_2$] is amphoteric, forming plumbites.

Minium (Pb_3O_4), or red lead, is formed by heating litharge in a blast of air at 600–700 deg fahr. It is used as a red paint pigment.

Lead Dioxide (PbO_2) is formed by treating red lead with nitric acid. It is essentially acidic, forming salts known as plumbates. Minium may be regarded as lead plumbate (Pb_2PbO_4).

Lead Carbonate ($PbCO_3$) is found as cerrusite. The basic salt known as white lead and corresponding approximately to the formula $Pb_3(OH)_2(CO_3)_2$ although the composition is variable, is formed by the corrosion of lead in carbon dioxide, acetic acid being added to aid in the process. White lead may also be formed by treating a solution of lead acetate with carbon dioxide, and also electrolytically. It is used as a white paint pigment.

Lead Sulfate ($PbSO_4$) is found as anglesite. It is precipitated by the mixture of solutions containing lead and sulfate. By the complete roasting of galena ore a product is sublimed which is called sublimed white lead, and which contains lead sulfate, lead oxide, and a small amount of zinc oxide.

Lead Acetate [$Pb(C_2H_3O_2)_2$] is made by treating litharge with acetic acid. It is the only common salt of lead, beside the nitrate, which is readily soluble.

Lead Nitrate [$Pb(NO_3)_2$] is formed by treating litharge with dilute nitric acid and evaporating the solution.

Lead Chromate ($PbCrO_4$), or chrome yellow, is formed as a yellow precipitate when a solution of lead nitrate or acetate is treated with one of sodium dichromate. It is used as a pigment. A mixture of chrome yellow and Prussian blue is sold as chrome green.

Lead may have valences of one, two, or four. Its ions are colorless.

Tin

Tin is obtained chiefly from the mineral cassiterite.

Stannic Oxide (SnO_2) is found as cassiterite. The ore is heated with coke to produce the metal, which is highly resistant to corrosion and is therefore used to coat tin cans. Tin forms two series of salts, corresponding to valences of two and four, called stannous and stannic, respectively.

$$SnO_2 + 2C \rightarrow Sn + 2CO \tag{55}$$

Stannic Chloride ($SnCl_4$) is formed by the reaction of chlorine gas and tin. It is a rather volatile liquid which fumes strongly in moist air. It is used as a mordant.

Stannous Chloride ($SnCl_2$) is formed in solution by treating stannic chloride with metallic tin. It tends to pass to the stannic form and is thus an active reducing agent. It is used as a mordant.

Stannic Sulfide (SnS_2) and **stannous sulfide** (SnS) are among the most insoluble of the sulfides. They are formed by treating solutions of the tin salts with hydrogen sulfide or a soluble sulfide. Stannic sulfide is soluble in solutions of soluble alkaline sulfides. Stannous sulfide is soluble in polysulfide solutions. Complex salts are formed.

Titanium

Titanium is very abundant in nature, being obtained from deposits of ilmenite and rutile.

Titanium Dioxide (TiO_2) is found as rutile. As a white pigment material it is obtained from solutions of titanium sulfate. Such solutions hydrolyze when boiled and yield a basic sulfate which, when calcined, is converted to the oxide. The corresponding hydroxide (titanic acid) is amphoteric.

Titanium dioxide is marketed as a high-grade white pigment with extremely high covering power and whiteness. It is obtainable in mixtures with " fillers " such as barium sulfate and calcium sulfate.

Titanium Sulfate [$Ti(SO_4)_2$] is obtained by treating ilmenite or rutile with strong sulfuric acid at elevated temperatures. The iron in the minerals is simultaneously converted to ferrous sulfate. Normal titanium sulfate cannot be isolated by crystallization to any definite composition. Titanyl sulfate ($TiOSO_4$) does, however, crystallize very well and may be dissolved to form solutions of basic sulfate.

Titanium Chloride ($TiCl_4$) is produced by treating ilmenite ore with dry chlorine gas. It is a volatile liquid similar to stannic chloride, and it fumes in the presence of moist air. It is used as a material for the formation of smoke screens and as a mordant.

Titanium also forms titanous salts in which the element is trivalent. Titanous ion is a strong reducing agent tending strongly to pass to the titanic state. Titanic salts in solution are colorless to amber. Titanous salts are violet.

16. CHEMISTRY OF GASES

The metallic elements and their compounds, with but rare exceptions, do not exist in the gaseous state at ordinary temperatures. Among the non-metals, however, numerous substances, both elements and compounds, are gaseous.

Kinetics

The molecules in a gas are supposed to be in rapid random motion with negligible forces of attraction or repulsion among them. As a consequence a gas may occupy any size or shape of container. Compression of a gas merely results in crowding the molecules; expansion does the reverse. Temperature is measured by the mean energy of translatory motion of the molecules; pressure is the result of the incessant bombardment on the containing walls. The fundamental assumption in the chemistry of gases is that the pressure and temperature depend only upon the number of molecules in a unit of volume and upon their mean energy. They do not depend upon the chemical nature. If temperature and pressure are given certain fixed values, the number of molecules in a unit volume is the same for all gases. This is *Avogadro's hypothesis*. The unit of volume which is generally taken is 22.4 liters since that volume of hydrogen weighs 2.016 grams, that volume of oxygen weighs 32 grams, and that volume of any substance is the molecular weight in grams. For this reason 22.4 liters is called the gram-molecular volume. It contains 6.06×10^{23} molecules at standard conditions of any gaseous substance. Standard conditions are when temperature and pressure are 0 deg cent and 760 mm of mercury, respectively.

Gas Laws

One of the most important consequences of this assumption is that the volumes of gases taking part in a reaction are proportional to the number of molecules involved. Thus at constant temperature and pressure

$$\begin{gathered} 2CO + O_2 \rightarrow 2CO_2 \\ 2V + 1V \rightarrow 2V \quad (V = \text{volume}) \end{gathered} \tag{56}$$

expresses the reaction of carbon monoxide gas with oxygen. Two volumes of carbon monoxide combine with one of oxygen to yield two of carbon dioxide. This rule applies even though one or more of the reactants or products may not be gaseous. Thus

$$C + O_2 \rightarrow CO_2$$

$$12 \text{ grams} + 1V \rightarrow 1V \qquad (57)$$

indicates that, in the burning of carbon, one volume of oxygen is required for every one of carbon dioxide produced.

$$2H_2 + O_2 \rightarrow 2H_2O$$

$$2V + 1V \rightarrow 2V \qquad (58)$$

indicates that two volumes of hydrogen will combine with one of oxygen to form two of water.

Table I. Common Gases

(From Kohlrausch, 1910)

Gas	Specific Gravity or Density*	Molecular Mass	Specific Heat (0°–200° C) Constant Pressure	$\frac{c_p}{c_v}$ ‡	Melting Point °C	Boiling Point °C	Water Dissolves cu cm † At 0° C	Water Dissolves cu cm † At 20° C	Symbol
Air (free of CO_2)	1.2928	28.98	0.238	1.40	....	−193	29	19	Air
Acetylene	1.1759	24.02	....	1.26	−81.5	−83.6	1730	1030	C_2H_2
Ammonia	0.7708	17.03	0.52	1.32	−78	−33.5	(12×10^5)	(7×10^5)	NH_3
Carbon dioxide	1.9768	44.00	0.218	1.30	−57	−78.2	(1800)	(900)	CO_2
Carbon monoxide	1.2503	28.00	0.243	1.41	−207	−190.0	35.4	23.2	CO
Chlorine	3.2197	70.92	0.121	1.32	−102	−33.4	(4600)	(2300)	Cl_2
Hydrogen	0.08985	2.016	3.41	1.41	−259	−252.6	21.1	18.1	H_2
Nitrogen	1.2507	28.02	0.244	1.41	−210.5	−195.7	23.5	15.4	N_2
Nitrous oxide	1.9777	44.02	0.225	1.28	−103	−90	1300	650	N_2O
Oxygen	1.4292	32.00	0.220	1.40	−227	−182.8	48.9	31.0	O_2

* Numbers in this column to be divided by 1000.

† These columns contain the number of cubic centimeters of gas that will be dissolved at a barometric pressure of 76 cm in 1 liter of water.

‡ This column gives the ratio of the specific heat at constant pressure to that at constant volume.

Temperature is a measure of the mean kinetic energy of translation of the molecules. Pressure is the energy of random bombardment in a unit of volume. If the volume of a fixed quantity of gas is held constant, the two must be proportional. Moreover, if the pressure is held constant a gas will expand and contract proportionately with the temperature. This is known as Charles' law. These relations may be expressed as:

$$P \propto T \quad (V \text{ constant})$$

$$V \propto T \quad (p \text{ constant})$$

or

$$PV = nRT \qquad (59)$$

which is the perfect gas law equation, where P is the pressure, V is the volume, T is the absolute temperature (0 deg cent = 273.2 deg abs), n is the number of gram-mols, and R is a universal constant.

It will be observed that at the zero of the absolute scale of temperature a gas would have either zero volume, or zero pressure, or both. Actually all gases become liquid before this point is reached, but this temperature (− 273.2 deg cent) has a theoretical significance as the absolute zero of temperature. It will also be noted that the volume is inversely proportional to the pressure if the temperature and quantity of gas are held constant. This is known as Boyle's law.

A vapor is distinguished from a true gas in that it may be converted to a liquid by increase in pressure. The minimum pressure necessary for the conversion is known as the vapor pressure of the liquid. Such a condensation is always accompanied by a liberation of heat which, unless removed by cooling, will raise the temperature of both the liquid and the residual vapor. This increase will continue to raise the vapor pressure until it becomes equal to the pressure of the vapor phase. Equilibrium will then be established and no further change will occur.

If heat is abstracted *at a constant temperature* under sufficient pressure, vapor will continue to condense. Conversely, if heat is applied liquid will vaporize (evaporate).

The heat required to vaporize a gram of liquid is known as the *latent heat of vaporization*.

The temperature at which the vapor pressure of a liquid becomes equal to the pressure of the atmosphere is known as the *boiling point*. At this temperature the liquid will continue to evaporate as long as heat is applied. In general, boiling points are lowered as the pressure decreases, and vice versa.

All gases become vapors at sufficiently low temperatures. The highest temperature at which this will occur is known as the *critical temperature*, and the vapor pressure of the liquid at this temperature is known as the *critical pressure*. In the vicinity of the critical temperature and pressure, the force of attraction between the molecules of a gas becomes appreciable and the simple assumptions which led to the gas law equation are no longer valid. Semi-empirical equations are then employed to relate the temperature, pressure, and volume. The one most generally accepted is van der Waal's equation.

$$\left(P + \frac{a}{V^2}\right)(V - b) = nRT \tag{60}$$

where a and b are constants for the gas.

This relationship is used whenever a more exact relation than that expressed by the simple gas law is desired, or where the temperature is very low, or the pressure very high.

Certain gases (actually vapors) may be liquefied at atmospheric temperatures, and the liquid vaporized at a lower pressure, at a lower temperature, absorbing heat in the process. Such is the principle of refrigerating machines. To qualify as a refrigerant, a substance must of course have a critical temperature above that of the atmosphere or available cooling water and should have a vapor pressure which is not too high to be obtained with an ordinary compressor. Also the vapor pressure at the lowest temperature to be attained should not be so low as to require a high vacuum. Ammonia, carbon dioxide, sulfur dioxide, and numerous organic substances are all suited to various requirements of refrigerants, and each has its specific use.

Air

Air is a mixture of gases in the following proportions.

	Per Cent by Volume	Per Cent by Weight
Nitrogen	78.03	75.80
Oxygen	20.99	23.22
Carbon dioxide	0.03	0.05
Argon	0.94	0.93
Neon Krypton Xenon Helium Hydrogen	0.01	

Oxygen is the constituent which supports the combustion of fuels and other combustible materials. Nitrogen may be obtained by burning off the oxygen and absorbing the carbon dioxide in an alkaline solution. It will then be contaminated with small quantities of the inert gases which are not readily removable. In this form it may be used for the synthesis of ammonia by the Haber process.

Air may be liquefied by chilling to a sufficiently low temperature. The constituents may then be separated by fractional distillation. Nitrogen (boiling point −196 deg cent) comes off first, next oxygen (boiling point −182.8 deg cent), followed by argon and neon.

The inert gases are monatomic and do not combine with any of the elements. For this reason they are used where an absolutely inert gas is required. Argon is used for filling the bulbs of incandescent lamps. Neon is used in gas tubes through which an electric current is passed to effect the characteristic orange-red glow. Air also contains water vapor and dust in varying amounts.

17. NITROGEN, PHOSPHORUS, ARSENIC, ANTIMONY AND BISMUTH

These elements constitute a family varying from the purely non-metallic nitrogen to bismuth which is distinctly metallic. That the division of the two classes of elements is not a sharp one is thus indicated.

Nitrogen

Nitrogen, a gaseous element, is very abundant in the atmosphere, but its comparatively inert behavior makes it difficult to obtain in a fixed, or combined, form. Its compounds are valuable elements in fertilizers and as a source of nitric acid.

Ammonia (NH_3) is made by passing a mixture of nitrogen and hydrogen over a catalyst of metallic oxides.

$$N_2 + 3H_2 \rightarrow 2NH_3 \qquad (61)$$

The reaction goes more rapidly at higher temperatures but also becomes less complete owing to the reversibility. Hence a compromise must be struck to obtain the best results.

The equilibrium may be expressed by a mass law equation similar to that for reactions in solutions.

$$\frac{(N_2)(H_2)^3}{(NH_3)^2} = K, \text{ the equilibrium constant} \qquad (62)$$

If the pressure on the mixture is increased it will be observed that the concentration of both the reactants and the product is increased. Since the numerator of the equilibrium equation varies as the fourth power of the concentration of the reactants while the denominator varies as the square of the concentration of the product, the latter must increase faster than the former to maintain the constancy of the quotient. Hence the proportion of products to reactants increases at high pressures and the reaction goes forward. Extremely high pressures are, in fact, used in the industry.

Most of the ammonia produced in this way is converted to nitric acid; a mixture of the ammonia gas and air is passed over a platinum catalyst at a red heat. The following reactions occur.

$$\left.\begin{array}{ll}
NH_3 + 2O_2 \rightarrow H_2O + HNO_3 & \text{(nitric acid)} \\
2NH_3 + 3O_2 \rightarrow 2H_2O + 2HNO_2 & \text{(nitrous acid)} \\
4NH_3 + 5O_2 \rightarrow 6H_2O + 4NO & \text{(nitric oxide)} \\
4NH_3 + 7O_2 \rightarrow 6H_2O + 4NO_2 & \text{(nitrogen tetroxide)} \\
4NH_3 + 3O_2 \rightarrow 6H_2O + 2N_2 & \text{(nitrogen)} \\
4NH_3 + 6NO \rightarrow 6H_2O + 5N_2 & \text{(nitrogen)}
\end{array}\right\} \qquad (63)$$

Any ammonia which is converted to nitrogen is, of course, wasted. In order to minimize this loss the temperature must be accurately controlled (750–800 deg cent). The nitrogen tetroxide, nitric oxide and nitrous acid are then further oxidized with air in the presence of water vapor.

$$\left.\begin{array}{r}
3NO_2 + H_2O \rightarrow 2HNO_3 + NO \\
2HNO_2 + O_2 \rightarrow 2HNO_3 \qquad\quad \\
2NO + O_2 \rightarrow 2NO_2 \qquad\quad
\end{array}\right\} \qquad (64)$$

Nitric acid ionizes practically completely in water, in which it is very soluble. It is a strong acid and a strong oxidizing agent. The chief uses are in the manufacture of salts used as fertilizers such as calcium nitrate and ammonium nitrate, and for the nitration of organic chemicals, particularly for dyes, explosives, lacquers, and celluloid. Nitric acid is also made from nitric oxide, produced by the direct combination of nitrogen and oxygen of the atmosphere in an electric arc. Sodium nitrate, or Chile saltpeter, mined chiefly in Chile, is also used as a source of the acid. (See p. 10–13.)

Nitrates of the metals are all very soluble in water. Nitrate ion, as well as the other simple ions containing nitrogen, such as ammonium (NH_4^+), and nitrite (NO_2^-), are colorless. Nitrogen may have valences of one, two, three, four, or five.

Phosphorus

Phosphorus, like nitrogen, is an important element of fertilizers. It is found as the mineral apatite [$(Ca_5)(Cl \cdot F)(PO_4)_3$], the important constituent of phosphate rock. Apatite is heated with coke and sand in an electric or fuel furnace. The calcium of the mineral combines with the silica of the sand while the coke reduces the phosphate to elementary phosphorus which is volatilized and condensed as solid white phosphorus or burned in air to the solid white phosphorus pentoxide (P_2O_5).

White phosphorus is very inflammable and for that reason is used as a constituent in the manufacture of matches. A less reactive red variety is obtained by heating white phosphorus to about 250 deg cent in the absence of air.

Phosphorus Pentoxide (P_2O_5), or phosphoric anhydride, is used as a dehydrating agent. It combines with water to form phosphoric acid.

Phosphoric Acid (H_3PO_4) is a syrupy liquid which is a mildly strong acid very soluble in water. Besides being produced from phosphorus pentoxide it is also manufactured by treating phosphate rock with dilute sulfuric acid.

$$Ca_3(PO_4)_2 + 3H_2SO_4 \rightarrow 3CaSO_4 + 2H_3PO_4 \qquad (65)$$

Superphosphate [$CaH_4(PO_4)_2$] (composition variable) is an acid calcium phosphate prepared by treating phosphate rock with strong sulfuric acid.

$$Ca_3(PO_4)_2 + 2H_2SO_4 \rightarrow CaH_4(PO_4)_2 + 2CaSO_4 \tag{66}$$

The acid salts are soluble, and may therefore be used to supply both calcium and phosphate to the soil.

The phosphates of sodium have already been discussed (p. 10–13). In general, all the normal phosphates of the metals are quite insoluble except those of the alkali metals and ammonium. The acid phosphates, on the other hand, are generally soluble. For this reason, phosphates tend to dissolve in acid solutions.

Arsenic

Arsenic is found in numerous ores of iron, nickel, lead, and zinc, and as orpiment and realgar. It is obtained chiefly as a by-product of metallurgical operations. Its uses are in dyeing, medicine, and vermin and insect poisons. Arsenic forms two series of compounds corresponding to valences of three and five. The former are called arsenious or arsenites, the latter arsenic or arsenates.

Arsenious Sulfide (As_2S_3) is found as the mineral orpiment. It is prepared in pure form, as are the heavy metal sulfides, by treating arsenious salts or arsenites with hydrogen sulfide or a soluble sulfide. It is a yellow insoluble precipitate.

Arsenic Sulfide (As_2S_5) is prepared by treating an arsenic salt or an arsenate with hydrogen sulfide or a soluble sulfide. It is yellow and insoluble. The sulfides of arsenic have the peculiar property, along with similar sulfides of antimony and tin, of dissolving in solutions of sulfides and of polysulfides to form complex sulfur compounds.

Arsenious Acid (H_3AsO_3) and **arsenic acid** (H_3AsO_4) are in reality amphoteric hydroxides which might be written $As(OH)_3$ and $AsO(OH)_3$. Here, however, the acid properties, though weak, are more pronounced than the basic so that they are ordinarily considered acids. Arsenious acid is produced when arsenious salts are treated with alkali, or arsenites with acids. The arsenates are very similar in properties to the phosphates.

Arsenious Oxide (As_2O_3), or white arsenic, is formed as a fume in the roasting of arsenic-bearing ores. It is the starting material for the preparation of other arsenic compounds. Important insecticides are **lead arsenate** [$Pb_3(AsO_4)_2$] and **paris green** [$Cu_3(AsO_3)_2 \cdot Cu(C_2H_3O_2)_2$].

Antimony

The chief antimony mineral is stibnite. The element is also obtained as a by-product from lead ores.

Like arsenic, antimony forms two series of compounds corresponding to valences of three and five; the metallic properties are, however, more pronounced. The element itself has a metallic luster and is used in many important alloys.

Antimony Trisulfide (Sb_2S_3) is found as the mineral stibnite. It may be formed from solutions of antimony salts in typical fashion as is also antimony pentasulfide (Sb_2S_5) from solutions of antimonic salts or antimonates. Both sulfides are soluble in solutions of sulfides or polysulfides.

Antimony Trioxide (Sb_2O_3) is formed by the combustion of antimony with limited oxygen. It has found some use as a white pigment. Antimony salts are used in medicine.

Bismuth

Bismuth is found chiefly as native metallic bismuth and as bismuthinite. The ores are smelted to obtain the metal which is used in low melting point alloys. Salts of bismuth hydrolyze extensively to basic forms.

Bismuth Subnitrate [$Bi(OH)_2NO_3$] is used extensively in medicine. It is formed by treating bismuth with nitric acid and hydrolyzing the nitrate with water.

Bismuth does not manifest any acidic properties as do nitrogen, arsenic, and antimony. It is purely basic and should therefore be classified as a metal.

18. THE HALOGENS—CHLORINE, BROMINE, IODINE, AND FLUORINE

Chlorine

Chlorine is found widely distributed as chlorides, the most important of which is sodium chloride, or common salt. The element is prepared as a yellow-green gas by the electrolysis of sodium chloride brine. (See Electrochemistry.) It is generally liquefied under pressure and shipped in cylinders or tank cars. Chlorine is used for a great variety of chlorination processes, as a bleach, and for the preparation of hypochlorites and chlorates.

The metallic chlorides have already been discussed. They are all quite soluble with the exception of cuprous, mercurous, silver, gold, and platinum. Lead chloride is sparingly soluble.

Hydrochloric Acid (HCl), or muriatic acid, is prepared from sodium chloride and sulfuric acid as has already been described (p. 10–12). It is the most corrosive of the common acids, and is used in the pickling of metals and for a variety of miscellaneous purposes.

Chlorine dissolves in alkaline solutions to form hypochlorites from which it may be released as required for the bleaching of fabrics, paper, and other products. Calcium hypochlorite has already been discussed (p. 10–14).

Sodium Hypochlorite ($NaOCl$) is formed when chlorine is passed into a solution of sodium hydroxide or sodium carbonate (which is cheaper).

$$\left.\begin{array}{l} 2NaOH + Cl_2 \rightarrow NaOCl + NaCl + H_2O \\ Na_2CO_3 + Cl_2 \rightarrow NaOCl + NaCl + CO_2 \end{array}\right\} \qquad (67)$$

Sodium hydroxide and chlorine are obtained as the products of the electrolysis of salt brine. By mixing the two directly as they are formed, sodium hypochlorite is obtained according to the above reaction. Dilute sodium hypochlorite is known as Javelle water and is used in laundry work At higher temperatures hypochlorites are converted into chlorates. Thus

$$3NaOCl \rightarrow 2NaCl + NaClO_3 \qquad (68)$$

Sodium Chlorate ($NaClO_3$) is formed in electrolytic cells similar to those used to produce sodium hypochlorite but operated at a temperature between 70 and 100 deg cent. The hypochlorite is converted directly to chlorate. Sodium and potassium chlorates are used in matches and explosives, and as oxidizing agents.

Bromine

Bromides occur in natural brines in small concentrations associated with much larger amounts of chlorides. Bromine is liberated when such solutions are treated with chlorine.

$$2NaBr + Cl_2 \rightarrow 2NaCl + Br_2 \qquad (69)$$

Recently such a process has been devised and operated for extracting the bromine content of sea water. Bromine is used extensively in the manufacture of the anti-knock compound, tetraethyl lead. Bromides are used in photography and in medicine.

Iodine

Iodine is found in the form of iodates in the mother liquor of Chile saltpeter. It is obtained by treatment with sodium sulfite and bisulfite.

$$2NaIO_3 + 3Na_2SO_3 + 2NaHSO_3 \rightarrow 5Na_2SO_4 + I_2 + H_2O \qquad (70)$$

The iodine is then purified by sublimation. It is also obtained from sodium iodide which is leached from the ashes of seaweeds by treatment of the solution with chlorine, a process similar to that used for the preparation of bromine. Iodine and its compounds are used in medicine and, to a very small extent, in photography. Iodine at room temperatures is a gray, submetallic, crystalline solid.

Fluorine

Fluorine differs somewhat from the other halogens in its extraordinary reactivity. It attacks all the metals except gold and platinum. Copper forms an adherent protective coating of copper fluoride. It is obtained chiefly from fluorite (CaF_2), or fluorspar, although it is a constituent of cryolite ($NaF \cdot AlF_3$) and of phosphate rock.

Hydrofluoric Acid (H_2F_2) is obtained by treating fluorite with sulfuric acid.

$$CaF_2 + H_2SO_4 \rightarrow CaSO_4 + H_2F_2 \qquad (71)$$

Hydrofluoric acid reacts with silica to form the volatile silicon tetrafluoride or, in the presence of water, fluosilicic acid or metallic fluosilicates.

$$SiO_2 + 2H_2F_2 \rightarrow SiF_4 + 2H_2O \qquad (72)$$

Hydrofluoric acid and the fluorides also attack silicates such as glass, producing an etch. They are accordingly used for etching as well as for cleaning. Hydrofluoric acid differs from the other halogen acids in being dibasic. It may therefore form acid fluorides such as sodium bifluoride ($NaHF_2$) which is obtained by treating the normal fluoride with hydrofluoric acid. The fluorides are used as insecticides; the bifluorides are used in laundering. Fluorine is a pale yellow-green gas.

The simple ions of all the halogens are colorless.

19. SULFUR, SELENIUM, AND TELLURIUM

Sulfur

Sulfur is obtained from extensive deposits of the native element and from the metallic ores.

Sulfur Dioxide (SO_2) is obtained as the gaseous product of the combustion of sulfur in air. It is also obtained in the roasting of ores. Its chief importance is in the fact that it is an intermediate product in the manufacture of sulfuric acid.

Sulfuric Acid (H_2SO_4) is obtained from sulfur dioxide by two important processes. In the chamber process, sulfur dioxide, air, and water are allowed to react to form the acid. The reaction is ordinarily very slow, but in the presence of oxides of nitrogen it is considerably catalyzed. The following intermediate reactions are believed to occur.

$$\left.\begin{aligned} SO_2 + NO_2 &\rightarrow SO_3 + NO \\ SO_3 + H_2O &\rightarrow H_2SO_4 \\ 2NO + O_2 &\rightarrow 2NO_2 \quad \text{(to be re-used)} \end{aligned}\right\} \tag{73}$$

The nitrogen compounds continue through a cycle and remain unchanged except for plant losses.

In the second method, known as the contact process, the sulfur dioxide and air are passed over a catalyst which may be platinum or vanadium compounds, to form sulfur trioxide. This is then dissolved in strong sulfuric acid, water being added to maintain the dilution. A solution of sulfur trioxide in anhydrous sulfuric acid is sold as oleum, or fuming sulfuric acid. It may be regarded as sulfuric acid which has been partially dehydrated. Sulfuric acid is manufactured in enormous quantities. It is the basic material of the chemical industries, and its uses are more extensive and widespread than those of any other chemical.

Hydrochloric and nitric acid plants are generally closely associated with sulfuric acid producing units and constitute an important outlet. The sodium sulfate produced as a by-product (see p. 10-12) is then marketed, to the glass industry in particular, or is converted to sodium sulfide as will be described below.

Most of the sulfuric acid produced is sold as 66 deg Bé acid, known as oil of vitriol, containing 93.195 per cent pure sulfuric acid. Weaker and stronger grades are also available. Oil of vitriol and, more especially, stronger acids and oleum, are strongly dehydrating and will char organic materials which contain water, such as cellulose. It is also a fairly strong oxidizing agent and a strong acid.

Sulfurous Acid (H_2SO_3) is produced when sulfur dioxide is passed into water.

$$SO_2 + H_2O \leftrightarrows H_2SO_3 \tag{74}$$

It is a weak, unstable acid which tends to dehydrate back to its anhydride, sulfur dioxide.

Sodium Sulfite (Na_2SO_3) and **sodium bisulfite** ($NaHSO_3$) are formed by passing sulfur dioxide into solutions of sodium carbonate. They are used as reducing agents, in tanning, paper-making, and the manufacture of dyestuffs.

Sodium Thiosulfate ($Na_2S_2O_3 \cdot 5H_2O$), or hypo, is produced by boiling a solution of sodium sulfite with sulfur.

$$Na_2SO_3 + S \rightarrow Na_2S_2O_3 \tag{75}$$

It is used as a reducing agent, particularly in photography.

Hydrogen Sulfide (H_2S) is a gas with an odor of rotten eggs. It is an undesirable impurity in industrial gases. It has very weakly acidic properties.

Sodium Sulfide (Na_2S) is produced by heating sodium sulfate with coke.

$$Na_2SO_4 + 4C \rightarrow Na_2S + 4CO \tag{76}$$

Solutions of sodium sulfide are strongly alkaline. It is used for removing hair from animal hides, in paper manufacture, and in the making of dyestuffs.

Elementary sulfur is usually obtained as the yellow amorphous brimstone. As a fine yellow crystalline powder, obtained by chilling sulfur vapor, it is known as flowers of sulfur; finely ground brimstone is called flour of sulfur.

Selenium and Tellurium

These elements are obtained in considerable quantity, particularly as by-products of the recovery of copper and nickel from their ores. Thus far the demand for them has not been commensurate with their availability. Selenium has been used in photoelectric cells and in glass. Both elements are similar to sulfur in their chemical properties.

20. CARBON, BORON, AND SILICON

Carbon and silicon are tetravalent in all their compounds, with very rare exceptions; boron is trivalent.

Carbon

The most important source of mineral carbon is coal. Carbon is an important constituent of all solid, liquid, and gaseous fuels and of all organic compounds as well as of the mineral carbonates of which limestone is the most important. In fuels it is either free as in charcoal or combined with hydrogen, oxygen, and small quantities of other elements. The carbon and the hydrogen combine, in burning, with the oxygen of the air, yielding, on complete combustion, carbon dioxide and water vapor.

$$C_xH_yO_z + NO_2 \rightarrow xCO_2 + \tfrac{1}{2}yH_2O \qquad (77)$$

This will be discussed in greater detail under Combustion and Fuels.

Carbon Dioxide (CO_2) is a constituent of the atmosphere and a product of the complete combustion of fuels. It dissolves to a slight extent in water at ordinary pressures and quite considerably when the pressure is raised. It is readily soluble in alkalis, forming carbonates and bicarbonates which, on the addition of acid, are converted back to carbon dioxide.

Carbon dioxide gas is readily converted to a liquid by the application of pressure and moderate cooling. When the pressure is released the expansion of a portion of this liquid will cool the remaining material to a solid, which is an increasingly popular refrigerant known as "dry ice." Many chemical industries which produce carbon dioxide as a by-product now find it profitable to convert the gas to the liquid or solid form.

Carbon Disulfide (CS_2) is produced by the reaction of coke and sulfur at a high temperature. It is used as a solvent for rubber, waxes, and fats, and as an insecticide.

Carbon Tetrachloride (CCl_4) is made by the reaction of carbon disulfide and chlorine gas. It is a solvent for many organic materials and is used for cleaning fabrics and as a fire extinguisher.

Boron

Boron is found in the minerals sassolite, borax, ulexite, and colemanite.

Boric Acid (H_3BO_3) is found as sassolite and is also produced by acidifying a solution of borax. It is a slightly soluble weak acid and is used as an antiseptic and preservative.

Borax ($Na_2B_4O_7 \cdot 10H_2O$) is found in nature and is also prepared by boiling ulexite ($CaNaB_5O_9 \cdot 8H_2O$) and colemanite ($Ca_2B_6O_{11} \cdot 5H_2O$) with sodium carbonate solution. It is used as a detergent and in the manufacture of glass and vitreous enamels.

Silicon

Silicon is the chief constituent, other than oxygen, of the earth's crust. It forms an endless variety of silicates, widely distributed.

Silicon Dioxide (SiO_2), or silica, is found as sand, quartz, opal, and chalcedony. It is dissolved by strong alkali, particularly at elevated temperatures.

Sodium Silicate ($xNa_2O \cdot ySiO_2$), of variable composition, is called water glass. It is prepared by fusing sand with sodium carbonate and dissolving in water. It is generally sold as a viscous liquid, but also as a soluble solid. Its solutions are used for the fireproofing and weighting of textiles, to cement glass, and as detergents.

Numerous metallic silicates may be formed by fusing salts or bases with silica. Most of them crystallize with difficulty. Certain compositions of mixed silicates may be melted to form glasses and vitreous enamels which are amorphous solids of variable composition and of a wide variety of properties.

Silicic Acid ($xSiO_2 \cdot yH_2O$), of variable hydration, is formed as a gelatinous precipitate by the acidification of water glass. It may be partially dehydrated, after carefully washing free of salts, to form a glassy solid, known as silica gel, which has remarkable absorptive and catalytic properties.

Silicon Carbide (SiC), or Carborundum, is produced by the reaction of coke and sand at a high temperature.

$$SiO_2 + 3C \rightarrow SiC + 2CO \qquad (78)$$

It is a hard substance used as an abrasive.

QUALITATIVE ANALYSIS

This outline has been taken from Qualitative Analysis by Treadwell and Hall (John Wiley); the reader is referred to this book for detailed directions regarding these procedures as well as numerous others.

21. PRELIMINARY EXAMINATION

This should never be omitted, for it often shows how the subsequent analysis may be considerably shortened, and in some cases makes the further examination unnecessary. It consists only of making the following few simple tests:

Heating in the Closed Tube

By a closed tube is understood a small glass tube about 10 cm long and 0.5 cm in diameter sealed at one end. Place a little of the substance in the tube so that none of it remains adhering to the sides, hold the tube in a nearly horizontal position, and cautiously heat in a flame, noting carefully whether any change takes place.

The Substance is Volatile: (*a*) *The substance sublimes completely* without any deposition of water; it contains no non-volatile substance.

The sublimate is white. The halogen compounds of ammonium,* mercuric and mercurous chloride and bromide, mercuric aminochloride, arsenic trioxide, and arsenic pentoxide may be present.

Arsenic pentoxide melts before being changed into the trioxide.

The sublimate is colored—

Gray: all oxygen compounds of mercury, cyanide of mercury, free iodine, and arsenic.

Mercuric cyanide leaves a brown mass, paracyanide, which only disappears after long-continued heating.

Yellow: arsenic sulfide, sulfur, mercuric iodide.

Mercuric iodide becomes red immediately on being rubbed with a glass rod.

Grayish black: mercuric sulfide.

(*b*) *The substance is completely volatile, with separation of water* and gaseous products: most ammonium compounds (with the exception of those of the halogens) and free oxalic acid.

By very cautious heating, oxalic acid may be sublimed; it usually decomposes, however, into water, carbon monoxide, and carbon dioxide.

The Substance is Only Partly Volatile. In this case gases and vapors may be evolved:

Oxygen from peroxides, nitrates, chlorates, iodates, etc.

Carbon dioxide from carbonates and organic substances; in the latter case it is usually accompanied with the separation of carbon and evolution of empyreumatic, combustible vapors.

Chlorine from chlorides of platinum, gold, copper, iron, etc.

Iodine from iodides, in the presence of oxidizing substances.

Sulfur from many sulfides and thiosulfates.

Arsenic from arsenites and arsenates, in the presence of carbon or organic substances.

Arsenites are reduced without the aid of charcoal:

$$10K_3AsO_3 = 6K_3AsO_4 + 6K_2O + As_4$$

Water from substances containing water of crystallization, from acid salts, organic substances, or from the phosphate, borate, chromate, vanadate, and tungstate of ammonium.

The water given off condenses in the cooler part of the tube and should be tested with litmus paper. If it reacts alkaline, it comes from ammonium compounds; if acid, it results from easily decomposable salts of the stronger acids.

Many fluorides when heated with water give off hydrofluoric acid, which etches the glass.

If a sublimate is formed, make the following experiment:

Mix a little of the substance with three times as much calcined sodium carbonate and heat in the closed tube. If *ammonium salts* are present, the smell of ammonia can be detected.

---

* In the case of ammonium salts, e.g., NH_4Cl, this is not a true sublimation. When heated NH_4Cl gives NH_3 and HCl gases which combine again when chilled.

Mercury **compounds give a deposit of gray metal;** ***arsenic*** **and its oxygen compounds also usually yield the gray metal (but no globules), accompanied by a garlic odor.**

The oxygen compounds of arsenic do not give the metal when heated with pure sodium carbonate. Commercial sodium carbonate, however, is usually contaminated with enough paper fibers to cause the reduction.

Test the Substance in the Bead

Make a borax or sodium phosphate bead in the loop of a very thin platinum wire, introduce it with a little of the substance into the oxidizing flame, observe the color of the bead both when it is hot and when it is cold, and then heat it in the reducing flame. Borax is usually used for this experiment, except when it is desired to test for silicic or titanic acids, or when the substance is white, in which case the salt of phosphorus is used. Only colored oxides are capable of coloring the borax bead.

Some oxides are reduced to metal, so that the bead appears gray in the reducing flame (see following table). $CuSO_4$ is white when anhydrous, but becomes blue immediately on the addition of water.

The following substances impart a characteristic color to the bead: iron, manganese, nickel, cobalt, chromium, uranium, copper, didymium, cerium, vanadium, titanium, and tungsten.

Since the coloration varies with the temperature and with the amount of substance used, the results to be expected, with the necessary conditions, are summarized in the table given below. The following abbreviations are used: h = hot; c = cold; h-c = hot and cold; s.s. = slightly saturated; sat. = saturated.

Color of the Bead	With Borax		With Salt of Phosphorus	
	In the Oxidizing Flame	In the Reducing Flame	In the Oxidizing Flame	In the Reducing Flame
Colorless	SiO_2 (without skeleton), alkaline earths, Hg, Pb, Bi, Sb, Cd, Zn, Sn, Ti	SiO_2 (without skeleton), alkaline earths and earths, Mn, Di, Ce, Cu (s.s.)	SiO_2 (usually with skeleton), alkaline earths and earths (sat. = turbid)	SiO_2 (usually with skeleton), alkaline earths and earths, Mn, Di, Ce, Cu (s.s.)
	W, Mo, Fe (s.s.–c)		W, Ti	
Gray		Ag, Pb, Bi, Sb, Cd, Zn, Ni		Ag, Pb, Bi, Sb, Cd, Zn, Ni
Yellow (or brown)	Fe (s.s.–h), Ag (h), Ce (h), U (h), V (h–sat.), Ni (c) (brown)	Ti (h), W (h), V (h), Mo (h)	Fe (s.s.–h), Ag (h), Fe (sat.–c), Ce (h), V (h), U (h), Ni (c) (brown)	Fe (h), Ti (h)
Green	Cr (c), Cu (h)	Fe (h–c), U, Cr, V (h)	Cr (c), Cu (h), Mo (h), U (c–sat.)	Cr (c), U (c), V (c), Mo (c)
Blue	Co (h–c), Cu (c)	Co (h–c)	Co (h–c), Cu (c)	Co (h–c), W (c)
Violet	Mn (h–c), Di (h–c), Ni (with cobalt)		Mn (h–c), Di (h–c)	Ti (c)
Red	Fe (h–sat.), Ce (h)	Cu (sat.), opaque; when very slightly saturated and with a trace of Sn, ruby red and transparent	Fe (h–sat.), Ce (h)	Cu as in the borax bead; Ti and W in the presence of iron = blood red

Heat a Little of the Substance upon Charcoal before the Blowpipe

If deflagration takes place a nitrate, nitrite, chlorate, iodate, etc., may be present.

Heat the Substance with Soda upon Charcoal before the Blowpipe

Mix as much of the substance as can be taken up on the end of a knife-blade with twice as much sodium carbonate, place it in a cavity on a piece of charcoal, and heat in the reducing flame of the blowpipe.

There is obtained:

(*a*) Metal without incrustation............	**As malleable button: Au, Ag, Sn, Cu, which can be pressed flat in an agate mortar.** **As gray metallic particles: Pt, Fe, Ni, and Co. Pt may be pressed flat in an agate mortar; Fe, Ni, and Co are magnetic and are attracted by a magnet.**
(*b*) Metal with incrustation...............	**As a brittle metallic button: Sb (white incrustation), Bi (yellow incrustation). The button may be reduced to a powder by grinding in an agate mortar.** As a malleable button: **Pb** (yellow incrustation).
(*c*) Incrustation without metal............	White, yellow when hot: **Zn.** Brown: **Cd.** White: **As** (garlic odor).

(*d*) White, infusible, strongly luminous mass. **Ca, Sr, Mg, Al,** and rare earths.

(*e*) **Sulfur** compounds are reduced to sulfides. If the melt is placed on a bright silver coin and moistened with water, the silver is blackened (Hepar reaction).

Test the Substance to See Whether It Imparts Any Color to the Non-luminous Flame

Introduce a little of the substance on a platinum wire into the base of the flame, and then into the fusion zone. Afterwards moisten it with dilute hydrochloric acid and repeat the experiment. The following indications may be obtained:

Sodium gives a yellow monochromatic flame; a piece of sealing-wax or a crystal of potassium dichromate appears yellow when illuminated by this flame.

Potassium (cesium and rubidium) gives a violet flame which is completely obliterated by the sodium flame. If the flame is observed through cobalt glass, the sodium flame disappears and the potassium flame appears pink.

Lithium gives a carmine-red flame (or a red line in the spectroscope).

Strontium also gives a carmine-red flame (which the spectroscope shows to consist of several lines in the orange, and a bright line in the blue).

Calcium gives a brick-red flame (in the spectroscope an orange and a green line are seen, both about an equal distance away from the sodium line).

Barium gives a greenish-yellow flame.

In the case of barium sulfate the green flame is either indistinct or not visible. In order to detect barium in this case, heat a small portion of the substance in the upper reducing flame, cool, moisten with hydrochloric acid (odor of hydrogen sulfide), and again heat, when the barium flame can be easily seen.

Thallium gives an emerald-green flame.

If a green flame is obtained, test another portion of the substance for boric acid, by treating with concentrated sulfuric acid and bringing near the flame. A green color indicates the presence of boric acid, but if copper is present this test is not reliable.

By heating the solid substance with potassium ethyl sulfate in a test-tube, boric acid is converted into $B(OC_2H_5)_3$, which is volatile and burns with a green flame. Copper chloride does not interfere with this test.

Lead, Arsenic, Antimony color the flame light blue, and **copper** compounds color the flame either green or blue.

22. SYSTEMATIC ANALYSIS OF THE METALS

Table I. General Scheme for Separating the Metals into Groups

<table>
<tr><td colspan="5">Solution may contain all the common basic constituents. <i>Add HCl in slight excess.</i></td></tr>

ELECTROCHEMISTRY

The close relationship between all chemical and electrical phenomena has already been indicated. Certain of the chemical industries, however, are so dependent upon the consumption of electrical energy, or upon its production or utilization, that they are conveniently classified as electrochemical. The subject may be divided into the electrochemistry of solutions, aqueous and non-aqueous; electrothermics; and thermionics and electronics.

23. ELECTROCHEMISTRY OF SOLUTIONS

Aqueous Solutions

The dissociation of electrolytes in solution to ions has already been discussed. Such solutions have the property of conducting an electric current through the migration of ions which bear charges of positive or negative electricity. Obviously, if a direct current is used, the ions can pass only as far as the electrodes, where their charges will be neutralized with the release of uncharged, electrically neutral matter. The quantity of matter discharged or deposited will be proportional to the quantity of electricity supplied by the electrodes (in coulombs). The total flow of current must be proportional to the number of ions which are neutralized and to the number of charges borne by each of them. The number of ions then is proportional to the number of gram-mols of the substance: 96,494 coulombs is sufficient to release a gram-mol of a monovalent radical, half a gram-mol of a bivalent radical, one-third gram-mol of a trivalent radical, etc. *This unit of charge is known as a faraday,* and the principle is known as Faraday's law.

In order to pass a current through a solution a certain voltage is required. The solution itself will have an ohmic resistance proportional to the length of the path between the electrodes and inversely proportional to the effective area. In addition there will be a potential drop across the thin film surrounding each electrode due to evolution of gas or a sharp concentration gradient. This may be reduced to some extent by efficient agitation. Finally, there will be the potential necessary to deposit the material which would be present at equilibrium even though no current were flowing. This is the minimum for deposition. Of course, if the solution is very dilute and the ions comparatively scarce, the required potential will be very high, and at high concentrations the reverse will be true. By Nernst's law,

$$E = \frac{0.058}{n} - \log C \text{ (at 18° C)} \tag{1}$$

where E is the electrode voltage drop.
C is the ion concentration in mols per liter.
n is the number of charges on the ion.

The law is strictly valid only for very dilute solutions but may serve as a convenient approximation for most practical cases. E_0, the voltage drop when $C = 1$, is a constant for each kind of ion and is called the electrode potential. The actual electrode potentials are impossible to measure accurately in absolute units, therefore, they are expressed relative to the potential of the hydrogen ion which is assumed to have a reference potential of zero volts. The more active a metal, the lower will be the deposition potential of its ions. Conversely, the electrode potential may serve as a measure of the activity of a metal.

Table I. Measured Values of Electrode Potentials

Lithium	−3.02	Tin (against Sn^{++})	−0.14
Potassium	−2.92	Lead (against Pb^{++})	−0.13
Sodium	−2.71	Iron (against Fe^{+++})	−0.04
Calcium	−2.5	Hydrogen	0.00
Magnesium	−1.86	Antimony (against Sb^{+++})	+0.01
Aluminum	−1.34	Bismuth	+0.2
Manganese (against Mn^{++})	−1.0	Copper (against Cu^{++})	+0.34
Zinc	−0.76	(against Cu^{+})	+0.52
Chromium (against Cr^{++})	−0.6	Mercury (against Hg^{+})	+0.80
(against Cr^{+++})	−0.5	Silver	+0.80
Iron (against Fe^{++})	−0.43	Palladium	+0.82
Cadmium	−0.40	Mercury (against Hg^{++})	+0.86
Cobalt (against Co^{++})	−0.29	Gold (against Au^{+++})	+1.3
Nickel (against Ni^{++})	−0.22	(against Au^{+})	+1.5

This table may be considered the activity series of the metals, those highest in the table being the most active.

Every chemical reaction may, theoretically, be represented as being separated into two electrode reactions, and the difference in potential (algebraically) between the two will be a measure of the reactivity. A highly negative potential difference would represent a spontaneous reaction which might be utilized to generate a current, whereas a high positive potential difference would represent a reaction which requires energy to drive it forward.

Electrowinning. Ores of copper, zinc, cadmium, and others are sometimes leached with sulfuric acid to give solutions of metallic sulfates from which the metals may be recovered by electrolytic deposition. Copper is quite low in the electromotive series and so it may be deposited at a very low voltage while the more active metals such as iron, which may be present as impurities, remain in solution. The positively charged copper ions are charged at the negative electrode, called the cathode, while oxygen is evolved at the positive electrode, called the anode.

Zinc and cadmium are more difficult to deposit and require higher voltages. Salts of metals lower in the electromotive series must not be allowed to accumulate if a pure and smooth deposit is desired.

Electrorefining. Copper, nickel, lead, tin, silver, gold, and other metals produced by smelting or electrowinning may be further purified in order to be more useful commercially. Electrodeposition is the most effective means of accomplishing this end. The principles are similar to those of electrowinning except that the anode, instead of consisting of an inert material which liberates oxygen, is formed of the impure metal which dissolved and is reprecipitated on the cathode while the impurities generally are made to settle in the form of a mud which may then be further treated to recover valuable by-products.

Electroplating is similar to electrorefining in principle but the anodes are made of pure metals or desired alloys while the composition of the electrolytic solution, temperature, current density, etc., are adjusted to give a smooth, attractive, adherent, and useful plate.

Electrolytic Caustic Soda and Chlorine. Solutions of sodium chloride brines may be electrolyzed to give hydrogen and caustic soda at the cathode and chlorine at the anode. Thus

$$\left.\begin{aligned}(2Na^+) + 2H_2O &\xrightarrow{\text{at cathode}} (2Na^+) + 2OH^- + H_2\\ 2Cl^- &\xrightarrow{\text{at anode}} Cl_2\end{aligned}\right\} \qquad (2)$$

The products of the anode and of the cathode would react if allowed to mix so that it becomes necessary to keep them separated by means of a semi-permeable diaphragm or by some mechanical scheme. Numerous cells have been designed to achieve this end. In the manufacture of sodium hypochlorite and sodium chlorate the chlorine and alkali are purposely allowed to mix.

Electric Cells and Batteries. Numerous combinations of electrolytes and electrodes may be used for converting chemical to electrical energy. Practically, the most useful of these are the lead storage and the Edison alkali cells.

In the lead storage cell, lead dioxide reacts with sulfuric acid at the anode to produce a positive charge.

$$\underset{+\text{Plate}}{PbO_2} + 2H_2SO_4 + \underset{-\text{Plate}}{Pb} \rightleftarrows \underset{+\text{Plate}}{PbSO_4} + 2H_2O + \underset{-\text{Plate}}{PbSO_4} \qquad (3)$$

At the cathode, metallic lead reacts with the acid to produce a negative charge. The lead ions formed at both electrodes combine with the sulfate to produce the sparingly soluble lead sulfate. Both electrode reactions are reversible so that, by impressing a current, the initial conditions may be restored and the cell will be recharged.

Nevertheless, owing to the energy dissipated by internal resistance, including polarization effects at the electrodes and some inevitable short-circuiting of current within the cells, called local action, the output of electrical energy is never quite equal to the input. The ratio of the two is known as the efficiency of a battery or cell.

The voltage of a cell on charging or discharging is the resultant or algebraic sum of the open-circuit emf due to the Nernst electrical potential and the voltage drop due to the internal resistance. For very low rates of charge or discharge the voltage approaches that of open circuit, but it is always somewhat greater on charging and lower on discharging. The internal resistance voltage drop may be considered to be the product of the current and the resistance by Ohm's law, but this resistance depends, in general, upon the rate and direction of the flow, the strength of the acid electrolyte, and the condition of the electrodes as well as the temperature. The acid gains in strength (usually measured by its specific gravity) on charging, and loses it on discharging, while the electrodes become coated with lead sulfate, on discharging, which disappears as the cell is charged. Fig. 1 shows typical cell voltage on charging and discharging as a function of the time. On changing the rate of current flow these curves will, of course, be greatly modified. The open-circuit voltage of a storage cell varies only from about 2.05 to 2.15 volts, the greater part of the voltage changes being due to the internal resistance factor.

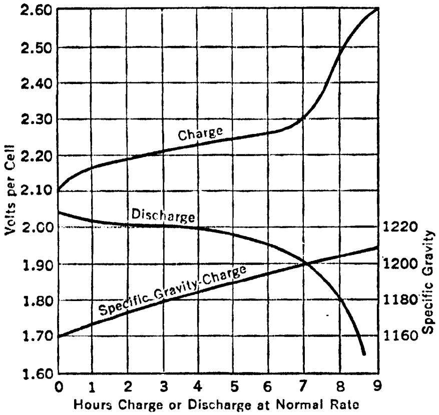

Fig. 1 Lead Storage Cell
(Planté Stationary Type)

The sp gr varies from 1.150 to 1.300. An approximate lower limit is shown in Fig. 1.

The Capacity of a cell is defined as the number of ampere-hours which it will supply when fully charged at some rate of discharge which must be specified.

The most important specifications for lead storage cells as well as for other cells are the following:

The energy efficiency, which is the ratio of the energy output to the input under specified conditions.

The capacity, as already defined.

The ampere-hour efficiency, which is the ratio of the number of ampere-hours output to the number of ampere-hours input under specified conditions.

The ampere rating, which is the number of amperes that may safely be passed through a cell for an appreciable time. For brief intervals considerably greater currents may be handled.

Certain rules must be observed for the proper care of lead storage batteries:

The cells should not be made to carry a greater current than that at which they are rated lest there be excessive temperature and gassing at the electrodes.

If the strength of the electrolyte is allowed to remain low for a considerable period, as when the battery is fully discharged, the lead sulfate which acts as a binder for the lead peroxide will disappear, with accompanying disintegration of the cell.

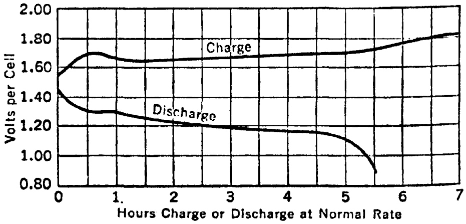

Fig. 2. Edison Storage Cell

If, on the other hand, the strength becomes too high, there will be excessive sulfating with injurious effects. The correct range of specific gravity for the acid is from 1.140 to 1.285, although it should not be allowed to remain at the lower extreme for very long.

In order to avoid corrosion at the liquid level, the plates should be kept fully covered at all times by adding distilled water occasionally. Tap water and other sources of impurity should be avoided, and the original acid should be of high purity to avoid disintegrating effects.

The batteries should be overcharged once every month to form enough sulfate to keep the deposit on the plates intact. The gassing so produced also helps to overcome the tendency of the stronger acid to settle to the bottom of the cells.

Finally, the electrolyte should occasionally be removed and replaced by fresh acid.

The Edison Cell is similar in principle to the lead storage cell. Nickel peroxide replaces the lead peroxide at the anode; iron replaces lead at the cathode; and potassium hydroxide replaces sulfuric acid as the electrolyte. The principal reaction is

$$5Fe + 5Ni_2O_3 \cdot 6H_2O + 9H_2O \rightleftarrows 10Ni(OH)_2 + 5Fe(OH)_2 \qquad (4)$$

Non-aqueous Solutions

The only important non-aqueous solutions used in the electrochemical industries are the fused salts. These are used only where the same result cannot be attained in an aqueous solution. The metals, aluminum, magnesium, calcium, sodium, and others, are prepared in this way.

Aluminum is produced from purified bauxite (Al_2O_3) dissolved in fused cryolite ($AlF_3 \cdot 3NaF$). Molten aluminum is deposited at the carbon cathodes while oxygen is liberated at the carbon anodes, reacting to form carbon monoxide so that the electrode is gradually consumed and must be replaced. In this way, the bauxite is decomposed proportionally to the metal produced while the cryolite remains substantially unaffected.

Magnesium is deposited from a fused bath of magnesium chloride to which a small amount of sodium chloride is added to lower the melting point. The cast-steel pot in which the bath is held acts as the cathode upon which the molten metal is deposited. Later the metal floats to the top. Chlorine is liberated at the graphite anodes.

24. ELECTROTHERMICS

In Electrothermic Processes, electric energy is supplied for the sole purpose of producing a high temperature. Several types of furnaces are used.

In the Resistor Type of Furnace a bed of solid granular material, usually carbon or graphite, is used. An electric current, alternating or direct, is passed through, liberating heat. The furnace charge itself may constitute the resistance. Thus, in the manufacture of silicon carbide (Carborundum), a mixture of sand and coke is placed between two graphite electrodes. (See Art. 20.) In graphite manufacture a similar construction is used but the charge is generally anthracite coal.

In the Arc Type of Furnace, electrodes, usually of graphite, are brought into contact and then drawn apart. The heat generated by the resistance of the air gap vaporizes the carbon across the arc, and a current continues to flow. Details of design vary widely. These furnaces are used extensively in the alloying of steel and in the manufacture of calcium carbide. In this process lime is made to react with coke at a high temperature.

$$CaO + 3C \rightarrow CaC_2 + CO \qquad (5)$$

Calcium carbide is extensively used in the manufacture of acetylene, from which numerous organic chemical products are derived.

Finely ground calcium carbide is made to react with nitrogen in a resistance-type furnace to form calcium cyanamid.

$$CaC_2 + N_2 \rightarrow CaCN_2 + C \qquad (6)$$

This is a useful method of nitrogen fixation since the cyanamid reacts with hot water in the presence of alkalis to form ammonia.

$$CaCN_2 + 3H_2O \rightarrow CaCO_3 + 2NH_3 \qquad (7)$$

Calcium cyanamid is mixed with carbon and salt in an arc furnace to yield sodium cyanide.

$$CaCN_2 + C + 2NaCl \rightarrow CaCl_2 + 2NaCN \qquad (8)$$

Induction Furnaces depend upon the production of heat directly in a metal charge by an electric current generated by a-c coil windings. Such furnaces are used for the refining of high-grade iron and steel. Temperatures are subject to very close control in this type of furnace.

25. ELECTRONICS AND THERMIONICS

These subjects in their relation to gas and vacuum tubes are discussed in Section 8. The phases most directly concerning the chemical industries are electrostatic precipitation and the manufacture of ozone and nitric oxide.

The electrostatic precipitator usually consists of a vertical cylindrical metal chamber; an electrode of wire or metal chain passes axially through the center of the chamber and receives a high potential electrostatic charge. The cylinder wall is grounded, and an electric discharge passes radially outward. The gas in the cylinder is thus ionized, as are the particles of dust or fog which are suspended in it. These are attracted to the grounded wall and are thus precipitated and recovered while the pure air or gas passes on. Such installations are in use for the recovery of solid fumes in the cement and phosphate industries and for cleaning the gases in contact sulfuric acid manufacture.

Ozone (O_3) is produced by the silent electric discharge through air at room temperature.

$$3O_2 \rightarrow 2O_3 \qquad (9)$$

Ozone is a highly active form of oxygen and is used for sterilization.

Nitric Oxide is produced by passing air across a high-temperature arc. The nitrogen and oxygen then combine to form nitric oxide, which is converted to nitric acid.

$$N_2 + O_2 \rightarrow 2NO \qquad (10)$$

METALLIC MATERIALS

1. GENERAL PROPERTIES OF METALS AND ALLOYS

By Bradley Stoughton

Price must always be an important factor in the choice of materials for engineering construction. The wide-spread use of iron and steel for many purposes is due largely to this feature. From the technical standpoint, however, the two properties of metals and alloys which most influence their selection as the chief materials of construction in our modern civilization are, first, strength combined with ductility, and, second, the ready ability to be shaped, i.e., to be changed in size or form. Illustrations of this latter property are: casting while liquid, die-casting during solidification, extrusion, rolling or forging while hot and very plastic, and (at atmospheric temperature), rolling, wire drawing, flanging, spinning, etc. In the category of shaping should be included machining, which can also be applied to some non-metallic bodies, as well as welding and soldering, which are unique for metal joining. Besides these two properties of most frequent importance there are special properties each of which is of prime importance in individual activities or industries, for example: hardenability, including the property of doing efficient cutting work at specified temperatures; electrical conductivity; magnetic permeability; magnetic retentivity; resistance to corrosion, staining, or rusting, although this property is often lacking in metals and is valued in them only when combined with some other useful feature. The same may be said of a metal's resistance to the effect of heat tending toward: loss of strength, "creep," grain growth, softening, melting. An instance of a useful combination of several properties producing a valuable result is found in tungsten, with its ability to be drawn into very fine wire, its strength, its toughness, and its high melting point, achieving together a new art in electric lighting. Other properties of metals of great value are: high melting temperature as in points in spark plugs; low melting temperature, as in fusible plugs for boilers, fire sprinklers, and electric fuses; reactivity to light, as in photoelectric cells, television parts; heat conductivity, as in radiators, cook stoves, cooking utensils, etc.; low coefficient of expansion, as in surveyors' tapes and clock pendulums; wide divergence in expansion and contraction with temperature changes, as in bimetallic thermostats; strength combined with denseness, as in food containers, pressure gas bottles; color for decorative purposes; colors of metallic oxides, or other compounds, for paint pigments, glass, porcelain, china; mere weight, as window sash weights, fillers for rubber tires; resilience.

The Nature of Metal. Metals are chemical elements. Of the known chemical elements more than half are admittedly metals, while about 20 elements have combinations of chemical and physical properties which leave them in dispute. All the admittedly metallic elements are solid, crystalline bodies except the liquids, mercury (quicksilver) and gallium. A crystalline body is composed of crystals so small that normally there are several million crystals to each cubic inch of volume, and the crystals are composed of several million space lattices per crystal. The space lattices, in turn, are geometrical arrangements of atoms, of which the cube and the octahedron are the commoner forms. The atom nuclei are held together in space lattices by hypothetical atomic bonds, which resist both tension and compression, thus giving solidity to the mass. Electrons are situated among the atomic nuclei and have a limited amount of freedom of motion, upon which is predicated a theory of heat and electrical conductivity, and, perhaps, of magnetism in the ferromagnetic metals, iron, nickel, and cobalt, and the ferromagnetic alloy of paramagnetic metals, aluminum, manganese, and copper. The nature of the atomic bonds would seem, by inference, to be a basis of strength, elasticity, resilience, hardness, expansion with temperature, and perhaps even of fusibility. The ability of atomic bonds to re-establish themselves after slip would seem to be the basis of plasticity. The lengths of atomic bonds range from 10 to 38 billionths of an inch and are several times greater than the diameter of the atomic nuclei, with the result that the latter are held so widely apart that short rays of the x-ray type pass between them and penetrate a body which will totally reflect the visible light rays and give the appearance of being composed of closely packed particles.

Physical Metallurgy. About 80 years ago metallurgists began to use the microscope for the examination of polished surfaces of metals. This form of research has been followed extensively during the past 50 years, and much has been learned of the structure of metallic bodies, especially as to the size, form relations, and (in connection with chemical and other types of investigation) the kinds of crystals. This study of structure is known as metallography. Next came a disclosure by physicists of the structure of atoms. The third step in the development of the modern science of physical metallurgy was the introduction of the use of the x-ray spectrometer to disclose the structure of space lattices—specifically their form, their size, and the arrangement in them of atoms. The most important results have been obtained not with pure metals, but with alloys.

Alloys. An alloy is a union of two or more metals, or of metals with a subordinate amount of a non-metal, as in the case of the most-used of all alloys, namely: steel, which is an alloy of iron with a small proportion of carbon. The specific requirement of an alloy is that, when melted, its components dissolve in each other. Metals which will not dissolve in each other cannot be made to form alloys together. In the liquid mass the atoms move freely until the body cools to the freezing temperature; thereupon the atoms begin to unite themselves into space lattices with atomic bonds. Sometimes the atoms of a metal may enter freely, and without limit in proportion, into the space lattices of the other metal, forming solid solutions of any proportion of either metal. In other cases the atoms of each metal segregate to form space lattices of and by themselves, which space lattices then form crystals of the individual elements. Again, a limited number of atoms of one metal enter into the space lattices of another metal, forming thereafter crystals of what are called "solid solutions." The freezing of a liquid solution of any proportion of two metals into a solid solution of the same proportions is known as freezing of Type I, and is expressed diagrammatically in Fig. 1. The complete decomposition of a liquid solution of two metals into two pure solid metals is known as Type II, Fig. 2. The freezing which results in only limited solubility in the solid state is called Type III, Fig. 3. There still remains the formation of structures when metallic compounds are present, such as Fe_3C, Cu_2Zn_3, etc., a discussion of which may be found in any reference book on physical metallurgy.

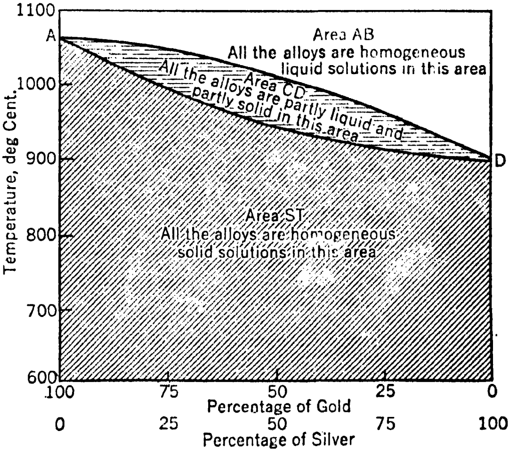

FIG. 1. Freezing-point Diagram of Alloys of Type I, in which a Homogeneous (Liquid) Solution Changes to a Solid Homogeneous Solution. The point *A* is the freezing point of pure gold; the point *D* is the freezing point of pure silver. Any solution in area *AB* will freeze to a corresponding solution in area *ST*. For example, a solution of 50 per cent gold in 50 per cent silver in liquid solution will freeze to crystals, each of which will be a solid solution of 50 per cent gold and 50 per cent silver. In this connection, it should be noted that, whereas the crystals may not all be alike on first freezing, the atoms of one element frequently migrate or diffuse through the space lattices of a solid crystal until equilibrium is established, that is to say, until all the crystals are alike.

Phase Changes in Solid Solutions. In the alloys of Type I, the crystals of solid solution, after formation, ordinarily cool to atmospheric temperature without further change. In the very limited number of alloys which form according to Type II there also seem to be no revolutionary changes after freezing is complete. But the solid solutions formed in Type III do not persist in unaltered form on cooling. Almost all limited solid solutions decrease their solubility with fall in temperature. In other words, the proportion of metal *B* which can be held in metal *A* in solid solution at a temperature of, say, 1000 deg cent, will be greater, and sometimes much greater, than the proportion which will saturate the same metal at 500 deg cent. Therefore, the structure of an alloy which exists immediately after freezing may be altered on cooling, and is then said to have undergone a phase change.

Influence of Structure on Properties. Some properties of metallic bodies are greatly dependent on their structure. The structure of a metallic body at a given temperature is due, first, to the formation of space lattices; second, the aggregation of space lattices into crystals; and third, changes which take place in the nature of the crystals on cooling after freezing. The nature of the crystal depends not only on its composition but also on its size. And finally, some of the properties of metallic bodies depend upon the

FIG. 3. Equilibrium Diagram of the Freezing of Alloys of Type III, in which Each Liquid Solution Changes into Either One or Two Solid Solutions. In area *MN* there is only one solid solution in each alloy. In area *ST* there is only one solid solution in each alloy. In area *OR* there are two solid solutions in each alloy, solid solutions consisting of a saturated solution of metal *B* in metal *A* and of metal *A* in metal *B*. Most of our commercial alloys are of this type, namely, those in which solid solutions of *B* in *A* form up to the limit of saturation, and, on the opposite end of the percentage scale, alloys of metal *A* in *B* up to the limit of saturation. Between these two saturation limits, the alloys consist of crystals of saturated solution of *A* in *B* and saturated solution of *B* in *A*.

nature of the extremely thin envelopes between crystals, sometimes called the "intercrystalline cement."

Allotropic Modifications. Some metals abruptly change their properties when heated above a critical temperature. On cooling again below this critical temperature, they revert to their former properties. For example, iron above its critical temperature range will dissolve carbon in any amount up to an upper limit of 1.7 per cent; below this critical range, it will not hold more than 0.03 per cent of carbon in solid solution. Other physical properties are in a somewhat marked degree coincident with the change in the power of dissolving carbon. In the case of iron, this change is known to be a change in space lattice: below 890 deg cent the pure iron crystal is made up of body-centered cubic space lattices, having 9 atoms per space lattice; above 900 deg cent the space lattice is face-centered, having 13 atoms to each space lattice. This change of number and position of atoms in the space lattice takes place within the solid crystal, and the change in the metal is said to be an allotropic change. Tin and several other metals undergo allotropic changes in the solid state. The temperature at which the change occurs is different for each individual metal.

CORROSION OF METALS

By Frank N. Speller

2. PRINCIPLES OF CORROSION

Corrosion of Metals. Corrosion of metals may be defined broadly as the chemical action of their environment, often resulting in their deterioration or destruction. In many conditions, most metals are unstable and tend to revert to a more stable combination, i.e., the metallic ores found in nature. Under most ordinary conditions of exposure, the corrosion products comprise mainly oxides (more or less hydrated), carbonates, and sulfides. At high temperatures the product may consist largely of oxides, although indications are that corrosion of this type also progresses more rapidly when some moisture is present. Corrosion may be entirely superficial or may attack the intercrystalline boundaries and cause disintegration in the metal, as dezincification of brass or so-called caustic embrittlement in boiler steel.

Recent work (1932) in the fundamentals of corrosion shows that the essential phenomena are the same for all metals and alloys, differing only in degree but not in kind. The discussion may be simplified, therefore, by considering the mechanism of corrosion with reference to iron.

It may be taken as established that in nearly all cases of corrosion at ordinary temperatures, comprising those most important in practice, the driving force of the corrosion reaction between metal and environment is electrochemical. The resultant electrochemical potential varies with the environment and the metal, and determines the tendency of the reaction to proceed. The rate of corrosion is determined mainly by the resistance to the continued progress of the reaction set up by certain of the corrosion by-products.

Established Facts Regarding Corrosion. *a*. In most cases both moisture and oxygen are necessary for corrosion. *b*. The initial rate of corrosion is usually comparatively rapid, slowing as protective films form. *c*. Surface films are important in controlling the rate and distribution of corrosion. *d*. Increased rate of motion increases corrosion in water up to a certain velocity; the rate may then drop where strong protective films are formed. *e*. Dissimilar metals in electrical contact accelerate corrosion of the one that happens to be anodic. Galvanic action is a most active agent of corrosion. It occurs when two metals, one electronegative to the other, are placed in contact and exposed to moisture. *f*. The composition of ordinary iron and steel has little or no effect on their relative rates of corrosion under water or underground. Under these conditions, the particular kind of metal is not usually so important as environment. *g*. Variation in the concentration of a solution in contact with a metal tends to localize corrosion. Where this is due to oxygen in solution, the surface to which the oxygen diffuses most readily is cathodic to the area that is protected from diffusion of oxygen. The smaller the anodic areas in relation to cathodic areas the greater is the rate of penetration at anodic points. *h*. Corrosion, like other chemical reactions, proceeds more rapidly with increase in temperature.

Corrosion in the Presence of Water. The above, and other facts (see F. N. Speller, Corrosion—Causes and Prevention, McGraw-Hill Book Co., 1926), are the basis of the electrochemical mechanism of corrosion, which is generally accepted to explain corrosion in the presence of water.

Iron, like all other metals, when in contact with water or a solution has a definite inherent tendency to enter the solution in the form of electrically charged particles (iron ions). The solution must remain electrically neutral, and these positive ions can enter it only if an equivalent number of positive ions of another element are displaced. Thus, iron immersed in a solution of copper sulfate begins to go into solution. Simultaneously, an equivalent amount of copper is plated out on the surface of the iron, and protects it somewhat from further action. Similarly, when iron is immersed in water, hydrogen is plated out and forms a thin invisible film on the iron surface.

The general mechanism of the corrosion processes is expressed in the following chemical equations. The typical primary reaction is

$$(1) \qquad \underset{\text{metal}}{Fe} + \underset{\text{ions}}{2H^+} \rightarrow \underset{\text{ion}}{Fe^{++}} + \underset{\text{atoms}}{2H}$$

The primary reaction is followed by either

$$(2)\ (a) \qquad \underset{\text{atoms}}{2H} + \underset{\text{dissolved}}{1/2\,O_2} \rightarrow \underset{\text{liquid}}{H_2O} \qquad \text{(the destruction of the hydrogen film)}$$

$$\text{or}\ (b) \qquad \underset{\text{atoms}}{2H} \rightarrow \underset{\text{gas}}{H_2} \qquad \text{(its removal as bubbles of gas)}$$

These permit reaction (1) to proceed with the accumulation in the solution of Fe^{++} which is oxidized and precipitated as rust by

$$(3) \qquad 2Fe^{++} + 1/2O_2 + H_2O \rightarrow 2Fe^{+++} + 2OH^- \rightarrow \text{Insoluble ferric hydroxide (rust)}$$

Factors Controlling Corrosion. Primary factors are those having to do with the initial tendency toward solution (reaction 1) and are mainly associated with the metal itself. Secondary factors are those that influence the subsequent rate of corrosion, and usually are more important than primary factors. They depend mainly upon the environment of the metal. The main factors influencing corrosion are listed below, regardless of their relative importance, which changes materially with the environment.

Primary Factors Having to Do Mainly with the Metal or Alloy.

1. Effective electrode potential of the metal in the solution.
2. Chemical and physical homogeneity and texture of its surface.
3. Its inherent ability to form an insoluble protective film.
4. Overvoltage of hydrogen on the metal surface.

Factors Which Vary with the Environment.

5. Hydrogen-ion concentration (*p*H) in the solution.
6. Effective supply of oxygen in the solution adjacent to the metal.
7. Distribution of available oxygen on the metal surface.
8. Specific nature, concentration, and distribution of other ions in the solution.
9. Effective rate of flow of the liquid past the metal surface.
10. Presence of solid particles (dirt), or of a coating of any kind as mill scale, on the metal surface, or contact with other conducting material in the presence of an electrolyte.
11. Temperature.
12. Whether the metal is under static stress conditions or exposed to cycles of alternating stress (the so-called corrosion fatigue).
13. Ability of environment to build up protective films on the metal.

In different environments the order of importance of the above factors changes materially. The standard electrode potentials of the elements as given in textbooks have little significance, except that they indicate the relative tendency of the metal to enter solution under certain specific conditions. If the concentration of the solution is changed, the order of standing of metals that lie close together in the electrochemical series, e.g., iron and cadmium, actually may be reversed. The relative influence of the important factors on corrosion of steel in water of different acidities is illustrated by the following table.

In Alkaline Zone ($pH > 10$) Corrosion slow	In Neutral Zone (pH 4.3 to 10) Corrosion medium	In Acid Zone ($pH < 4.3$) Corrosion rapid
Protective films	Oxygen concentration	Hydrogen-ion concentration
Oxygen concentration	Protective films	Hydrogen overvoltage
Composition of metal	Hydrogen-ion concentration	Composition of metal
Hydrogen-ion concentration	Composition of metal	Oxygen concentration
Hydrogen overvoltage	Hydrogen overvoltage	Metal-ion concentration
Metal-ion concentration	Metal-ion concentration	Protective films

Factors that head the list dominate others in their influence and are termed controlling factors. Thus, in the alkaline zone protective films are much more influential than any other factor; in the acid zone they form with difficulty and are readily removed, and have little influence under acid conditions.

A lesser but often considerable amount of corrosion is found in the absence of oxygen. The dominant reaction then is reaction 2 *b* (see above). accompanied by the evolution of hydrogen. This may be due to acid conditions, the presence of hydrogen sulfide, or to a high concentration of chloride. The mechanism of corrosion at high temperatures is not so well understood. It probably is due mainly to direct chemical attack, and may be accelerated by some electrochemical action where moisture is present.

Though all the above factors are important under some conditions, the following deserve special attention and should be more clearly recognized.

Oxygen. In most cases the oxygen concentration and the rate at which oxygen diffuses to the metal is a controlling factor when metal is immersed in water or buried in soil. The part to which the oxygen diffuses most readily is cathodic to the adjacent areas that are shielded by protective coatings or other material. That is, the points that are less accessible to oxygen corrode more rapidly than areas to which the oxygen has freer access. This principle, and the galvanic effect from contact between dissimilar materials, generally cause local corrosion or pitting.

Surface Films. Clean metallic surfaces exposed to air quickly acquire a film of oxide, which, at ordinary temperatures, is thin and invisible. At higher temperatures it is thick enough to give well-known characteristic colors, varying with the temperature. The nature and properties of the film depend upon the composition of the metal itself and its environment. Aluminum and stainless steels, for instance, owe their high durability in certain environments to the formation of a continuous and permanent film that is stable under the conditions of exposure. In other environments the film may not form or may be quickly dissolved. The metal, therefore, has short life under such conditions. The addition of 0.25 per cent copper to ordinary steel increases its life in atmosphere two to four times, owing to the formation of a dense adherent film, apparently consisting of iron oxide with a little copper oxide, on the surface of the metal. When copper steel is immersed in water or buried in soil the protective film does not form. Under such conditions, copper steel has been no more durable than ordinary steel without copper.

If the metal has no inherent power to form a protective film in solution, a film may be built up by adding film-forming reagents, as the chromates or alkalies, to the water. When the metal is removed from the solution, however, these films are only temporary. To secure permanent protection it is necessary to maintain in the water the proper concentration of chromate, or other material, used for this purpose. Films when formed should be self-healing, so that, if they are injured or removed in any way, a new film will form immediately to protect the metal. Chromium will form a very resistant invisible film under oxidizing conditions, but in dilute hydrochloric acid, where such films cannot exist, chromium dissolves even more rapidly than pure iron. Metals which acquire a stable film by contact with an oxidizing solution are termed passive. In this condition they are, at least, temporarily resistant to corrosion when removed from the film-forming solution. The presence of thin invisible oxide films on passive material has been determined by the change in potential of the metal and by the removal of the films from the surface by selective dissolution of the underlying metal. (See U. R. Evans, Thin Films in Relation to Corrosion Problems, *J. Inst. Metals*, Vol. 46, pp. 7-23, 1931.) Where the corrosion products form spongy layers of irregular thickness, they do not protect, and may even accelerate the normal action by interfering with the rate of diffusion of oxygen to the surface of the metal.

Corrosion Fatigue. Metals subjected to repeated application of stress fail at considerably below their static ultimate tensile strength. However, the metal may be cyclically stressed indefinitely, without apparent injury, below the so-called fatigue or endurance limit. For carbon steels, this endurance limit is about one-half the tensile strength. Even a small amount of corrosion present with cyclic stress will considerably reduce the endurance limit. Concentrated stress tends to accelerate the rate of corrosion. A notch is soon formed at the point of maximum stress, and after this reaches a certain depth, the metal under cyclic stress fails by ordinary fatigue. The combined action of stress and corrosion is termed " corrosion fatigue." The amount of cyclic stress that a metal will stand under these conditions depends on the character of the corrosion and on the nature of the protective films formed by the metal or its environment. Hence, it is difficult to conceive of a fixed corrosion fatigue limit for any metal under all conditions of exposure. Corrosion factors predominate in corrosion fatigue. Therefore if there is a so-called corrosion fatigue limit, it is independent of the tensile strength. Heat treatment of steel raises the tensile strength and the air endurance limit, but if it does not increase resistance to corrosion it will have no material influence on the resistance to corrosion fatigue. Even 18 per cent chromium steel and 18-8 per cent chromium-nickel steel show a considerable reduction in their endurance limit in corrosive environment. Carbon steels in the as-rolled condition may fail at less than one-half of their air-endurance limit when kept continuously wet, depending upon the composition of the water and the amount of oxygen present.

An exceedingly small amount of corrosion is sufficient to depress the endurance limit of the metal under stress. In practice, therefore, it is important to prevent contact between stressed portions of metal and corrosive solutions. When inhibitors have been added to water that ordinarily causes failure at a relatively low stress by corrosion fatigue, the endurance of the steel has been maintained at the same stress as in dry air. This apparently is due to the formation and maintenance of a protective film on the surface of the metal under stress.

3. PRINCIPLES OF CORROSION TESTING

Relative Corrosion. Difference of opinion regarding the relative corrosion of iron and steel and other metals apparently is due to failure to appreciate that different factors control in different environment. Factors external to the metal usually determine the corrosion rate; they vary considerably with environment. The relative rate, therefore, may vary under different conditions of exposure. This should be the basis on which all corrosion tests (laboratory or service) are designed. Thus, in a study of metals under atmospheric conditions, the dominant factor should be an excess of oxygen. If the endurance of metal under water is in question, the test should be made in that environment alone. It is a mistake to take the results of tests made under one type of corrosion, e.g., in the atmosphere or in acids, and to apply the conclusions to conditions in which entirely different factors control. An extreme instance is the well-known acid test, made by exposing the metals to dilute sulfuric acid. A thorough investigation of this test in comparison with results of corrosion of the same metals under atmospheric and water conditions led to the following conclusions: An acid test conducted by the procedure followed by the committee is not capable of consistent repetition; further, the data from such an acid test should not be used to forecast the relative life of ordinary ferrous materials in the atmosphere. (See Report of Sub-committee V on Total Immersion Tests, *Proc. A.S.T.M.*, Vol. 31, Pt. I, p. 180, 1931.)

Clearly, the subject of relative corrosion should be studied on the basis of type of service. The service test is the final criterion of the value of the metal, although judiciously made laboratory tests, with proper consideration given to the factors involved, will show under accelerated conditions a fair approximation of results in service. Three common types of service to be considered are atmospheric, water, and soil corrosion.

4. PREVENTION OF CORROSION

Deterioration of metals may be prevented or reduced in three ways: (1) By using a more resistant metal. (2) By the application of a suitable protective coating. (3) By making the environment less corrosive. The amount of protection depends specifically upon the corrosive nature of the environment and must be chosen to suit the conditions and with a view to economy.

Protective Coatings. To obtain protection against corrosion three methods are in general use:

1. Applying impervious coatings such as paints, varnishes, lacquers, vitreous enamels, etc.
2. Applying coatings of protective metals which either mechanically exclude moisture and corroding materials from the metal surface, or which, being electronegative to iron, are themselves corroded in preference to the surface beneath.
3. Producing inert or non-corrodible coatings by heat or chemical treatment of the metal surface.

Protection from Atmospheric Corrosion

Paints, Varnishes, etc. A large variety of paints, lacquers, and similar protective materials has been developed. See Sec. 12 for a brief treatment of these. See also publications of American Paint and Varnish Mfrs. Assoc., distributed by the Institute of Paint and Varnish Research Laboratory, Washington, D.C.

Cast-iron water pipes are usually coated by dipping in a hot mixture of coal-tar and coal-tar pitch; riveted or welded steel pipes by dipping in hot asphalt. Ships' bottoms are coated with red lead or other inhibitive primer and a varnish paint to prevent rusting. Over this is a similar paint containing poison, as mercury chloride or a copper compound, or a greasy copper soap is applied hot, to tend to prevent the accumulation of marine growths. Galvanized iron and tin surfaces should be thoroughly cleaned with benzine and scrubbed before painting. When new, they are partly covered with grease and chemicals. These must be removed or paint will not adhere. Weathering for six months prior to painting serves the same purpose in preparing galvanized steel surfaces.

Galvanizing is a method of coating steel or iron articles with zinc, the product being known as galvanized steel or iron. For a discussion of various galvanizing processes and the corrosion resistance of galvanized surfaces, see pp. 11-54 and 11-55.

Lead Coatings. Lead is very resistant to some types of corrosion, and lead coatings on steel have been somewhat used. Lead, however, is difficult to apply, either by electroplating or hot dipping, in a coating sufficiently free from pinholes to be effective when submerged in corrosive water. The atmospheric resistance of such coatings is usually quite good. Hot-dipped lead sheets, known as terne plates, are extensively used.

Wrought steel or iron pipes protected on the interior by thick lead tubes mechanically applied, when carefully installed with suitable fittings and valves, are effective for carrying corrosive acids and similar liquids.

Electroplating with Other Metals is a method of depositing impervious and adherent metallic coatings on conductive surfaces by electrolysis. The following metals are most commonly used for this purpose:

Copper. Because of its resistance to corrosive influences, copper is widely used as a protective metal coating, frequently being the base coating for subsequent nickel or chromium deposits.

Nickel. Nickel is harder than copper and has excellent resistance to corrosive atmospheric conditions. Because of its lustrous gray-white color, it is often used as a metal coating where appearance is a factor as well as durability.

Chromium. Chromium is a hard, white metal which is non-tarnishing and which has good light-reflecting properties. Chromium deposits are difficult to obtain, but excellent coatings are produced under closely controlled electroplating conditions.

Silver. Silver has excellent resistance to oxidation and corrosive atmospheric conditions. It is used as an electrodeposited metal coating chiefly because of its efficiency as a carrier of electricity and as a reflector of light rays. Because it is susceptible to tarnishing from sulfur compounds in the air, it is frequently protected by a coating of lacquer, when used for reflectors.

Cadmium. Cadmium is a white metal which, being electronegative to iron is widely used for the protection of iron and steel parts against atmospheric corrosion. A thin layer gives good protection and is useful in protecting threaded parts where tolerances are close.

Tin. A tin coating, being electropositive to iron, must be free from pinholes, or accelerated corrosion will set in where the steel is exposed. Tin itself is resistant to corrosion.

Oxide Coatings. Oxide coatings for the protection of steel are obtained by oxidizing the metal by heat or chemical treatments. The oxide coatings are always oiled, which probably accounts for their resistance to corrosion.

One method is to heat the metal to about 400 deg cent, in the presence of steam and hydrocarbons, until a heavy black coating is produced.

Another method is to apply solutions of chemical reagents until a heavy rust film is obtained. The rust is then removed by scraping, leaving a thin adherent coat of oxide on the metal. The process is repeated until the desired depth of color is obtained. The surface is then oiled.

Burned Oil Finish. A deep black oxide coating is obtained by heating steel in volatilized oil vapors at a temperature of about 400 deg cent, or by first coating the steel with oil and then heating. In other processes the steel is heated in oil and sawdust, or in burned bone and charcoal to obtain the black oxide.

Coslettizing. Phosphate coatings are used extensively for the rust proofing of steel and to serve as base coatings for paints and lacquers. The Coslettizing process consists of immersing the steel in a hot ferric phosphate solution containing some phosphoric acid. The grayish white coating becomes black when oiled.

Parkerizing. The Parkerizing process of producing durable phosphate coatings on steel uses a patented mixture containing manganese and iron phosphates. It is otherwise similar to the Coslettizing process.

Bonderizing. Bonderizing is a modification of the Parkerizing process used to produce a base coating for finishing with paints and lacquers.

Granodizing. In the Granodizing process the article is made the cathode in a hot solution of zinc phosphate and phosphoric acid. A dense black coating is produced on iron, zinc, cadmium, and other metals, which is resistant to weathering. An immersion Granodizing bath, without application of voltage, is also in use.

Anodizing. Aluminum and its alloys are treated by the anodizing process which produces adherent oxide films for protection against corrosion, for electrical insulation, and for decorative effects.

Rust-resisting Metals. No metal or alloy has so far been produced that is equally durable under all conditions. The development of the alloy of chromium and iron, with and without nickel, has made available for industrial purposes a class of materials combining unusual resistance to corrosion with desirable physical properties. See p. 11–37. Copper-steel has found a wide commercial application on account of its slow rusting properties under atmospheric and similar conditions of exposure. See p. 11–37. These steels, copper, Monel metal, aluminum, and their alloys afford the engineer a wide choice of material. The selection of the most suitable metal for any particular condition will depend upon economic and structural conditions. (For the corrosion-resistant properties of specific metals, see discussion under each metal.)

Protection against Underwater Corrosion

The main factors controlling the rate of corrosion in water are dissolved oxygen, temperature, rate of motion, and the composition of the water. The chemical composition of ferrous metals, within rather wide limits, seems not to have a marked influence on the character or amount of corrosion. The high-chromium series of steels are an exception to this. With cold water the rate of corrosion is usually slow, but in hot water the corrosive action is accelerated according to the temperature, the rate being doubled for every 25 deg fahr increase in temperature.

Localized corrosion or pitting is usually much deeper near mill scale, especially where the scale is thick and firmly adherent, undoubtedly owing to the electronegative character of the scale with respect to the iron. Old rust acts somewhat similarly but is less harmful. Removal of the mill scale and rust greatly reduces the tendency to pitting, provided the metal itself is fairly homogeneous and free from strains. Surface finish is a greater controlling factor in corrosion than is the variation in the composition of the metal itself.

Within certain limits, corrosion varies directly with the temperature and the rate of flow and also with the composition of the water. Corrosion is likely to be more rapid on unprotected metal with increasing velocity of the water. The amount of corrosion is almost directly proportional to the amount of oxygen in solution in the water. Hot water heating systems show practically no corrosion after 35 or 40 years of use, whereas hot water supply systems, operating at the same temperatures, have deteriorated in from 6 to 8 years. The only difference between the two is that the heating system carries no oxygen whereas the water in the supply system is usually saturated with it.

In some cases it is more economical to prevent internal corrosion by removing dissolved oxygen from the water, especially hot water. Oxygen removal may be accomplished: (1) By mechanical deaeration, for which two or three satisfactory designs of apparatus are in use. (2) By the chemical combination of the oxygen with some material such as scrap and sheet iron. The two methods may be combined by using mechanical deaeration to remove the major portion of the oxygen and chemical treatment for the residual oxygen.

It is now generally recognized that no one metal will meet all requirements of service. Ordinary brass pipe (70 Cu, 30 Zn) is adequate where the water is fairly pure and almost free from chlorides; red brass (85 Cu, 15 Zn) is much more durable where the water carries considerable amounts of soluble salts and is less likely to suffer dezincification. This grade is preferable for sea water. Copper pipe is usually more durable than brass for practically all domestic water service.

Protection against Undersoil Corrosion

Soil Corrosion is highly localized and usually is caused by electrochemical action resulting from variations in the soil and solutions therein. Low alloy steels, e.g., steels with less than 10 per cent chromium, do not show enough advantage under severe soil corrosion to warrant their use from an economic standpoint, and solution of the problem of longer life of underground pipe is practically limited to a selection of suitable protective coatings.

Soil corrosion varies considerably from point to point on pipe lines. On long lines serious damage is confined to 5 per cent or less of the line as a rule. (See W. T. Smith, Economy in Wider Use of Protective Coatings on Pipes, *Eng. News-Rec.*, April 21, 1932.) It is therefore advantageous to survey the soil of the territory through which the pipe line will run, before deciding upon the type of protective coating, if any, to be used. Much progress has been made in the study of soil factors at the U. S. Bureau of Standards, so that a careful survey, judiciously interpreted, with regard to all the factors involved, should give an approximate idea as to the corrosivity of the soil. (See U. S. Bureau of Standards Research Papers Nos. 95, 298, 329, 359, 363, and 638.) This, with experience on pipe lines situated in similar soils, affords a fairly sound basis for selecting the most economical coating for a particular location.

Bituminous Coatings have been mostly used for underground protection up to now. These consist of the well-known coal-tar and asphalt dip coatings, preferably applied, after removing all grease, dirt, and loose mill scale, by vertically dipping the pipe in a bituminous bath at about 350 deg fahr. The melting point of the asphalt mixture can be varied between 140 and 190 deg fahr to suit climatic conditions. Coatings of this type, properly applied at the mill, are suitable only for mild corrosive conditions, but afford good protection on the inside of water mains. Often, in wet, marshy places, or in alkaline or acid soils, more substantial protection is required. A thicker coating may be applied at the trench, but, to prevent rusting in transit, the pipe should either receive an asphalt or coal-tar dip coating, or a coating of suitable bituminous primer, applied cold at the plant before shipment. Bituminous coatings are now usually reinforced with fabric or with saturated felt wound spirally on the pipe over the dip coat. Asbestos base reinforcement is preferable. In certain soils, unless these bituminous coatings have a high melting point and are unusually rigid, they are subject to soil stress; that is, some soils have a tendency to cling to the coating and pull it away from the pipe when the soil shrinks by drying, or irregular pressure in the trench may distort the bitumen and cause thin spots in the coating. In such soils a shielding material should be used to prevent damage to the coating by soil stress. Experience shows that many bituminous coatings that would otherwise have afforded adequate protection have been destroyed or rendered ineffective in this way. Thin, stiff, rolled-steel sheet (26 gage) or copper foil may be used as a shield. Other materials are being tried for this purpose. Asphalt mastics consisting of 30 per cent bitumen and 70 per cent of a graded sand have been used with good results, especially for protection of pipe conveying hot oil through very corrosive soils. These mixtures are applied about $^3/_8$ in. thick, but are too expensive for ordinary use.

In soils where the electrical conductivity is high and fairly uniform, as in New Orleans, it has been found practicable to maintain the coated pipe lines at a lower potential than the soil by imposing a current on the pipe to prevent the destruction of the coating wherever it happens to be broken.

Portland Cement Concrete has been used for about 40 years for protecting pipe in highly corrosive soil. It has a record as one of the most practical means of affording permanent protection. The minimum thickness is usually about 1 in., the mixture being applied in a wooden box, or more recently, a portable steel form, surrounding the pipe. Concrete coatings offer some resistance to stray electric currents but should not be relied upon to protect pipe against electrolysis. Where pipe lines pass under electric railways, or in situations where complete electrical insulation is necessary, the line has been effectively protected by boxing and coating with hot asphalt with a minimum thickness of about 1 in. for a distance of 100 ft on each side of the track.

Electrolysis is caused by current leaving the pipe directly to the ground when the potential of the pipe or other underground steel structure is higher than the earth. Two primary factors of electrolysis mitigation are: (1) The reduction of the flow of current through the earth and the metallic structures buried in the earth. (2) The reduction of the anodic portions of such structures to a minimum, where the current is not substantially eliminated, in order to reduce the area of destructive corrosion as far as possible. Damage from this cause may be lessened so far as underground pipe is concerned by: (1) Use of insulated joints to prevent the current entering or flowing on the pipe line. (2) Use of insulating coatings. (3) Reversal or neutralization of the polarity of pipe by bonding the structures to a negative bus-bar to secure suitable electrical drainage, insuring that the potential of the metal is lower than that of the ground. A discussion of the details of this problem will be found in Corrosion—Causes and Prevention, by F. N. Speller, Chapter XV, and in the Report of the American Committee of Electrolysis, 1921, A.I.E.E.

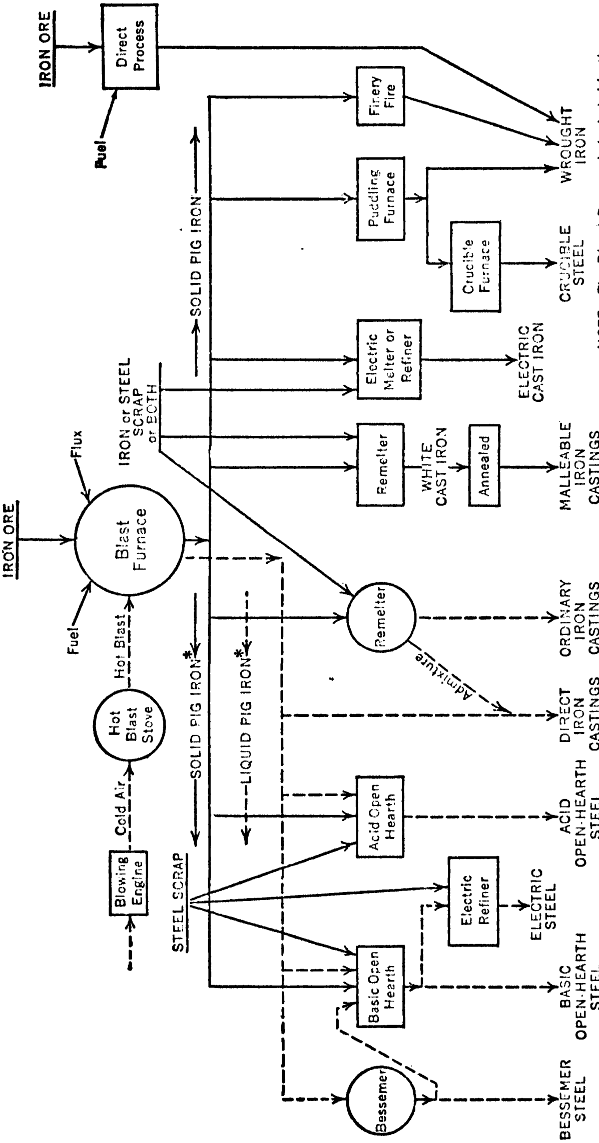
For the protection of cast-iron and lead pipe, use the methods recommended for steel except that Portland cement or lime should not be used in contact with lead. Drainage of the trench should be provided where practicable by filling in around the pipe with sand or laying it on broken stone or gravel. This is particularly recommended where the soil carries irregular patches of soluble salts (alkali) that tend to set up local differences of concentration, tending to cause pitting.

IRON AND STEEL

By Bradley Stoughton

5. METHODS OF MANUFACTURE

"Iron and Steel." The term "iron and steel" embraces a series of industrial alloys of iron and carbon, extending from 99.9 per cent iron and zero carbon, to 94 per cent iron and 5 per cent carbon, with traces of other elements, and sometimes other alloying metals, such as manganese, nickel, tungsten, etc., when the iron may fall to 65 per cent.



NOTE:- The Direct Process is included in the summary on account of its antiquity, although it is no longer of industrial importance.

*Open hearth furnaces sometimes use Solid Pig Iron and sometimes Liquid Pig Iron.

Fig. 1

Iron is a chemical element, and excepting aluminum, is the commonest metal in the earth's crust. The magnetism of the earth is explained on the supposition that it is essentially an iron ball. On the exterior, or crust, iron rarely occurs in metallic form, but usually is combined with oxygen. The rare deposits of unoxidized metal are supposed to be the remains of meteorites.

Steel is iron containing less than 1.7 per cent carbon. It is produced in a fluid state by either the open-hearth, Bessemer, electric, crucible, or duplex process. It is distinguished from cast iron by containing less carbon; from wrought iron by being produced in a fluid condition, and therefore free from slag, except for rare traces of less than 0.10 per cent.

Manufacture of Iron and Steel. Iron ore is mined from the earth and smelted in blast furnaces to produce pig iron. Pig iron is an impure product, weak as to tensile strength, and non-malleable. It is easily melted and may be cast into a great variety of useful forms. A somewhat malleable casting may be made by annealing a specific variety of iron casting in oxides (see Malleable Castings). However, if a malleable product of high tensile strength is desired, the pig iron must be refined and purified. This is accomplished by oxidizing the carbon and other impurities out of the pig iron, in a basic or acid open-hearth, a Bessemer, an electric, or a puddling furnace, the iron being charged to the furnace either in liquid or solid form. This converts it into a metal which can be rolled or forged, and which has toughness, strength, ductility, and other qualities lacking in pig iron or cast iron. This metal is called steel, except only the product of the puddling furnace, which is called wrought iron. Wrought iron is sometimes cut up into bars, remelted in crucibles, and used as "crucible steel." These, in brief, are the processes whereby practically all iron and steel of commerce are made. Fig. 1 is a skeleton outline, for easy reference.

6. PIG IRON

Pig Iron is the product of the iron blast furnace. It contains 2 1/2 to 5 per cent of carbon, 94 per cent and over of iron, and small amounts of silicon, sulfur, phosphorus, and manganese. Table I gives the analyses of various grades of pig iron.

Table I. Analyses of Pig Irons or Cast Irons

Figures in bold-faced type indicate essential constituents; figures in light-faced type are approximately correct, but are not the determining factor for the grade in question.

Trade Name	Total C, per cent	Si, per cent	S, per cent	P, per cent	Mn, per cent
No. 1 soft	3.00 ±	**2.75 to 3.25**	**0.05 and under**	0.30 to 1.50	0.10 to 1.00
No. 1 foundry	3.25 ±	**2.25 to 2.75**	**0.05 and under**	0.30 to 1.50	0.10 to 1.00
No. 2 foundry	3.50 ±	**1.75 to 2.25**	**0.06 and under**	0.30 to 1.50	0.10 to 1.00
No. 3 foundry	3.75 ±	**1.25 to 1.75**	**0.065 and under**	0.30 to 1.50	0.10 to 1.00
Gray forge	3.50 ±	**0.75 to 1.75**	**0.07 and under**	Under 1.00	0.10 to 1.00
Standard acid Bessemer pig	3.50 to 4.00	**1.00 to 1.50**	**Under 0.08**	**Under 0.09**	0.20 to 1.00
Basic pig	3.50 to 4.00	**Under 1.25**	Under 0.08	0.10 to 1.50	**1.50 to 2.00**
Malleable Bessemer	3.50 ±	0.75 to 2.00	Under 0.07	Under 0.20	0.50 ±
Ferrosilicon *	0.50 to 2.00	**10.00 to 50.00**	Under 0.04	Under 0.10	0.20 ±
Silicospiegel	1.00 ±	**5.00 to 15.00**	Under 0.02	Under 0.10	**15.00 to 25.00**
Ferromanganese	6.00 to 7.00	0.50 to 1.00	Under 0.03	....	**40.00 to 80.00**
Ferrophosphorus	1.00 ±	1.50 ±	Under 0.05	**10.00 to 25.00**	
Spiegeleisen	4.50 to 6.00	1.00 ±	Under 0.04	....	**15.00 to 35.00**

* Ferrosilicon of 10 per cent grade, ferromanganese, silicospiegel, and spiegeleisen are made in blast furnaces, by variations of the usual practice and by using special ores. Ferrosilicon of 20 to 50 per cent grades, and several other so-called *ferroalloys*, are made in electric furnaces. These include ferrochrome, ferrotungsten, ferromolybdenum, ferrotitanium, ferrovanadium, etc. They are all practically pig irons with large amounts of the alloying metal. When these alloys are free from [illegible] they are made by the thermit and other processes.

Chemistry of Pig-iron Manufacture. Iron ore may be considered simply as oxide of iron, Fe_2O_3 or Fe_3O_4, mixed with a small amount of gangue, usually silica. When heated in contact with carbon and reducing gases the ore loses oxygen and is reduced to a spongy form of metallic iron. If this is heated in contact with carbon, it dissolves the latter to the extent of 1 or 2 per cent. Finally, if it be melted, it dissolves carbon up to 4 or 5 per cent, in direct ratio to the temperature attained; it will also dissolve, at the same time, any reduced silicon, manganese, or phosphorus, and any iron sulfide available.

The gangue requires some flux with which it may unite, in order that it may become fusible at the temperature of the blast furnace. The actual manufacturing unit is a brick lined steel shell roughly 30 ft outside diameter and 150 ft to top of charging apparatus. The other essential features are: 3 or 4 hot blast stoves roughly 110 ft high by 22 ft diameter; blowing engines of sufficient capacity to compress 60,000 to 75,000 cu ft of atmospheric air per minute to 30 lb per sq in. pressure; mechanical devices for handling, etc. The necessary heat is obtained by burning fuel (usually coke) with red hot air blown into the furnace through tuyères which are situated around its circumference a few feet from the bottom.

These data are summarized in the diagram, Fig. 2,* which is a skeleton outline of a section through the furnace stack, showing the temperatures and the chemical reactions normally occurring at each level. The stack is filled with a bed of solid fuel, extending from the bottom to the widest portion, located about 22 ft from the bottom. This lowest portion is the smelting zone; its temperature is from 2500 to 3000 deg fahr; only the fuel can remain unmelted in this zone. The temperature there is produced by burning the fuel with the air driven in through the tuyères, whose location is indicated. Above the smelting zone are alternate layers of ore and fuel, with which the flux, consisting of limestone, is mixed. As the iron is melted it trickles down through the smelting zone, dissolving carbon from the coke, all the phosphorus which has entered the furnace with the raw materials, all the manganese and silicon which have been reduced by carbon and heat, and also all the sulfur which has not been converted to CaS. In practice, as a rule, the hotter the smelting zone, the more silicon will be reduced and the more CaS will be formed; therefore a " hot " iron is usually relatively high in silicon and low in sulfur.

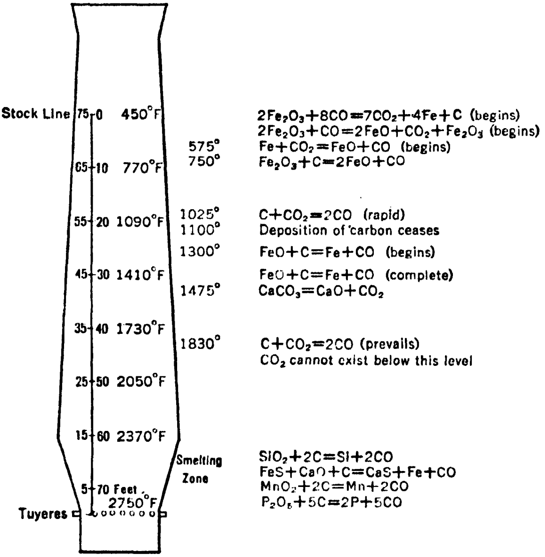


Fig. 2

At the top of the smelting zone the gangue and flux dissolve in each other, thus forming a fusible " slag " or " cinder," which trickles down, dissolving ash of the burned fuel, and any CaS that may be present, and floats in a liquid layer on top of the melted pig iron in the hearth. It is drawn off at intervals through a " slag hole " in the side of the hearth. The pig iron collects in the hearth in the interstices between the fuel, and is " tapped " about 4 to 6 times in 24 hours, through a tap hole in the front of the hearth, at its lowest level. From 125 to 200 tons of pig iron are obtained from a modern furnace at each tap.

Foundry Pig Iron. Pig iron intended for foundry uses is made with an abundance of fuel and flux (e.g., limestone); therefore the temperature of the smelting zone is hot and the slag is rich in lime. The high temperature tends to produce iron with high silicon content, and the high temperature and limey slag both tend to give iron low in sulfur. The amount of phosphorus will depend on the amount that goes into the furnace with the ores, and the same is true to a large extent of manganese, except that a slag rich in silica will tend to absorb some manganese away from the iron.

Charcoal Pig Iron. This is pig iron made in blast furnaces using charcoal for fuel. The furnaces must be small, because the strength of charcoal is not sufficient to bear the weight of many layers of material above the fuel bed. The smelting practice differs in the very important respect that elimination of sulfur is not the controlling factor. Charcoal contains only 0.05 per cent of sulfur, as compared with 1 per cent of sulfur in coke. This permits operation with a much colder furnace and an acid slag, thus getting low sulfur and low silicon at the same time. Some charcoal furnaces are run with cold blast, producing "cold-blast charcoal iron." Low-silicon iron is often wanted for chilling purposes; if made in a coke furnace, it is likely to run somewhat high in sulfur, which injures its strength. Therefore, charcoal iron is often preferred for chilled railroad car wheels, for chilled iron rolls, etc. It brings a price about 25 per cent higher than coke iron, and it costs more to make, under like conditions of supply. Some attribute the higher reputation of charcoal iron to tradition only; others, to the presence of strengthening oxide of iron;* still others, to differences in practice.

---

* From: Stoughton, The Metallurgy of Iron and Steel, Fourth Edition, 1934, p. 89.

Acid Pig Iron is a trade name given to iron suitable for the acid steel-making processes, that is, the Bessemer (only the acid Bessemer process is employed in America) and the acid open-hearth processes. It must be low in phosphorus, because the acid steel-making processes cannot purge metal of phosphorus, and steel must contain less than 0.10 per cent phosphorus or it is likely to be exceedingly brittle.

Basic Pig Iron is the trade name given to pig iron containing too much phosphorus for the acid steel-making processes, and not enough silicon for foundry pig iron. It may carry a little sulfur also, as the basic steel-making processes will remove some sulfur, and also remove as much phosphorus as commercial considerations indicate. Basic pig iron also commonly contains from 1.75 to 2 per cent of manganese, because this assists in the operation.

Forge Pig Iron is pig iron suitable for refining in the puddling furnace.

Electric Pig Iron is pig iron made from ore in electric furnaces.

"Synthetic" Pig Iron is pig iron made from melted scrap by dissolving in it the desired proportions of carbon, silicon, etc.

Manufacture of Ferroalloys. Ferrosilicon of 10 per cent grade, silicospiegel, ferromanganese, and ferrophosphorus are made in the blast furnace, by adopting variations of the usual pig-iron practice, and by using special ores. Ferrosilicon of 20 to 50 per cent grade, ferrochrome, ferrotitanium, ferrotungsten, ferrovanadium, etc., are made in electric furnaces of special types. These same alloys, free from carbon, are made by the thermit and other processes.

Direct Iron Castings. By this is meant castings poured from liquid pig iron direct from a blast furnace. This practice has been in vogue for years for making ingot molds for use in steel works, and for other purposes. It requires a regular and uniform operation of the blast furnace, so that the iron may be suitable at all times. The normal blast-furnace operation produces cast iron which varies greatly in quality. Direct casting also requires supervision by one whose eye is trained to distinguish the quality of the iron, and determine approximately the percentages of silicon and sulfur therein, by its appearance as it runs from the furnace. An important American manufacturer of automobiles makes engine castings by partly filling a ladle with pig iron at the blast furnace, and then adding iron melted in a nearby cupola. The cupola metal is adjusted to correct or modify the metal coming from the blast furnace.

7. CAST IRON

Ordinarily, pig iron is not a finished industrial product. (See Direct Iron Castings above for exception.) It is converted into iron castings by mixing various grades of iron, to obtain the desired quality, analysis, and properties. This mixture is then melted and cast into the desired form, ready for immediate use, or for machining. In its restricted sense, cast iron is the form assumed after pig iron has been again melted and cast into its finished form.

The Cupola is the usual means for remelting pig iron to produce cast iron in its more restricted sense, namely, the finished castings. It consists of a cylindrical shaft provided with one or two rows of tuyères near the base, through which air is forced at a pressure of about $^1/_2$ lb per sq in. The charge consists of pig iron and coke in the proportion of about 200 lb of coke for each ton of metal. A little limestone is usually also introduced as a flux. The molten metal drawn off at the bottom is poured into the molds by means of cup-shaped ladles fitted with long handles, one of which has a cross bar for tipping the ladle in pouring, or, for larger work, by means of ladles carried on wheels or by cranes and tipped by gears.

Mixing Iron for Foundry Cupolas. Almost all foundry mixtures are made up of new iron with varying proportions of cheaper metal, such as the "return scrap" from the foundry, cast-iron or steel scrap purchased outside, etc. The uncertainty of analysis of outside scrap, and the circumstance that it has undergone at least once the chemical changes due to melting, is the chief bar to its use in greater proportions. From 10 to 90 per cent of iron scrap is commonly used in foundry cupolas, depending upon market prices and the grade of iron to be made. Perhaps 25 per cent of scrap will approximate the average proportion used in America. The proportion of steel scrap will depend on the grade of iron to be made. The more the steel, the closer the grain of the castings made, and the greater the strength. The analysis of steel may be taken as about 0.15 per cent Si, 0.08 per cent S, 0.08 per cent P, and negligible proportions of other elements. Scrap from alloy steels, such as nickel, manganese, chromium, etc., should be avoided. In cupola melting, the sulfur content of the metal will increase from 0.025 to 0.065 per cent, depending upon the proportion of coke used in the charges and the percentage of sulfur in the coke; that is, a mixture estimated to contain 0.030 per cent S may contain after melting from 0.055 to 0.095 per cent. On the other hand, the silicon in the mixture will decrease by from 0.25 to 0.40 per cent during melting, so that a mixture estimated to contain 2.25 per cent Si will have only 2.00 to 1.85 per cent after melting. The better the practice, the less will be the silicon loss.

---

* See p. 481 of J. E. Johnson's The Principles, Operation, and Products of the Blast Furnace.

Mixing is customarily regulated by the silicon and sulfur desired in the castings. From the analyses of the pig iron available for use (see Table 1), from the estimated analysis of the scrap, and from known experience of the increase of sulfur and loss of silicon during melting (which each foundry must determine for itself), the charges are made up to produce the desired result.

Addition of Ferrosilicon in the Ladle. The silicon content of the castings may be increased by adding some 50 per cent ferrosilicon to the metal in the ladle, which must have a slight excess of heat to melt the ferrosilicon. The full amount of silicon thus added will not necessarily be found in the castings, as some is oxidized by the oxygen of the air and some by the oxide in the metal.

Addition of Soda Ash in the Ladle. Beginning about 1929, iron foundries began the use of soda ash in the ladle of melted iron. By means of this flux the sulfur may be reduced as much as from 0.10 to 0.05 per cent in the cast iron.

Addition of Calcium Silicide in the Ladle. A commercial alloy of calcium and silicon may be used instead of ferrosilicon. It is said that the calcium will carry away some sulfur and oxygen while the silicon will help to remove oxygen and then increase the silicon in the metal. The vendors furnish the analysis of the alloy.

Air Furnace Melting. Castings very low in sulfur cannot be made from cast iron melted in cupolas, and the analysis also is likely to vary from hour to hour. Cast iron of the most delicate specifications, therefore, customarily is melted in a so-called air furnace which is similar to a puddling furnace. This is especially true of iron for chilling purposes, which must be closely limited in composition, and of iron for making malleable-iron castings. Also, for a very large casting, required to be of exactly the same chemical composition throughout, the metal is melted in the air furnace, and all tapped out at one time, instead of in a thin and continuous stream of some hours' duration, as from the cupola.

Innovations in Furnaces. Better control of the cupola operation has done much to prolong its activity in foundry practice, but it is not, at best, a perfect melting instrument. Its chief claim to usefulness is its low cost of installation and operation. Only in those rare cases when it is operated with judgment and skill does it perform satisfactorily as to temperature, uniformity of composition of product, and control. As a means of producing the new type of cast iron with very high strength, and of producing alloy cast irons, it is only partially and occasionally successful. One method of meeting this situation has been by supplanting the cupola with an electrically heated " forehearth " into which the cupola metal is tapped, and in which the metal is heated to the desired temperature for casting. Desulfurizing with soda ash, or a similar flux, is also sometimes practised in the forehearth. Many foundries have abandoned the cupola for making the best quality of cast iron and do all this work in electric furnaces, of which the Detroit rocking furnace is one of the commonest installations. Superheating cast iron just previous to casting into molds seems to produce a greater number of small and widely disseminated particles of graphite which give the metal 50 to 100 per cent greater strength than the same metal having the graphite in the usual type of flakes. It is thought that this result is brought about by the graphite precipitating in the freezing mass on a large number of nuclei. It is claimed by the Detroit Furnace Co. that the agitation given to the iron in the rocking furnace has the effect of still further increasing the number of nuclei for precipitation. The electric furnace, or the electric forehearth, seems to be almost essential for the manufacture of alloy cast irons, which are non-uniform in composition if the alloying metal or metals are added in the cupola, and are chilled too much if they are added in the ladle.

Definitions Relating to Cast Iron. *Fracture.* A freshly broken surface.

Gray Iron. Pig iron or cast iron whose fracture has a gray color due to precipitated carbon, e.g., graphite.

White Iron. Pig iron or cast iron whose fracture is white.

Mottled Iron. Pig iron or cast iron whose fracture is white with gray spots, or gray with white spots.

Chilled Iron. Pig iron or cast iron which would be gray if slowly cooled, but which has been rapidly cooled, so that the chilled surfaces are white and the interior and other surfaces are gray in color. The white surfaces are very hard, and resist wear and abrasion; the gray parts are relatively tough, and soft so that they may be machined, if desired.

"*Black-Heart*" *Iron.* Malleable cast iron whose fracture had a very dark gray, or black, color in the center, due to precipitated carbon in particles of very small size. The outer rim may be white in color, owing to removal of carbon in the annealing process.

Effect of Carbon on Cast Iron. The amount of carbon in cast iron is largely dependent on the presence of other elements. While 4 per cent is the ordinary maximum, the carbon may run as high as 7 per cent if much manganese is present. The presence of silicon in large proportions, on the other hand, may reduce the solubility of the carbon to as low as 1 per cent. The percentage of carbon present in cast iron in the combined form influences very largely the physical properties of the cast iron; thus, to get the maximum tensile strength, the combined carbon should be about 0.47 per cent; for the maximum transverse strength it should be about 0.70 per cent; and for the maximum crushing strength it should be above 1 per cent. The hardness of cast iron increases regularly with the increase in the percentage of combined carbon. In gray iron the carbon exists almost wholly as graphite, having been precipitated as such in the process of solidifying. The graphite, known as "kish," gives the iron a somewhat spongy nature and a dark color. The condition is brought about in part by slow cooling, which tends to produce large crystals as well as graphite carbon. In white iron the carbon is almost wholly combined and the iron has a more homogeneous texture and lighter appearance, and is composed of smaller crystals. Rapid cooling in solidifying tends to produce white iron. In mottled iron the proportions of combined and graphite iron are nearly equal, the fracture having, as the name indicates, a mottled appearance, due to the dark gray portions in the white matrix. Graphite decreases strength, increases porosity, and increases permeability to gases or liquids under pressure, but too much lowering of graphite means increasing the combined carbon to the point where strength is lowered and brittleness becomes dangerous.

Effect of Silicon on Cast Iron. A few tenths of 1 per cent of silicon has a direct effect of its own in increasing the strength and density of iron, but usually there must be from 0.75 to 2.50 per cent of silicon in iron castings, not for its direct effect, but for its effect on promoting the presence of graphite. Without this amount of silicon most of the carbon in the cast iron would be in the combined form. The rôle of silicon, therefore, is that of a graphite-producer. But, after the silicon exceeds about 3.0 to 3.5 per cent, its effect in promoting graphite seems to decrease, and cast iron with 4 or 5 per cent of silicon is nearer white again.

Effect of Sulfur on Cast Iron. The action of sulfur on the carbon is almost exactly opposite to that of silicon, but some 15 times as powerful, so that 0.01 per cent of sulfur will counteract the graphite-producing effect of 0.15 per cent of silicon. Sulfur also has a bad effect on cast iron in that it increases "dirtiness," segregation, and liability to "checking" in cooling. It also causes "red shortness," i.e., brittleness when in a heated condition. If possible the sulfur content should be below 0.05 per cent. Sulfur comes from the fuel and increases in the cast iron every time it is melted. The necessary use of scrap tends to build up sulfur in castings, and cast iron of second quality often contains above 0.10 per cent of sulfur. This means that more silicon must be used to keep combined carbon down and promote graphite formation.

Effect of Phosphorus on Cast Iron. The effect of phosphorus is to increase the fusibility and fluidity of the metal. It also causes the iron casting to retain for some time the pasty stage during solidification. This has the effect of decreasing density, bringing the graphite out in relatively large flakes, and of decreasing shrinkage by increasing the expansion during solidification. It is therefore used up to 1.5 per cent in castings which need to be very fluid when poured, as for example in ornamental castings where well-defined impressions are wanted. Phosphorus also tends to increase the brittleness of the iron.

Effect of Manganese on Cast Iron. Manganese must always be present in cast iron to the extent of at least twice the sulfur, in order that all the sulfur shall be in the form of MnS, rather than FeS. This lessens the bad effects of sulfur. Beyond this point the manganese in excess of that present as MnS makes harder and more brittle white cast iron.

It tends to fine the grain, slightly strengthen the casting, and keep carbon in the combined form. *Spiegeleisen*, so called on account of its white, glistening fracture, is a pig iron containing a large proportion of manganese (see Table I, p. 11-13). It is very hard, resisting cutting by cast-steel tools. If the proportion of manganese rises above 20 per cent, reaching sometimes as high as 80 per cent, it is known as *ferromanganese*.

Shrinkage of Cast Iron During Cooling. In cooling, white cast iron and steel shrink about twice as much as gray cast iron. Gray cast iron shrinks the same as the others in one respect, but its shrinkage is counteracted by an expansion which occurs because of the separation of graphite. Thus, during the solidification period, graphite separates and makes room for itself by pushing the crystals of metal apart. A decided expansion of gray iron castings is therefore noted during freezing. Subsequently the iron contracts, but, on cooling to the line *PSK* (Fig. 3), more graphite separates, and temporarily the contraction is much lessened. On this account, pattern-makers are accustomed to allow a shrinkage of $^1/_8$ in. per ft for gray cast iron, and $^1/_4$ in. per ft for white cast iron and steel.

" Chilling " Cast Iron. Cast iron rapidly cooled will retain the carbon in solution, unless the silicon be too high. This gives white cast iron instead of gray cast iron. Advantage is taken of this by using metal molds, thus producing a sudden cooling of the hot metal as it comes in contact with the comparatively cold surface of the mold. Such castings will have a white surface and gray interior. The less brittle interior protects the casting from breaking under shock, which it would do if it were white throughout, while the hardness of the surface resists wear. In this way is obtained a chilled tread on railroad freight-car wheels, to resist the wear against the rails, with a less brittle flange to resist the shocks of service. Likewise, a chilled surface on crushing rolls, with a less brittle interior, is obtained. The silicon must be high enough to give gray iron in the part which is cooled slowly through the range of solidification (freezing), but not high enough to cause the formation of graphite in the chilled surfaces.

" Growth " of Cast Iron. Cast iron subjected to long-continued temperatures of 500 deg fahr or above tends to separate out graphite. This causes an expansion of the casting, and, if repeated many times, will deform and ruin it. This becomes serious when using cast-iron fittings for superheated steam, which is often above 500 deg fahr. Any influence in the iron, such as the presence of silicon, which tends to cause graphite precipitation, will increase the difficulty; steel, and white cast iron low in silicon, which do not easily precipitate graphite, are relatively free from it.

Properties of Cast Iron. The strength of cast iron depends chiefly on the strength of the metallic matrix of the iron and the resistance which the metal part opposes to strain. If the graphite flakes are almost continuous, fracture will occur by splitting apart the graphite sheets; on the other hand, if the matrix structure is so built as to oppose strain with the maximum proportion of metallic part of the iron, and if the metallic portion is strong by virtue of containing 0.85 per cent of combined carbon, then high strength is obtained. On the basis of this reasoning, there was first developed in Germany a so-called " pearlitic cast iron " (pearlite is that structure in steel consisting of all small crystals of Fe_3C and containing 0.85 per cent of carbon). In this and other " high-strength " cast irons, ease of fracture through graphite flakes was lessened by:

1. Reducing the amount of total carbon in the iron.

2. Reducing the size of the graphite flakes by increasing their number. This is done chiefly by superheating the iron before casting. This apparently results in the graphite precipitating during freezing, and later, around a large number of isolated nuclei, instead of a few widely separated nuclei upon which the flakes continue to grow. The superheating may be done in a cupola, or, better, in an electric furnace. It is said that agitating the iron before casting further increases the number of nuclei.

3. Distributing the graphite as uniformly as possible.

By these methods there has been developed a " high-strength carbon cast iron," which has a tensile strength of 35,000 to 55,000 lb per sq in., as compared with a previous maximum of about 30,000 lb. This cast iron also has a slight ductility as measured by the elongation before rupture.

Table IV, p. 11-25, gives some of the properties of gray cast iron and high-strength cast iron.

Alloy Cast Iron. The same result in a more intense degree has been achieved by adding nickel up to 1.50 per cent and chromium up to 0.50 per cent or else molybdenum from 0.50 to 1.50 per cent. By these alloying elements cast iron having uniformly tensile strengths of 70,000 lb per sq in. can be made. The chief objections to them is not the cost of the alloy additions, but the difficulty of using a cupola for melting them (unless an electric " forehearth " receives the cupola metal and superheats it when the alloying elements are added), and the presence of the alloying metals in the " return scrap."

Non-magnetic Cast Iron. By adding at least 7 per cent of manganese, or 20 per cent of nickel, or a corresponding amount of some other alloying element, or elements, a cast iron may be produced which is a solid solution at atmospheric temperature. It is sometimes called "austenitic cast iron," because austenite is the name given to the solid solution of iron and carbon. It is approximately as non-magnetic as copper, and is used for parts of electrical machinery.

Heat-treated Cast Iron. Cast iron is heat-treated to make it soft even when the combined carbon is as high as 0.85 per cent. For this purpose it is best to use a long anneal at a low temperature (in the neighborhood of 500 deg fahr), or it may be much lessened in strength. On the other hand, it may be cooled with moderate rapidity from a yellow heat, in order to make the grains of the metallic part very small, or it may even be quenched (if the shape permits) to make it hard.

Malleable Cast Iron. For many years, cast iron with small, isolated graphite flakes has been manufactured by the so-called malleable cast-iron process. In this process, iron castings, usually thin, are first cooled so as to produce white cast iron with the carbon all in combination. This white iron is hard, not easily worked, and brittle. The castings are then heated to about 1650 deg fahr and " soaked " there for several hours, or even for several days, and then cooled slowly. By this operation the combined carbon is reduced almost to zero, and the graphite is precipitated from Fe_3C as small flakes of what is called " temper carbon." This is the fundamental mechanism of the process, but it may be further refined by packing the white castings in iron oxide, so that the carbon when it is precipitated from Fe_3C is oxidized to CO and separates from the metal, reducing the total carbon from perhaps 3.50 per cent to perhaps 2.50 per cent. On the skin of the castings the carbon may be almost completely removed, leaving tiny holes or pores in the metal. The castings have a tensile strength of at least 50,000 lb per sq in. and an elongation of at least 10 per cent in 2 in. Some of the properties of a representative cast iron are given in Table IV, p. 11–25. They are easily machined, may be deformed without rupture, will withstand heavy blows, and the skin will endure much battering without cracking.

Use of Cast Iron and Malleable Cast Iron. The improvement in the manufacture of steel castings has limited the field of commercial employment of iron and malleable-iron castings, but cast iron is still employed wherever weight or compressive strength of a casting is the controlling factor, and where as a structural part for a machine or building it does not have to withstand shock, tensile stress, or bending. Iron castings have the advantage of being capable of manufacture with simple apparatus right in the field, remote from centers of civilization. Malleable cast iron was losing some of its trade, but recent great improvements in qualities have enabled it to hold its own and even extend its field for castings of small size, where moderate tensile strength, small ductility, and slight bending are required. It has the advantage over steel of better resistance to shocks within the limit of its strength. For pipe fittings, household hardware, and many small or thin articles, it can excel steel castings in price, and give all that is necessary in service. Chilled cast iron is the cheapest very hard material that is made; for resisting wear and affording a useful amount of strength it is unexcelled, and it finds a large field in railroad freight-car wheels, rolls with hard surface, parts of crushing machinery, inserts in brake shoes, etc.

8. WROUGHT IRON

If commercial iron is mechanically mixed with a suitable amount of slag there results a malleable material called wrought iron which does not harden when suddenly cooled. It melts at a full white heat, but becomes pasty at a lower temperature, in which condition it can be readily welded. It is ductile when cold.

Process of Manufacture. Practically all wrought iron is produced from pig iron by indirect processes, although direct processes for production from the ore exist. The direct process has always proved a commercial failure, although tried in almost every conceivable manner and locality. The indirect processes may be divided into two general classes based upon the type of furnace used: (*a*) reverberatory or puddling furnaces; and (*b*) charcoal hearths. The best iron is made upon hearths, but puddling furnaces produce the larger quantity. The essential difference between the two processes is that in hearths the chief source of oxidation is atmospheric air, and the fuel is burned in contact with the iron, whereas in puddling furnaces the chief source of oxygen is magnetic oxide of iron, and the fuel is burned in a chamber separate from that containing the iron. A description of these processes follows.

Puddling. This method consists of melting pig iron in a reverberatory furnace heated either by coal or natural gas. The furnace hearth is lined with oxide of iron. The pig is exposed for about 2 hours to the continuous action of a flame hot enough to melt it but not hot enough to keep pure iron in a molten state. When purified by the iron oxide

and the oxidizing flame, the molten iron becomes less fusible and finally pasty. After reaching this condition it is puddled by being worked into balls by hand labor. It is then taken from the furnace and squeezed or hammered into blooms, and then rolled into small bars, about $^3/_4$ in. thick and from 2 to 6 in. wide, called " muck bars." After cooling, these muck bars are cut into short pieces about 2 ft in length, piled into bundles, fastened by iron wire, reheated to welding heat, and rerolled into merchant bars. If the iron is subjected to a second piling, heating, and rerolling, it is called " double refined iron."

Charcoal Hearths. The following are the more important hearth processes.

1. *Finery Process.* Charcoal fineries produce " knobbled " iron of a high degree of softness which is much used for boiler tubes.

In the finery process the pig iron is first melted down in a coke or charcoal refinery to remove the silicon, phosphorus, and sulfur, and is then transferred in a molten condition to a charcoal hearth which is still hot from its previous charge. Damp charcoal is thrown in, a low-pressure, unheated blast turned on, and the metal agitated to keep it in contact with the blast. After an hour or more the metal is collected into a ball and hammered to remove some of the slag, cut up, and reheated in piles. Gray iron may be used in this process.

2. *Walloon Process.* The Walloon process was formerly used in Sweden for producing wrought iron from Dannemora pig iron, the resulting product being shipped to England, particularly to Sheffield, for conversion into blister steel for use in fine toolmaking.

In the Walloon process long pigs are melted gradually by being pushed forward into a charcoal fire. The molten iron drops through the blast, becoming decarburized, and collects in a pasty mass at the bottom of the furnace. The partially refined iron is then raised to the top of the charcoal fire, and melted down with the addition of rich slag and hammer scale. The metal is then balled, reheated, and hammered.

3. *Lancashire Process.* The Lancashire process is used principally in Sweden, but was formerly used in the United States.

The Lancashire process somewhat resembles the Walloon process. Pig iron is melted between two layers of charcoal, the liquid dropping down through the blast and becoming oxidized. The molten metal collects in a pasty mass at the furnace bottom where it is allowed to remain for 20 or 25 minutes; it is then mixed with decarburizing slag and remelted in a similar manner. Finally the pasty mass is removed from the hearth and hammered.

4. *Aston Process.* A newer method of manufacturing wrought iron on a large scale has been developed in which refined iron is poured into molten slag. A sponge ball is formed which is compressed and worked by mechanical devices until the right consistency is obtained. The sponge ball is then formed into the usual wrought-iron shapes. The process lends itself to control of quality and more uniformity of product.

Grades. Wrought iron may be graded as follows: (1) charcoal iron, the purest grade of wrought iron; (2) puddled iron, classified according to quality into stay-bolt (grade A) and merchant iron, grades B and C; (3) busheled scrap, a heterogeneous product made from iron scrap—steel is frequently mixed with the iron scrap, causing considerable irregularity in the resulting product.

Properties. Wrought iron possesses the important qualities of toughness, ductility, malleability, and weldability, but its properties are only slightly changed by tempering.

Coefficient of expansion........	0.00000648 per deg fahr (Clarke)
Electrical conductivity........	0.16 (Cu = 1.00) (Lazare Weiler)
Melting temperature..........	2732 to 2912 deg fahr (Pouillet, Claudel, Wilson)
Specific heat.................	0.1138 g-cal per g per deg cent, Btu per lb per deg fahr (Röntgen)
Specific gravity..............	7.4 to 7.9 (Kent)

Tension. The average results of a great many tensile tests made at the Testing Laboratory of Columbia University on good wrought iron for general purposes are as follows:

Yield point, lb per sq in.................................	**31,000**
Ultimate strength, lb per sq in...........................	**51,000**
Elongation in 8 in., per cent.............................	**21**
Reduction in area, per cent...............................	**30**
Modulus of elasticity, lb per sq in.........................	**28,200,000**

Shear and Torsion. J. Platt and R. F. Hayward (*Proc. Inst. C.E.*, Vol. 90) give the following values for " crown " best wrought iron which had an ultimate tensile strength of **48,400** lb per sq in.:

Ultimate strength in single shear, lb per sq in.	**42,050**
Elastic limit in torsion, lb per sq in.	**20,530**
Modulus of elasticity in torsion, lb per sq in.	**12,800,000**

Compression. The ultimate compressive strength of good wrought iron is not well defined. Practically, its yield point in compression should be considered as the ultimate for compression. This yield point is about the same as the yield point in tension.

The strength of wrought iron is affected by its chemical composition and the mechanical work and heat treatment it has undergone, and it also varies for different temperatures. Wrought iron has a well-defined yield point in both tension and compression, which is from 2000 to 4000 lb per sq in. higher than the elastic limit. Beyond the yield point wrought iron is a plastic material which flows rapidly as the maximum strength is approached. The ultimate strength in tension increases with the amount of carbon, which, however, is rarely greater than $^1/_{10}$ of 1 per cent. The strength of iron entirely free from carbon and phosphorus is probably between 39,000 and 40,000 lb per sq in.

Effect on Wrought Iron of Its Common Ingredients. Carbon, sulfur, phosphorus, and oxygen all reduce the softness, malleability, and resistance to rusting of wrought iron. Slag is believed to protect the enveloped grains of wrought iron from rusting, but its presence increases the differences of electric potential between the microscopic particles and, to this extent, increases the rate of rusting. This is presumably the reason why wrought iron corrodes faster in acid waters than does low-carbon steel free from solid particles.

Effect of Reheating and Rerolling. Within limits, puddled iron is much improved in quantity by being cut up, piled, reheated, and rerolled or hammered. However, it is found that only in special cases is it advantageous to reheat puddled iron more than twice. The following figures (Johnson) show the effect of reheating and rerolling on the tensile strength: The original bar had a tensile strength of 43,000 lb per sq in.; after the second working this rose to 52,860 lb per sq in., and after the sixth working it became 61,820 lb per sq in.; the tensile strength then diminished with the number of workings until after the twelfth working it became the same as that of the original bar.

Effect of Work on Wrought Iron. Mechanical treatment is important for wrought iron not only to refine the grain, but also to distribute the metal and slag and produce the so-called fibrous structure characteristic of wrought iron.

9. HIGH-PURITY IRON

Iron containing less than 0.10 per cent of total impurities has been produced by two chief methods: namely, electrolysis and extensive refinement in an open-hearth furnace. Representative analyses of these products are given in Table II.

Table II. Analyses of High-purity Iron

	Armco Ingot Iron %	Electrolytic Iron %
Carbon	0.012 *	0.006 *
Manganese	0.017 *	0.000 *
Phosphorus	0.005 *	0.005 *
Sulfur	0.025 *	0.004 *
Silicon	Trace *	0.005 *
Iron (about)	99.9	99.95

* National Metals Handbook, 1933 Edition, p. 367.

Manufacture of Armco Ingot Iron. Using selected raw materials, the usual basic open-hearth process is employed, with the addition of a final period of superpurification during which additions of pure iron oxide to the slag reduce the carbon and manganese to below 0.02 per cent each. The resulting iron is heavily charged with oxide, which is reduced by the use of pig iron in the furnace and aluminum in the ladle.

Manufacture of Electrolytic Iron. Anodes are commonly ingot iron, soft steel, or pig iron. Electrolytes are usually ferrous chloride, with sometimes calcium chloride, and a trace of free acid, at a temperature of 15 to 90 deg cent, and either circulated or mechanically stirred. The cathodes are generally rotating mandrels or moving plates. The current density is variously from 12 to 75 amp per sq ft and the voltage drop about 3 to 4 volts per cell. The deposited metal is usually annealed to remove hydrogen and chlorides, which latter, if present, cause rusting. It is often vacuum melted.

Properties and Uses. See Table IV, p. 11-25, for some of the properties of electrolytic and ingot irons. High-purity iron is valued for its toughness, ductility, lessened activity in rusting, and high electrical and magnetic properties. Application of these advantages has been made in the use of Armco ingot iron for holding or transporting water, both hot and cold, as in factory and house boilers and heating systems, culverts, fumes, gutters, wire fences, welding electrodes of high ductility, etc. Attempts to make and sell iron of greater purity than Armco ingot iron have been successful technically, and commercially for a time, but have endured only in a few special cases, because the increase in usefulness as superior properties are achieved is not sufficient to command an adequate market at the higher price necessary. For some years the improved magnetic properties of iron of 99.9 per cent purity over that of only 99.80 per cent were sufficient to support the manufacture of electrolytic iron at more than double the price. Table III gives some comparative figures. But, after the introduction of permalloy and similar alloys of very high permeability, the commercial manufacture of electrolytic iron for this purpose ceased. Electrolytic iron, because of its softness, can be used in place of copper for projectile bands, etc., and was so used in Germany during the World War. It is still used for iron plates of great toughness, which are plated first with nickel and then with chromium, for printing plates in the U. S. Bureau of Engraving. At one time it was made commercially for the production of very thin-walled tubes with high heat conductivity. Ingot iron stands severe bending, and lends itself to rapid and economical fabrication. Hot working of steel can in many cases be displaced by cold working of pure iron. It constitutes an excellent base for vitreous enameling. Its electrical properties of high conductivity, high permeability, and low retentivity have made it useful in the electrical field for polepieces, magnet cores and shoes, and in the form of wire for solenoids, induction coils, telephone repeater coils, audio transformers, vibrator coils, rail bonds, and transmission lines.

Table III. Magnetic Properties of High-purity Iron

National Metals Handbook, 1933 Edition, p. 387

	Maximum Permeability	Coercive Force, oersted	Hysteresis Loss, ergs per cu cm per cycle	Residual Induction, gauss	Saturation, gauss
Iron A	180,000	0.025 †	190 †		
Iron B	9,500	0.9 *	2690 *		
Iron C	20,000	0.08 *		6000 *	22,000
Iron D ‡	61,000	0.09 *	300 *		

Iron A, hydrogen annealed ingot iron; Iron B, annealed ingot iron; Iron C, iron by the carbonyl process; Iron D, annealed vacuum fused electrolytic iron.

* For B_m 10,000.
† For B_m 14,000.

10. KINDS OF STEEL

Steel was originally produced by the action of a hot fire directly on iron ore and the addition of carbon to the iron so produced. The modern processes, however, involve the fusion of the ore. The United States law defines steel as iron which is produced by fusion by any process, and which is malleable when first produced. The technical definition is that steel is iron containing up to 1.7 per cent of carbon and not containing admixed slag. The following is a rough comparison of properties of cast iron, steel and wrought iron.

	Per Cent of Carbon	Specific Gravity	Properties
Cast iron	5 to 2	7.2	Not malleable, not temperable
Steel	1.50 to 0.02	7.8	Malleable and temperable
Wrought iron	0.15 to 0.05	7.7	Malleable, not temperable, contains slag

It should be observed that the percentage of carbon alone is not sufficient to distinguish steel from wrought iron; also, that the mean values of specific gravity stated are in each case subject to considerable variation; further, only the hard steels (carbon above 0.50 per cent) are much affected by tempering, the softer grades resembling wrought iron.

Manufacture. The three principal methods of manufacturing steel are the Bessemer process, the open-hearth process, and the electric-furnace process. A combination method known as the *duplex process* is sometimes used. In this process the refining action is started in a Bessemer converter, and after partial refining the molten steel is transferred to an open-hearth furnace, where the refining process is finished. Formerly, a method known as the crucible process was commonly used.

Bessemer Steel is made in a Bessemer furnace or converter, which is a pear-shaped vessel lined with firebrick or its equivalent, and which can be rotated on trunnions, to receive and discharge metal. It will hold from 10 to 25 tons of liquid iron in the lower end, in a bath about 20 in. deep. During the " blow," the converter stands vertically, the melted pig iron lying in a pool at the lower end. Through this pool several thousand cubic feet of unheated, atmospheric air is blown per minute. The oxygen of the air first burns away the silicon and manganese, then the carbon, and before the carbon is entirely burned away, begins to burn the iron. Spiegeleisen or ferromanganese is then added to deoxidize the metal and to give it the amount of carbon desired in the finished steel. In the ordinary or "acid" Bessemer process the lining of the converter is a silicious material. This necessitates using an acid (silicious) slag in the process, so that phosphorus cannot be removed from the charge. In the "basic," or Thomas-Gilchrist, process, the lining is of magnesium limestone, and limestone additions are made to the bath, thereby producing and maintaining a basic slag, into which phosphorus will enter if oxidized. Basic Bessemer steel is not made in the United States.

Open-hearth Steel may be made from either: all steel scrap, or all pig iron from which the silicon, manganese, carbon, with perhaps phosphorus and some sulfur, are removed by oxidation with iron ore. In most cases, a mixture of steel scrap with pig iron and iron ore is used as raw material. The furnace is a reverberatory furnace heated by preheated air and by the burning of preheated gas, oil (or tar), or, rarely, pulverized coal. Because of the preheated flame producer, the furnace can melt, or keep melted, the purest forms of iron. After the charge is melted and brought to the proper temperature for casting, its chemical composition is adjusted with suitable additions of carbon, manganese, and silicon, together with alloying elements, such as nickel, chromium, vanadium, etc., when ordered. It is then tapped into a ladle and thence into molds. The raw steel scrap of the process is added in the solid condition, but pig iron is often added molten from a nearby blast furnace. In the Talbot modification of the process, melted blown metal from a Bessemer converter is used instead of cold steel scrap. The blown metal is chemically about the same as steel scrap. In this case the furnace is not drained of metal when tapped, but a reservoir of liquid steel is left for a foundation for a new charge of melted pig iron and melted blown metal. In the so-called Duplex process, blown metal from an acid Bessemer converter is poured into a basic-lined open-hearth furnace. In the Bessemer converter, the silicon, manganese, and carbon are oxidized out of the pig iron, after which the phosphorus, and some sulfur, are removed in the basic open-hearth furnace. The open-hearth process may be either basic or acidic, according to the character of the lining, which also determines the character of the slag utilized in the process. Phosphorus will be oxidized in either type of furnace, but only a basic slag will absorb phosphorus; therefore the basic process is the type usually employed, since raw material either high or low in phosphorus may be purified. The basic slag has the objection that it leaves more oxygen in the finished steel, with the result that basic steel may contain more dissolved oxygen and oxides (so-called "inclusions"); acid steel is often preferred, especially where service under "fatigue" conditions is anticipated.

Electric Furnace Steel is made either in an arc or resistance type of furnace. The resistance type of furnace generates a current of electricity in the steel bath either with a "primary" alternating current using an iron core in the conventional method, or with a high-frequency alternating current without a core. In either case, the liquid metal is heated by virtue of the resistance of the metal to the passage of the current induced in it. The greatest tonnage of steel is made in the arc type of furnace, but the high-frequency induction type makes much of the alloy steel. Some large steel-making furnaces are of the cored induction type.

Electric-arc Furnace. The operation and design of the electric arc furnaces are similar to those of fuel-fired furnaces, except that the arc, instead of a flame, heats the charge. One great advantage of electric heat is that, since the charge is out of contact with products of combustion, the furnace atmosphere may be neutral or reducing, if desired, whereas the atmosphere of a combustion furnace is always oxidizing. Heat from an electric arc can be used more economically at very high temperatures, e.g., the refining stages of steel production, than at low temperatures. The electric arc furnace is therefore sometimes used for "super-refining," that is, for the final stages of desulfurization and deoxidation of liquid steel from a basic open-hearth furnace.

The High-frequency Electric Furnace consists of a crucible in sizes from 600 lb to 5 tons each, in whose contents is induced a "secondary" current by a primary current of relatively high frequency traversing a coil encircling the crucible. This has all the advantages of the old crucible process and two advantages in addition: It may be made in sizes larger than the 100-lb maximum of the crucible process, and the "motor effect" produced by the current gives to the bath a stirring action which is almost invaluable in steel manufacture. This type of furnace is used very largely for the melting of alloy steel scrap. Stainless steel, high-speed steel, and even steel containing vanadium may be melted with loss of none, or very little, of the costly alloying elements. In Europe it is used somewhat for the refining of pig iron, giving a rapid reaction on account of the stirring action, which promotes extensive contact between metal and oxidizing slag. The electrical efficiency of this type of furnace is lower than that of the arc type, but, on the other hand, its loss of heat by radiation is less.

Crucible Steel is commonly made in pots or crucibles holding about 100 lb of metal. The raw material should be wrought iron with charcoal, or pure cast iron. Other mixtures which will produce a steel having the desired chemical composition make inferior crucible steel. Manganese in some form is usually added to remove oxides from the iron. Some silicon is usually absorbed from the crucible, and carbon also if the crucible is made of graphite and clay. The crucible being covered, the steel is not affected by the oxygen or sulfur in the flame. The quality of crucible steel depends on the freedom from objectionable elements, such as phosphorus, on the complete removal of oxide, slag, and blowholes by "dead-melting" or "killing" before pouring, and on the kind and quantity of different elements, such as carbon, manganese, chromium, tungsten, and vanadium, which are added in the mixture, or after melting, to give particular qualities to the steel. Only minor amounts of crucible steel are produced in the United States today (1936).

How to Distinguish between Acid and Basic Steel. (This does not include acid and basic electric steel.) Acid open-hearth or Bessemer steel may be distinguished from basic steel by being lower in manganese, sonims, and oxygen, but higher in silicon, phosphorus, and sulfur. It also dissolves more slowly in dilute sulfuric and hydrochloric acids. Comparisons should be made by experts, because the exact figures will depend on the country of manufacture and the purpose for which the steel is supplied.

How to Distinguish between Basic Open-hearth and Acid Bessemer Steel. Basic open-hearth steel has lower manganese, silicon, phosphorus, and sulfur and higher sonims and oxygen than acid Bessemer steel. It dissolves more rapidly in dilute acids. For the same tensile strength the ductility of basic open-hearth steel will exceed that of Bessemer steel, except sometimes in castings.

How to Distinguish between Acid Open-hearth and Bessemer Steel. Acid open-hearth steel will have fewer sonims, less oxygen and manganese than acid or basic Bessemer steel, and less phosphorus than acid Bessemer steel.

How to Identify Electric Steel. Electric steel may easily be distinguished from open-hearth and Bessemer steels. It has fewer sonims, manganese is under 0.40 per cent, usually less sulfur (e.g., under 0.03 per cent); it has higher elongation and reduction of area for the same tensile strength than any steel except crucible, and it dissolves much more slowly in dilute sulfuric and hydrochloric acid than basic open-hearth steel, which alone equals it in low phosphorus.

11. EFFECT OF COMMON INGREDIENTS ON THE PROPERTIES OF STEEL

The Properties of Steel most commonly desired are strength and ductility. Unfortunately there is more or less incompatibility between these two. That is to say, as the strength of steel increases, the ductility usually decreases; and, conversely, as the ductility increases, the strength usually decreases. Other properties of steel that are likewise of importance, either because they are desired or not desired, are hardness, ability to be machined, brittleness, electric conductivity, magnetic permeability, magnetic hysteresis, permanent magnetism, and weldability. Table IV gives some of the properties of hot-worked carbon steel. Pure iron has a tensile strength of about 40,000 lb per sq in., when in its softest condition, at which the ductility is great, being approximately equal to that of copper, and the malleability is equal to or greater than that of copper. The strength of iron is increased by the presence of several ingredients customarily accompanying it in industrial use, but the most important strengthener is carbon, because this will increase its strength with the least decrease in ductility.

Effect of Carbon. The effect of increasing percentages of carbon on the physical properties of steel can be seen from Table IV.

Effect of Manganese. Manganese increases strength and hardness, decreases the content of oxygen, and lessens the bad effect of any oxygen or sulfur left in the steel.

Effect of Phosphorus. Phosphorus increases strength, brittleness, segregation, and fluidity when molten, and greatly decreases resistance to shock. It increases crystal size with normal heating.

Effect of Sulfur. Sulfur slightly increases the strength of steel, but it also makes it dirty, oxidized, segregated, brittle under shock, and with a tendency to crack at red heat, either when cooling (as in a casting), or when being rolled or forged. Sometimes the cracks are microscopic, but nevertheless they weaken the steel. When the manganese is at least twice the sulfur, the bad effect of the latter is lessened because then the sulfur is in a compound, MnS, instead of FeS.

Table IV. Some Properties of Hot-worked Steel and of Cast Irons

Name	Approximate Per Cent Carbon	Physical Properties						Brinell Hardness

Note. The figures in this table are representative of the properties of steel in commercial shapes. Variations may be expected relative to size and shape. The values given are not suitable as a basis for purchase specifications as they are not assured minima.

* Contains less than 0.1 per cent total of carbon, manganese, sulfur, phosphorus, and silicon.

† Completion of melting.

‡ The melting point of cast iron varies greatly with its composition. It begins to melt at about the temperatures given, but is not completely melted until a temperature 200 to 300 deg fahr higher is reached.

§ Coefficient per deg fahr at 60 deg fahr.

‖ Figures supplied by manufacturer.

** Some of the strong cast irons (including alloy cast irons) have a measurable permanent elongation and reduction of area before breaking, such as a fraction of 1 per cent.

Effect of Copper. A small percentage of copper dissolves in steel and forms a solid solution. Copper increases the hardness of steel, and less than 1 per cent of copper is used to lessen the rusting or corrodibility of steel. It seems also to decrease segregation and make the grain size finer.

Effect of Silicon. Silicon increases strength and hardness and decreases ductility. The chief purpose of having silicon in steel is to increase the solvent power of the metal for gases, especially oxygen and carbon monoxide. This influence decreases the blowholes in soft steel, but increases the volume of the pipe in ingots and castings. In castings, silicon of 0.20 to 0.40 per cent is often added for strength. Silicon increases crystal size.

Iron Oxides. Oxygen occurs in steel in three forms: CO, FeO, and, perhaps, Fe_2O_3. In any form its presence is harmful, producing brittleness in both hot and cold steel, besides causing liability to blowholes. There is probably no constituent more harmful to steel than oxygen, but unfortunately no satisfactory method has as yet been found (1936) of rapidly determining small traces of this gas. The effect of oxygen is somewhat similar to that of sulfur and, in common parlance, makes the steel " rotten."

Nitrogen and Hydrogen. Both nitrogen and hydrogen occur in steel, and one of the theories to explain the superiority of electric and crucible steels is based upon the relative freedom of these materials from the two gases. The amount of nitrogen and hydrogen present is usually very small. Hydrogen dissolves very easily in iron at a high temperature but is evolved in part as the metal cools. In order to obtain entire freedom, however, it is necessary to heat and cool several times in vacuo. Nitrogen is important in connection with arc welding, when a needle-like constituent appears, which is thought to be a crystal of iron nitride.

12. METALLOGRAPHY OF IRON AND STEEL

Microscopic Constituents of Iron and Steel. Iron and steel are not simple, homogeneous substances, like glass, but, like the crystalline rocks (granite, for example), are composed of grains and crystals of different constituents. Thus, there may be, in slowly cooled iron castings: crystals of graphite, cementite, ferrite, and pearlite. The strongest simple steel made (excluding alloy steels, etc.) consists entirely of pearlite. Not only the kinds of metaral, but also the size of the crystals in which they occur has a very important effect on the qualities of the material which they compose. Thus, large crystals of graphite, etc., indicate weak and non-ductile metal. There are also other constituents which appear under the microscope, such as silicide of iron, nitride of iron, and also minute particles of slag, oxides of iron, manganese, and silicon, sulfide of iron or manganese, carbide of manganese, etc.

Ferrite is pure iron. It is soft, ductile, malleable; it can stand a great amount of cold work without annealing; it is not strong. It has a tendency to form in rather large crystals during cooling from solidification, or from a high temperature. It will not harden on rapid cooling, and can be formed of small-sized crystals if heated to a bright red heat and cooled very rapidly. This greatly increases its strength. Wrought iron is some 90 per cent ferrite crystals enveloped in slag; ingot iron is 90 per cent ferrite and over; pure iron is 100 per cent ferrite. Some ferrite often occurs in cast iron, apparently by precipitation of cementite into graphite and ferrite. This precipitation is the normal reaction of the malleable cast-iron annealing process.

Ferrite has a greater electric conductivity than any of the other metarals in iron or steel. It is about 6 times as resistant as copper. Alpha ferrite is the most magnetic substance known, having the greatest magnetic force, greatest permeability, and lowest hysteresis, when measured at high, as well as low, magnetizing forces. Alpha ferrite has a body-centered cubic space lattice. At 1400 deg fahr it becomes paramagnetic. At 1670 deg fahr it changes to a face-centered cubic space lattice and is known as gamma iron, whose most distinguishing characteristic is that it will dissolve carbon up to a limit of 1.7 per cent. At 2550 deg fahr the space lattice again becomes body-centered and the iron is often called delta iron.

Cementite is carbide of iron, Fe_3C. Its hardness is 6 to 6.5 on Moh's scale, and U on the mineralogical scale. It will scratch glass, but not quartz. It is magnetic below 400 deg fahr. It occurs in flat crystals which decrease the tensile strength of iron and steel, but increase their hardness and cutting properties. It is present in goodly quantities in white cast iron.

Graphite is a great weakener, because it occurs in flat plates, themselves made up of smaller plates, which separate under strain and allow the piece to break. The larger the crystals of graphite the less the tensile strain it will withstand. When a piece of gray cast iron is broken, only the separated flakes of graphite along which the piece has broken, and which give the fracture its gray color, are seen.

Pearlite is an aggregate made of alternate crystals of ferrite and cementite. Its chief characteristic is the minute crystal size of the components. Pearlite has about 7 parts by weight of ferrite to 1 part of cementite, and therefore contains about 0.85 per cent of carbon. Steel of this carbon is the strongest simple steel known, doubtless because of the absence of large crystals of ferrite or of cementite. The reason for the occurrence of pearlite in steel is explained on p. 11–28 and Fig. 3.

Austenite is a solid solution of ferrite and cementite in each other. It forms when the metal solidifies, and remains a solution until it cools to about 1350 deg fahr. Theoretically the solution would remain if the iron or steel were cooled instantaneously from a bright red heat to atmospheric temperature, but, in practice, this degree of rapidity is impracticable, and only a portion of the austenite is preserved by rapid cooling. But 10 per cent of manganese and above in the steel will preserve austenite to temperatures below 0 deg fahr, as will 12 to 25 per cent of nickel. Austenite is non-magnetic; it resists wear, but is not brittle.

Martensite is the chief constituent of rapidly cooled steel. It is the imperfectly preserved austenite, which cannot be cooled rapidly enough to prevent some decomposition, but was not slowly cooled, so as to precipitate into pearlite with or without some excess ferrite or cementite. It is a common constituent of hardened steels, and may occur in cast iron which is cooled rapidly through the range of red heat. It is strong, hard, and brittle. It differs from austenite in being magnetic, but is not as much so as the same steel slowly cooled.

Sorbite is imperfectly resolved pearlite. That is, it is a step beyond martensite in the decomposition of the solid solution. The ferrite and cementite are not fully formed, but may be said to be in a preliminary state of precipitation. Sorbite has some of the strength of martensite and some of the ductility of fully precipitated steel. It is obtained by cooling steel with medium rapidity from the temperature where it is a solid solution to atmospheric temperature, or accomplishing a similar result by other means.

Sonims is the name given to solid, non-metallic impurities in iron and steel, including slag particles, sulfides of iron or manganese, oxides of iron, manganese, silicon, aluminum, etc., or dirt from ladle or furnace linings. Just as muddy water will not clear itself without standing quietly for a time, so these sonims will remain suspended in some steel baths or ingots until caught in the solidifying mass. The crucible and electric processes give the best opportunity for the metal to clarify itself. Sonims occur to a very harmful extent only as a result of bad practice in steel making, such as lack of care in adding oxidizing agents too near the end of the process, or adding deoxidizers in the ingots when the steel is too cold to allow oxide of aluminum, for example, to rise to the surface, etc.

Equilibrium Diagram of Iron and Steel. The constituents present in the form of crystals or grains in any series of alloys can be learned from a study of the so-called equilibrium diagram, such as that shown in Fig. 3. The iron-carbon alloys (like every other series of alloys) are in a condition of chemical solubility when liquid. Upon freezing, the first crystals are born as small solids within the liquid mass. These crystals may still preserve the condition of chemical solubility present in the liquid, or they may form as crystals of the individual metals in the alloy, or as chemical compounds of these metals. For example, all the liquid iron-carbon alloys up to as much as 1.7 per cent of carbon will preserve the chemical solubility of the liquid. They will form crystals of solid solution. That is why all alloys having carbon from zero to 1.7 per cent are known as steel (except when they also contain particles of intermingled slag, when they are known as wrought iron). But if the alloy contains more than 1.7 per cent carbon, then, when it freezes, two kinds of crystals will form in it: one a saturated solid solution containing 1.7 per cent of carbon, the other Fe_3C, called cementite. This is white cast iron. Fig. 3 does not show how gray cast iron is obtained since the iron-carbon alloys all freeze to crystals of solid solution and cementite, but no graphite. If about 0.75 to 2.50 per cent silicon is present, however, then some or all of the cementite breaks down into iron and graphite, both during the freezing and during the subsequent cooling.

Decomposition of Crystals of Solid Solution. Whatever their carbon content, the crystals of solid solution formed during freezing break down upon further cooling. If the carbon content is near the saturation value (1.7 per cent), the solid solution crystals lose carbon in the form of Fe_3C, while for a very low carbon content, crystals lose iron in the form of ferrite crystals. The separation of Fe_3C is shown by the line *ES* in Fig. 3, and the separation of Fe is shown by the line *GS*. Consider the following three cases of iron-carbon alloys, cooled slowly:

1. An alloy containing 98.5 per cent iron and 1.5 per cent carbon. Within a solid solution crystal in this alloy, cooling from 1875 deg fahr, there might be seen, under a microscope (if the appropriate conditions could be obtained), crystals of Fe_3C beginning to appear. The mass is plastic because hot. Some of the Fe_3C crystals migrate to the

outer boundaries of the crystal; others remain imbedded in the inside. The residual solid solution, in which the crystals of Fe_3C are appearing, gradually loses its carbon and approaches a composition of 0.85 per cent of carbon. When this amount of carbon is left dissolved in the solid steel, and simultaneously the temperature has dropped to 1350 deg fahr, the residual solid solution entirely * breaks up into crystals of Fe_3C and of Fe, in the form of pearlite. See p. 11–27. This final precipitation requires a few seconds of time and continues while the temperature is falling through a few degrees, but is not a continuing action like the gradual separation of the Fe_3C from the initial solid solution.

2. An alloy containing 99.65 per cent iron and 0.35 per cent carbon. As this alloy cools from a temperature of about 1510 deg fahr, there begin to appear, in the midst of the crystals of solid solution, microscopic particles of iron, which migrate to the boundaries of the crystal and appear in larger and larger proportions until the metallic body remaining as a solid solution is deprived of iron down to 99.15 per cent iron and 0.85 per cent carbon. Simultaneously the temperature has fallen to 1350 deg fahr because the solid solution always retains amounts of iron and carbon in chemical solubility in exact relation to the temperature, and always comes to 99.15 per cent iron and 0.85 per cent carbon when the temperature has fallen to 1350 deg fahr. At this temperature, the 0.85 per cent solid solution undergoes a complete separation into crystals of iron and Fe_3C, associated together as pearlite, as in the previous case.

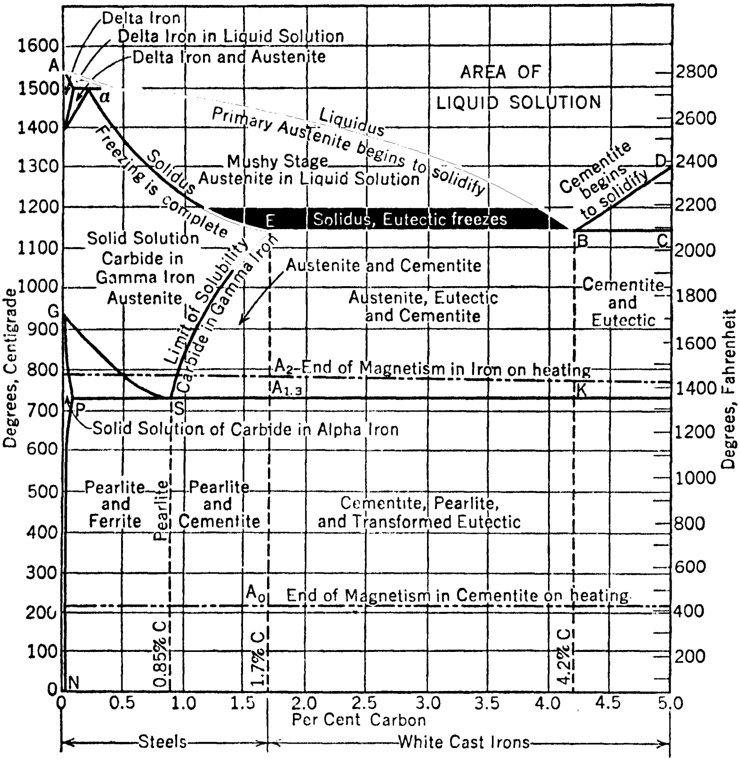

Fig. 3. Equilibrium Diagram of Iron-carbon Alloys

3. An alloy containing 99.15 per cent iron and 0.85 per cent carbon. Since the lines *GS* and *SE* in Fig. 3 intersect at 1350 deg fahr for an alloy of 0.85 per cent carbon, the

---

* The trace of carbon which remains in solution to lower temperatures is intentionally disregarded, because this is so small (0.03 to 0.015 per cent) that it does not affect the principle here involved.

solid solution crystal of this alloy will not lose iron or Fe_3C upon cooling. The resultant steel therefore at atmospheric temperature consists of 100 per cent pearlite.

Every known slowly cooled alloy of iron and carbon will contain pearlite, since every alloy from 0.01 to 6.6 per cent carbon will have crystals of solid solution in it when it has frozen, and every one of these solid solutions will drop out of itself either Fe or Fe_3C as it cools until the temperature has dropped to about 1350 deg fahr, when the solid solution will completely separate into crystals of Fe and Fe_3C, combined in a pearlitic mixture. The Fe or Fe_3C crystals which drop out in the cooling process are much larger crystals than the Fe or Fe_3C crystals which compose the pearlitic mixture. The 0.85 per cent carbon alloy is the strongest of all single steels since it has no large crystals of Fe or Fe_3C in its crystal boundaries to weaken it.

" Critical-point " Curves of Iron and Steel. The curves in Fig. 3 are the so-called " critical-point " curves, and the changes occurring at these points are second in importance only to the actual manufacture of the iron and steel itself. The effect of elements (carbon, silicon, etc.) on iron and steel, of heat treatment, etc., can best be discussed by relating it to these " critical points." The effect of other elements, including those entering into alloy steels, is discussed on pp. 11–24, 11–26.

Effect of Manganese on Critical-point Curves. The curves in Fig. 3 represent the changes occurring in iron-carbon alloys. If manganese be added to the alloys, the line *PSK* will occur at lower temperatures, depending on the amount of manganese. When the manganese content is as high as 7 per cent, this line will be reduced below the temperature of the earth's atmosphere. That is, the changes represented by these lines will never occur during cooling to atmospheric temperatures. This is the basis of the alloy steel known as manganese steel, which is discussed on p. 11–37.

Effect of Nickel on Critical-point Curves. Nickel, like manganese, reduces the temperature at which the changes represented by the lines *PSK* occurs. When the nickel content of steel is 12 per cent, the temperature at which these changes occur is below that of the atmosphere. At 25 per cent nickel, however, the temperatures begin to rise again. This leads to the most extraordinary alloys, such as nickel-steel bars which are magnetic at one end and non-magnetic at the other, and also alloys with unusual coefficients of dilation.

Effect of Chromium on Critical-point Curves. Chromium added to steel has the effect of slightly raising the line *PSK*, and slightly lowering the line *GS*. The maximum effect is with 5 per cent of chromium. However, these effects of chromium are not so important as its influence in reducing the speed at which the transformations (changes) represented by these lines occur. That is, if steel of, say, 0.50 per cent carbon be cooled from 1600 to 1100 deg fahr, at a moderately slow rate, the normal changes will occur. But, if a few per cent of chromium be present, the cooling must proceed very slowly. Conversely, if the cooling is rapid, for the purpose of suppressing the change as much as possible, the suppression will be more complete if a few per cent of chromium are present. Chromium thus intensifies the effect of rapid cooling on steels that are hardened by heat treatment.

13. THE MECHANICAL WORKING OF STEEL

Effect of Work on Iron and Steel. All work breaks up the crystals of iron or steel. This is more noticeable in wrought iron and low-carbon steel, for the grain of properly heated high-carbon steel is always smaller than that of low-carbon material. But if the mechanical work is stopped while the steel is still hot, the crystals will grow again to some extent. Work should, therefore, be continued to a low red heat, and extended to every part of the steel. This is difficult when rolling or forging thick pieces, whose interior is almost always of coarser grain than the surface.

The more work given to steel, the better will be the grain, provided that the finishing temperature is near the line *PSK* in Fig. 3. This, however, reaches a limit when the steel is finished at a moderate thinness. In other words, railroad rails rolled from 18-in. ingots have as good a grain as if they were rolled from ingots twice as large, but rails rolled from ingots 6 in. square would not have sufficient mechanical kneading. Six-inch ingots will, however, give a good crystalline structure to 7/8-in. wire rods, or 1-in. bars for concrete reinforcement.

Working Steel at a Blue Heat is Injurious. Not only are wrought iron and steel much more brittle at a blue heat (see p. 11–31), but, though they are probably not seriously affected by even prolonged simple exposure to blueness, if they be worked in this range of temperature they remain brittle after cooling.

Rolling vs. Forging. Rolling is the quickest and cheapest method of shaping, but it does not give quite so good a crystalline structure as either forging or hot pressing, and is more likely to tear the hot metal. It has less control over the finishing temperature, but finishes the steel more truly to form.

Cold Rolling gives more accurate and finished shape than hot rolling, and a better crystalline structure, with consequently greater strength and higher elastic limit. The hardness, as measured by the weight required to produce equal indentation, is increased by 50 per cent. Unless cold rolling is followed by annealing, it leaves the metal with strains and internal stresses. It gives the steel a better surface and brighter appearance. Only the final operations are done cold, and the steel is pickled and freed from scale before cold rolling begins. If annealed afterwards, it is protected from oxidation. High-carbon steel should not be rolled cold because the hardening and embrittling effect is too great.

Effect of Finishing Temperature in Rolling. The strength and ductility of steel depend to a high degree upon the fineness of grain, and this may be obtained by having the temperature of the steel rather low, say at a red heat, 1300 to 1400 deg fahr, during the finishing stage of rolling. In the manufacture of steel rails a great improvement in quality has been obtained by so finishing.

Hot Pressing. When it is desired that the kneading effect of mechanical work shall extend into the interior of large pieces, the shaping is performed by pressing hot under a press exerting a pressure of a few hundred to several thousand tons. Armor plate and other large pieces are shaped in this way.

Cold Pressing. Thin plate for structural purposes, automobiles, etc., is formed by pressing cold, sometimes in one operation and sometimes in several progressive ones, depending on the extent of distortion. The effect of this cold pressing is about the same as that of cold rolling, but leaves more intense strains in the metal. Often the shape is such that it is impossible to prevent the plate from springing back to an intermediate form, unless iron of more than 99 per cent purity is used.

Cold Punching, Deformation, etc. When steel is punched and sheared cold, bent, or otherwise deformed, severe strains are set up which ruin the strength of the metal immediately adjacent to the deformation. By punching or shearing the edges are cracked, and the metal should be cut away if reliance is to be placed on the edge to withstand strain.

Surface Decarbonization of Steel. When steel is rolled or heated, a coating of oxide forms on the surface. On subsequent heating this oxide reacts in the solid with the layer of steel underneath and deprives it of a part, or all, of its carbon. Thus, all hot-rolled steel has a film of decarbonized metal between the oxide coating and the unaffected steel. This layer is softer and, moreover, will not be hardened by heat treatment.

14. THE EFFECT OF HEAT ON STEEL

There are seven ways in which heat affects most metals, including steel:

1. The properties are different at different temperatures.

2. An oxide or scale forms above certain temperatures.

3. Some temperatures cause an increase or growth in grain size.

4. When the temperature approaches the melting point of the steel, a new damage known as "burning" occurs. (Burning is sometimes erroneously confused with the phenomenon of grain growth.)

5. Rapid cooling from certain temperatures develops hardness and brittleness in steel entirely different from the softness and ductility of the same steel when slowly cooled.

6. Rapid cooling from other temperatures increases the strength of the metal over its strength when slowly cooled.

7. In heating or cooling steel, there may be unequalized strains existing in the metal which will be released, producing shrinkage or warpage, or else the cooling through given ranges of temperature may produce strains which manifest themselves in warped material. Sometimes the distortion may result in the formation of a crack. In extreme cases, the change in volume may result in actual bursting with explosive violence.

Variation of Properties with Temperature

A few properties of steel are at their highest point at very low temperatures and decrease with temperature rise. The relation is not uniform and regular, however, but sudden changes, or even temporary reversals of trend, occur at certain temperatures, especially at points of allotropic or other critical change. The most important properties which are at their highest at lowest temperatures are strength, elasticity, hardness, brittleness, electric conductivity, and magnetism. Other properties are at their lowest point at low temperatures and rise with temperature, but, again, the relation is not uniform. The most important of these crescendo properties are ductility and malleability.

Strength and Ductility. Fig. 4 gives a general idea of the relative strength and ductility of steel at all temperatures from that of liquid air to that near the melting point. Average steel is relatively very strong and brittle at the temperature of liquid air, but both these properties decrease greatly to atmospheric temperature. Then both strength and brittleness increase again, reaching a maximum at about 260 deg cent (500 deg fahr). This is called the "blue heat," because a blue oxide will cover steel if it be left a few minutes at this temperature. Iron and steel must not be worked or strained at this temperature. They will crack even under light blows, and their toughness and ductility are very low. These properties again improve as red heat is approached.

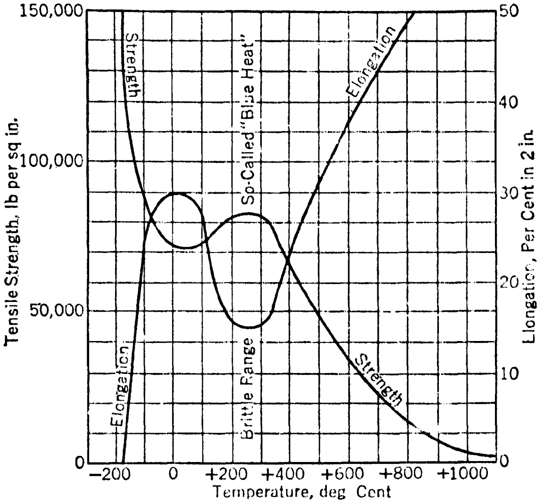

Fig. 4. Approximate Tensile Strength and Elongation in 2 in. of Structural Steel at Various Temperatures from that of Liquid Air to the Usual Rolling Temperatures

Impact Resistance. The resistance of steel to shock decreases very much with lowered temperature, so that some steels are too brittle to use in impact service even in cold climates, although they would give satisfaction at all temperatures not far below freezing.

Creep (see p. 5–07) is most important at temperatures where a metal has a low combination of strength and ductility, e.g., 500 deg cent for steel. The action is illustrated graphically in Fig. 5. Part *ab* of the curve in Fig. 5 represents elongation which occurs within the yield point of the metal when the load is first applied. The load is unvarying and continuous. During passage of time, there is a slow permanent elongation of the specimen as indicated by *bcde*. At *e* the specimen fractures, because of the weakening due to deformation. To strain a metal beyond its yield point and then to allow it to rest results in what is called a "strain hardening," i.e., an increase in the value of the yield point. The same action occurs in extremely slow straining, so that sometimes an alloy after months of creep will become strengthened by the operation to the point where it will no longer yield to the strain. This is indicated in the line *cf* in Fig. 5.

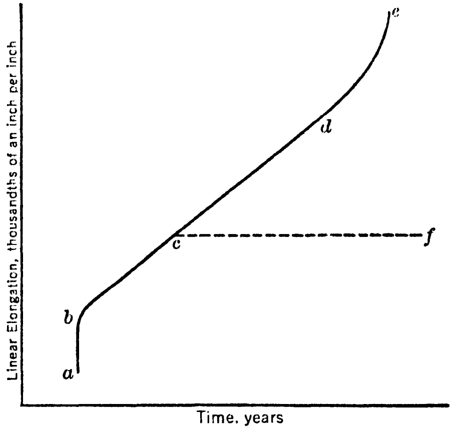

Fig. 5. Illustrating "Creep" in Metals

Grain Growth

Grain Growth is caused by the elimination of grain boundaries and the merging of two or more grains into one large grain. Some grains grow to large size in a few minutes, and others require months. Everything else being equal, the larger the grains in a metallic body, the lower will be its strength and ductility. Therefore, large grains are dreaded in all metals, but especially in steel, because this is used so much more for structural purposes.

Grain Growth in Pure Iron, Wrought Iron, and Very Low-carbon Steel. The iron-carbon alloys which are very low in carbon are subject to grain growth at temperatures between about 500 and 850 deg cent (932 to 1562 deg fahr). This is a very slow growth, requiring weeks or months, but is hastened by repeated strains. It is therefore to be feared in iron chain which is used in hot places, wrought-iron tie rods in furnaces, etc. Grains of this type sometimes grow as large as one's thumbnail. The action is not to be expected in steel with more than 0.12 per cent of carbon. The grains are restored to small size by heating to about 900 deg cent (1652 deg fahr).

Grain Growth in All Steels. Steels of any proportion of carbon suffer grain growth in consequence of being heated above 700 deg cent (about 1300 deg fahr). Steels with 0.85 per cent of carbon are the simplest to discuss and will be chosen for this brief summary: this steel, when heated to 700 deg cent (1292 deg fahr), is just at the point of the *V* in Fig. 3. At this temperature it assumes the smallest grain size which can be given to it by heat treatment. The further steel is heated above that temperature, the more the grain will grow in size.

Even steel of the best quality, if rendered coarse grained by " overheating," will suffer in its valuable properties and may become quite unfit for use. Medium- and high-carbon steel will lose both strength and ductility; low-carbon steel will lose strength even up to 50 per cent of the original but does not seem to be materially damaged in ductility unless the overheating is continued for a long time or at a very high temperature.

Cure for Overheating. If steel containing 0.85 per cent carbon, e.g., steel consisting entirely of pearlite, be heated from some point below the line *PSK* in Fig. 3 to some point above that line, a new crystallization will occur and will largely obliterate previous crystallization. It seems as if dissolving the ferrite and cementite in each other produces forces which obliterate almost all existing crystalline forms. This process is known as " restoring " or, by some writers, " refining " the steel.

The cure for coarse crystallization in steel with less than 0.85 per cent carbon is to reheat it from below the line *PSK* to above the line *GS*, at which the last of the ferrite goes into solution (see Fig. 3).

Steels with more than 0.85 per cent carbon may be restored in every case by reheating them over the line *PSK*, just as with pure pearlite.

It is emphasized that steel must be heated to the appropriate temperature, because the result cannot be produced by cooling to the temperature. Once steel has acquired a coarse grain structure, it will remain coarse until heated through the critical temperature.

Hardening of Steel by Quenching

Temperature for Hardening. If steel be raised to a bright-red heat and then rapidly cooled, as, for example, by plunging it into water, it becomes harder and at the same time stronger and more brittle. One circumstance is absolutely necessary to produce the increase in hardness, viz., that the temperature from which rapid cooling takes place shall be above the critical temperature of the steel so that the best grain structure is obtained. For steel containing less than 0.85 per cent carbon, the best temperature for hardening is just above the line *GS*, Fig. 3. For steel with 0.85 per cent or more of carbon, the best temperature is just above the line *SK*.

Carbon and Hardness. The hardness of steel increases with every increase of carbon. With 0.10 per cent carbon the hardness begins to be perceptible by crude tests, but it is only for a carbon percentage greater than 0.75 that ordinary steel acquires sufficient hardness to be used commercially, e.g., for springs, saws, etc. Metal-cutting tools are usually made of steel containing 1 per cent or so of carbon; very hard implements, such as files, will contain 1.5 per cent or slightly more.

Rate of Cooling and Hardness. The degree of hardness of steel also varies with the speed of cooling from above the critical range of temperature. When the cooling is very slow, e.g., when it takes several days to cool, the steel will be as soft as it is possible to make it. When it is taken out of the furnace at a bright-red heat and plunged into a heavy oil with a low conducting power for heat, it becomes quite hard and springy, provided its carbon is in the neighborhood of 0.8 per cent or above. Quenching in water makes it harder still, and so on, the degree of hardness increasing with quenching liquids of greater heat-removing ability, such as ice water, ice brine, ice-sodium chloride solution, and mercury near its freezing point (−39 deg cent, −38 deg fahr).

Critical Hardening Speed. Every steel has what is called its critical hardening speed. This may be taken to be the speed at which steel should be cooled to produce the maximum amount of martensite.

Theory of Hardening of Steel. To get hardened steel, it must first be heated until it has become a solid solution of cementite in iron. This solid solution is not very hard. But if it be cooled rapidly to atmospheric temperature it becomes very hard, whereas, if it had been cooled slowly, it would be soft. The theories of hardness may be summarized as follows:

1. Slip is prevented by submicroscopic particles of cementite.
2. Slip is prevented by extreme fineness of grain.
3. Slip is prevented by intralattice carbon atoms.
4. Hardness is due to internal stress, because of:
    a. Lattice distortion.
    b. Suppression of expansion at about 350 deg fahr.
5. Hardness is a characteristic of a supersaturated solid solution.

The first theory is the one which seems to have the largest amount of support at present (1936). In other words, the solid solution decomposed enough, even in spite of the rapid cooling, to separate out particles of cementite too small to be seen even by the microscope but hard enough and numerous enough to wedge the mass tightly together so that it will not yield to slip or strain until it breaks.

Tempering. Hardened steel is too brittle to be used without some degree of tempering, except for a small variety of purposes, such as the points of armor-piercing projectiles and the face of armor plate. If it be heated to about 200 deg cent (392 deg fahr), quite a little of the brittleness and a part of the hardness will be lost. It is then in condition to be used for steel engraving tools, lathe tools, and other implements to cut metals. If it be heated to 250 deg cent (480 deg fahr), it would be tempered still further, and so on.

Heating for Annealing, etc. Annealing has for its object the treble purpose of (1) relieving any strains put upon the metal during its cooling, or by mechanical treatment or otherwise; (2) restoring the grain of the metal to that minute size which gives it the best possible qualities; or (3) softening it after hardening. These three objects may be accomplished in one annealing operation. The usual temperatures of true annealing lie between 700 and 1000 deg cent (1290 and 1830 deg fahr). Temperatures from 200 to 700 deg cent (1292 deg fahr) are sufficient to relieve strains in the metal and to soften it after mechanical treatment or hardening. This operation, using low temperatures, is known as "lonealing." To produce a new grain size, however, the steel must be heated slightly above the critical temperature and cooled slowly from that point so as to be in a soft condition. If, because of cold rolling, wire drawing, or other mechanical work, in the cold, a small grain size is already present, it is bad practice to form a new grain size. In this case the steel should be lonealed.

15. USES OF CARBON STEELS

Crucible Steel and Electric Steel. Crucible steel and electric steel excel all others in price and quality. Their high quality is due to freedom from gases, oxides, and defects other than metallic impurities. These steels may be used only for purposes which warrant the high price. Authorities differ as to whether crucible or electric steel is superior. In America, electric steel is made at the rate of more than a million tons per year, whereas the production of crucible steel has decreased from 20,000 to 1700 tons per year.

Bessemer Steel. The Bessemer product is losing ground, not so much on account of the limited field for which it is adapted, but because low-phosphorus pig iron from which it is made is becoming yearly more rare and costly, owing to the exhaustion of low-phosphorus ores. For small railroad rails, small structural shapes (angles, channels, standard beams, etc.), pipe, wire, and tin plate, Bessemer steel is as good as any obtainable provided the phosphorus be kept at a moderately low figure.

Basic Open-hearth Steel. For more important structural members, for large railroad rails, which must be relatively high in carbon, and, therefore, low in phosphorus, so as to be strong yet not brittle in cold weather, the basic open-hearth steel is especially appropriate. The same is true for structural plate, boiler plate, etc. Most modern steel, therefore, is made by the basic open-hearth process.

Acid Open-hearth Steel. It is easier to get low-phosphorus material for melting in the acid open-hearth than for the Bessemer converter, since in the former 75 to 90 per cent of the material usually consists of steel scrap. Therefore, acid open-hearth steel low in phosphorus and in sulfur is obtainable, and is the highest quality of steel in the market, next to crucible and electric. It excels basic open-hearth steel because of its relative freedom from oxygen, to which basic steel is liable on account of its highly oxidized basic slag. For steel castings this freedom from oxygen is especially valuable, as oxygen and oxides in steel tend to produce " blowholes " in castings. The acid open-hearth is not universal, but is generally preferred, for steel casting work. It is also preferred for fatigue members of important bridge and other structural work, on account of the smaller content of oxides which lower the resistance of the steel to this type of stress.

16. ALLOY STEELS

Alloy Steel. Steel is an alloy of iron and carbon. An alloy steel is a steel to which has been added, in addition to the carbon, an amount of some element sufficient to produce a distinguishing effect. The alloying element is usually a metal, and its effect must be such as to alter the properties of the steel so as to put it into a slightly different class from ordinary carbon steel. For example, manganese and silicon are contained in practically all carbon steels in small amount. But, if the proportion of manganese or silicon is sufficiently large to give properties to the steel which do not ordinarily occur in carbon steel, then the steel is classed as an alloy steel.

Nickel and chromium are the two alloying elements most often used. The weight of these two metals used in alloy steels exceeds the weight of all other alloying elements taken together.

The best alloy steels are made in the electric furnace or crucible, but 75 to 80 per cent of the tonnage comes from basic open-hearth furnaces. The greatest amount of alloy steel is used because of combined strength and ductility (95 per cent of all steel is important because of its strength). In some cases, however, other properties of alloy steels, such as hardness, heat resistance, corrosion resistance, etc., may be most important.

Binary Alloy Steels. If an alloy steel contains one alloying element besides the steel, it is called a " binary " alloy steel. Examples of these are: nickel, chromium, tungsten, vanadium, silicon, manganese, and molybdenum steels.

Ternary Alloy Steels. Very often, alloy steels are made up of steel and two alloying elements. These are called " ternary " alloy steels. Examples are: chrome-vanadium, chrome-nickel, silicon-manganese, and chrome-molybdenum steels.

S.A.E. Specification Numbering System. A numeral index system is used for numbering S.A.E. steels, in which the first figure indicates the class to which the steel belongs: thus " 1– " indicates a carbon steel, " 2–," a nickel steel; and " 3–," a nickel-chromium steel. In the case of the alloy steels, the second figure generally indicates the approximate percentage of the predominant alloying element. Usually the last two or three figures indicate the average carbon content in " points," or hundredths of 1 per cent. Thus " 2340 " indicates a nickel steel of approximately 3 per cent nickel (3.25 to 3.75), and 0.40 per cent carbon (0.35 to 0.45); and " 71360 " indicates a tungsten steel of about 13 per cent tungsten (12 to 15) and 0.60 per cent carbon (0.50 to 0.70). The basic numerals for the various qualities of steels specified are:

Carbon steels..............	1	Chromium steels.............	5
Nickel steels..............	2	Chromium-vanadium steels....	6
Nickel-chromium steels.......	3	Tungsten steels..............	7
Molybdenum steels...........	4	Silico-manganese steels.......	9

S.A.E. steels are purchased on the basis of requirements as to chemical composition. Requirements as to physical properties and finish have been omitted for all steels except steel castings because the majority of steels for automotive purposes are either worked or given special heat treatment by the purchaser.

Binary Alloy Steels for Strength

Nickel. Nickel decreases the crystal size of steels, and especially the size of crystals of pure iron. For this reason, the addition of nickel to structural steel results in an increase of strength, without a proportionately great decrease of ductility. Through the same cause it increases the hardness of steel, and, therefore, is used for such purposes as railroad rails on curves. It is valuable in steel that is to be case-hardened, because it decreases the crystal size of the " core." The full benefit of nickel is obtained only when the steel is heat-treated for strength in the usual way, namely: it is heated to the lowest possible temperature to get all the iron and carbon in solid solution, quenched in oil or water to prevent precipitation of iron crystals in large size, and then reheated to some point below the line *PSK*, Fig. 3, to restore ductility to the steel. Nickel steel of

3.5 per cent nickel is superior to carbon steel which has been treated in this way, and excels especially in elastic limit.

Silicon. Many bridges have been built in the past five years using what is called "silicon structural steel." This is stronger than carbon steel of equal ductility. The silicon is usually between 0.50 and 1.05 per cent, and it is customary to raise the manganese of structural steel from about 0.50 to between 0.67 and 0.95 per cent. By this analysis the silico-manganese steels, much used for springs, are approached.

Silicon has the effect of decreasing the solubility of carbon in iron, both in the liquid and the solid state. In the solid solution, therefore, the end of the *V* in Fig. 3 is found occurring at a less amount of carbon than the usual 0.85 per cent. With 1 per cent of silicon, the solid solution will have its maximum solubility at about 0.45 instead of 0.85 per cent carbon. Since the point of the *V* is always the strongest steel, a stronger steel with less carbon in it is obtained in this way, and therefore, greater ductility, because the less the carbon, the greater the ductility.

Medium Manganese Structural Steel. The manganese in ordinary carbon steel is between 0.40 and 1 per cent. Increasing the manganese to about 1.50 to 1.75 per cent results again in a steel with much higher strength and without loss of ductility. The steel also withstands the shock test excellently. For this reason it is being used for railroad rails, which thus less easily develop transverse fissures in the heads, probably caused chiefly by blows from the driving wheels of locomotives. The steel is also being used in place of nickel steel in structural parts of some bridges.

Comparison of Nickel, Silicon, and Manganese Structural Steels. It is possible to secure a little better combination of strength and ductility in 3.5 per cent nickel steel than in silicon or medium manganese structural steels. Nickel steel has also had a long service in important structures, as compared with the length of time during which the others have been used. But 3.5 per cent nickel steel costs about twice as much as does either of the others. All three of these alloy steels are generally used in large members of structures without any heat treatment. In this respect, nickel steel has the advantage, because it can be improved to a greater extent by quenching and reheating. All three of the steels, when in the unheat-treated condition, have similar properties.

Vanadium. Vanadium is one of the most powerful scavengers that can be added to liquid steel for the special purpose of removing oxygen. After the removal of all the oxygen that can be eliminated by means of manganese and silicon, the addition of 0.25 per cent of vanadium will result in further oxygen elimination, leaving about 0.15 per cent vanadium in the steel. This vanadium has the effect of increasing the strength and hardness of the metal. In fact, the hardness is increased so much that ordinary alloy steel is not used with more than 0.2 per cent of vanadium remaining in it. Vanadium, like nickel, decreases the grain size of steel, but vanadium acts on the Fe_3C as well as the Fe grains. Vanadium also acts apparently during the phase when steel is freezing, so that it is especially beneficial in steel castings, whose properties it improves materially. Except for castings, not very much vanadium binary steel is made, but vanadium is added in extremely small doses to make ternary and quarternary alloy steels, some of which have great strength or hardness.

Molybdenum Structural Steel. From 0.25 to 0.75 per cent of molybdenum added to ordinary steel, which is then heat-treated, produces a structural steel which has increased elastic limit without correspondingly decreased ductility. Molybdenum resembles vanadium in not being used extensively in binary steels, but in being added in small doses to improve the properties of other alloy steels, such as the important chrome-molybdenum steel used in airplane structures, and also nickel-molybdenum steel.

Ternary Alloy Steels for Strength

Chromium in Ternary Alloy Steels. Chromium intensifies the effect of rapid cooling on steel. Tool steel which has been quenched for hardness is much harder for the presence of 0.5 to 2 per cent of chromium than steel of the same analysis in carbon and other elements which contains no chromium. Therefore, chromium is used only in steels which are to be heat-treated.

Chrome-nickel Steel. Thus a steel which contains about 1.5 per cent of nickel and 0.6 per cent of chromium will have, after heat treatment, almost the same strength and ductility as 3.5 per cent nickel steel which has also been heat-treated, but it will not cost as much. Table V gives data for the comparison of all these binary and ternary structural steels. The heat treatment of chrome-nickel steel is based on the principle already given: heat the steel until the solid solution is complete; then quench in oil or water; and, finally, reheat to some temperature below the line *PSK* in Fig. 3 to restore ductility. The best temperature for first quenching must be determined by experiment for all steels of different analysis; the temperature for reheating will depend on how much ductility

Table V. Some Mechanical Properties of Some Structural Alloy Steels

Steel	Analysis, per cent								Ultimate Strength, lb per sq in.	Yield Point, lb per sq in.	Elongation, per cent in 2 in.	Reduction of Area, per cent	Izod Value	Heat Treatment	
	C	Mn	Si	Ni	S	Cr	V	Mo						Quench in	Then draw at
Silicon	0.10	0.60	1.00						72,000	52,000	27‡	59		As rolled

is estimated to be necessary, always remembering that the greater the ductility the lower the elastic limit.

Chrome-vanadium Steel. Heat treatment and general mechanical properties of chrome-vanadium steel compare with those for chrome-nickel steel. Table V indicates some of the differences.

Silicon-manganese Steel. Silicon-manganese steel greatly resembles chrome-vanadium in strength and for service in springs. It is widely used in Europe for automobile springs, and to some extent in this country, although many American makers favor chrome-vanadium as being less brittle.

Chrome-molybdenum Steel. Chrome-molybdenum steel has not as good a combination of strength and ductility as nickel, chrome-nickel, and chrome-vanadium steels, but it is quite easy to roll and draw into tubes, to fabricate, and to weld, so that it is very popular for airplane structural parts.

Alloy Steels for Hardness

Effect of Chromium on Hardness. Chromium intensifies the effect of rapid cooling; consequently it greatly increases the hardness of quenched steel, if the carbon is high enough to produce hardness on quenching. Chromium is almost universally added to increase the hardness of cutting tools, the amount being usually about 1.50 up to 2.50 per cent for protective armor plate, etc. It is also used to decrease the wear in parts of crushing machinery. For simple abrasion hardness, high-manganese steel is also very commonly used.

High-manganese Steel. Steel, when it contains manganese in excess of 7 per cent, acquires an entirely new property which reaches its maximum efficiency when the manganese is about 13 per cent. This property consists in a toughness so great that the steel may be tied cold into a knot without producing any cracks, and a resistance to wear which makes it commercially unmachinable with the usual cutting tools. The toughness is developed only if the steel is heated above 1000 deg cent (1800 deg fahr) and cooled as rapidly as possible by quenching in water. The steel is made in the form of castings and can be shaped a little on the surface by grinding with emery wheels. Unfortunately, its elastic limit is too low to permit its being used as a cutting tool.

High-speed Steel. When carbon steel is quenched and then tempered, it begins to lose its hardness at 200 deg cent (400 deg fahr). This makes it impossible to use this steel for metal cutting at high speeds, because the friction of cutting warms the cutting tool to the temperature where it loses its hardness (sometimes called its " temper "). By the addition of about 18 per cent of tungsten to such steel it acquires the property of " red hardness," that is, of remaining hard even when at a low red heat (535 deg cent = 1000 deg fahr). Before it will have this characteristic of resisting tempering it must be heated to about 1150 deg cent (2100 deg fahr) and cooled in oil or in an air blast. In practice chromium is usually added up to 4 per cent and vanadium up to 2.5 per cent to this " high-speed steel," for the sake of further adding to its hardness and cutting power. Cobalt is now (1936) often added to intensify its properties. Nine per cent of molybdenum will replace the 18 per cent of tungsten to give this " red hardness " characteristic.

Super-speed Cutting Tools. The new " super-speed cutting tools " are not alloy steels, but often take the place of alloy-steel tools. Their base is the carbide of tungsten, WC, the hardest substance known next to the diamond. See p. 11–81.

Corrosion-resistant Steels

Steels and Cast Iron Which Resist Corrosion. Nickel steel rusts less than carbon steel, especially if the nickel is 25 per cent and higher. Alloys of iron with not more than 0.50 per cent of copper rust less than plain carbon steel, especially in slightly acidulated waters, such as the rivers which flow from coal-mining districts. Alloys with nitrogen (e.g., nitrided surfaces) also seem by recent studies to have a powerful resistance. The alloys of iron with silicon, beginning about 11 per cent silicon, not only do not rust at all, but even offer great resistance to acid attack which dissolves iron readily. Iron castings with 13 per cent of silicon are made for chemical purposes. But the material which is of most extensive industrial and household importance is the so-called stainless steel.

Stainless Steels. Stainless steel is a general term given to certain alloys of iron, chromium, and nickel that have high resistance to heat and corrosion. They are generally designated by the percentage of chromium; an 18–8 stainless is understood to be an alloy containing 18 per cent Cr and 8 per cent Ni. The composition and physical properties of the commonly used alloys are given in Table VI.

General properties of the alloys in Table VI are as follows: Tensile strength is higher than that of ordinary steels of equal carbon content, and fabricating and forming methods,

* Cold-rolled, annealed. † Hot-rolled, annealed.

hot or cold, should be modified accordingly. Heat treatment does not harden them appreciably but cold working does. As the heat conductivity is lower than that of steel, a longer time is required for heating heavy sections for forging, etc. All the above alloys resist oxidation at high temperatures, this quality being more pronounced in some than in others. The highest resistance to corrosion is obtained only when the sheets are entirely free from foreign matter, e.g., are highly polished. Polished stainless steels are resistant to corrosion in atmosphere at ordinary temperatures, and to many chemical solutions used in the industries. Manufacturers of the material should be consulted as to the alloy to be selected for resistance to corrosion by any particular liquid or gas.

Heat-resisting Alloy Steels

Tungsten steel is the strongest material known at the temperature of exhaust valves in gas engines, but it has a tendency to scale. High-chromium steels do not scale at this temperature, but they lack strength. Chromium up to 38 per cent has been used, but the most popular combination is steel with about 18 per cent chromium and 8 per cent nickel. See Table VI. This heat-resisting steel is sold under many trade names which give no indication of its analysis.

COPPER AND COPPER-BASE ALLOYS*

By the members of the staff of The American Brass Co. and W. M. Corse

17. COPPER

Composition of Commercial Copper. The composition requirements of the A.S.T.M. specifications for copper are almost universally accepted by the trade. These standard specifications cover *lake copper*, *electrolytic copper*, and *fire-refined copper* other than *lake*. In order to be classed as lake, copper must originate on the northern peninsula of Michigan, U.S.A. Lake copper is further divided into low-resistance lake, offered for electrical purposes, and high-resistance lake. Low-resistance lake, whether fire or electrolytically refined, shall have a purity of at least 99.900 per cent, silver being counted as copper. Low-resistance lake copper wire bars shall have a resistivity not to exceed 0.15436 international ohm (meter, gram) at 20 deg cent (annealed), while ingots and ingot bars shall have a resistivity not to exceed 0.15694 international ohm (meter, gram) at 20 deg cent (annealed). Lake copper having a resistivity greater than 0.15694 international ohm (meter, gram) at 20 deg cent (annealed) shall be known as high-resistance lake copper. Its purity shall be at least 99.900 per cent, copper, silver, and arsenic being counted together. The A.S.T.M. specifications for purity and electrical resistivity of electrolytic copper are the same as those for low-resistance lake copper. Fire-refined copper, other than lake, is intended for use in rolling into sheets and shapes for mechanical purposes and is not intended for electrical purposes nor wrought alloys. Its chemical composition shall be as follows:

	Per Cent
Copper plus silver, minimum	99.7000
Arsenic, maximum	0.1000
Antimony, "	0.0120
Bismuth, "	0.0020
Iron, "	0.0100
Lead, "	0.0100
Nickel, "	0.1000
Oxygen, "	0.0750
Selenium, "	0.0400
Tellurium, "	0.0140
Tin, "	0.0500

Physical and Mechanical Properties of Copper. Average physical properties of copper are given in Table I. The mechanical properties of cast and rolled copper are given in Tables II and III, respectively. For electrical properties of copper conductors, see p. 11–93.

Corrosion. Copper is dissolved by the common acids, especially in the presence of air or other oxidizing agents, and it usually does not give satisfactory service in resisting the action of ammonia or most sulfur compounds. Some of the principal uses are in the shipbuilding industry where its property of resisting the action of corroding sea waters is valuable; in buildings, to resist the action of atmospheric corrosion particularly in industrial centers and upon the seacoast. In case of doubt, engineers not familiar with the corrosion-resisting properties of copper should consult manufacturers of the material, giving complete information as to the conditions under which the metal is to be used.

---

* The material on Copper and Wrought Copper-base Alloys was prepared by The American Brass Company, Waterbury, Conn., and that on Sand-cast Copper-base Alloys, by Mr. W. M. Corse.

Table I. Physical Properties of Copper

Physical Properties	Value
Density, 20° C	8.90 g per cu cm, or 0.322 lb per cu in.
Melting point	1981 deg fahr
Specific heat, 25° C	0.0919 { g-cal per g per deg cent Btu per lb per deg fahr
Linear coefficient of expansion (av. 25 to 300° C)	0.0000177 per deg cent
Thermal conductivity, 20° C	0.923 g-cal per sec per sq cm per deg cent per cm
Electrical resistivity, 20° C	1.699 microhm-cm
Temperature coefficient of resistivity, 20° C	0.00393 per deg cent
Magnetic susceptibility	0.085×10^6
Optical properties	Selectively reflecting
Modulus of elasticity	16,000,000 lb per sq in.

Oxygen-free High-conductivity Copper. A copper of special grade, made under carefully controlled conditions, is available. The atmosphere of the furnace and the method of casting prevent the entrance of oxygen and the formation of copper oxide. Wire and other shapes made from this material exhibit much superior characteristics in two respects. The ductility, as evidenced in elongation, torsion, and bending, is made greater. OFHC wire may be twisted two or three times as many turns as regular copper. This copper also may be subjected to the action of reducing gases at elevated temperatures (as in brazing) without the usual danger of embrittlement. Conductivity and tensile strength are the same as for tough pitch electrolytic copper. The fatigue resistance is apparently unchanged.

Because of the superior ductility of oxygen-free copper, it is useful in difficult operations of deep drawing, spinning, and edge bending. Where the embrittlement hazard must be avoided in welding, brazing, or hot-working operations, this copper may be used to advantage, in spite of the higher cost.

Fabrication. Copper may be hot or cold forged, hot or cold rolled, hot extruded, hot pierced, and drawn, stamped, or spun cold. It can be silver soldered, brazed, and welded, the last by the electric arc or oxyacetylene method. For welding, deoxidized copper is recommended instead of the usual electrolytic or lake copper because it gives more satisfactory welds. Copper cannot be cut by the oxygen jet as can iron or steel, because of the high heat conductivity of the metal. It is annealed at 480 to 1400 deg fahr, depending upon the properties desired, and in a slightly oxidizing atmosphere. For ordinary commercial annealing 1100 deg fahr is considered good practice. A reducing atmosphere will injure the copper, making it brittle and unfit for use. Copper is easily electrodeposited from the alkaline cyanide solution, or more usually from the acid sulfate solution.

Hardening of Copper. The search for the so-called lost art of hardening copper is still popular with many inventors, as evidenced by the number of inquiries on this subject and the applications in the Patent Office. Two ways of hardening copper are: by cold working, or by alloying with other elements such as zinc, tin, silicon, aluminum, or nickel.

Electrical Uses of Copper. See p. 11–92.

18. COPPER-BASE ALLOYS

Brasses and Bronzes. Brass is essentially a copper and zinc alloy, whereas bronze is primarily a copper and tin alloy. However, there is no sharp dividing line between the two. Many brasses contain tin, and bronzes often contain zinc. The term " bronze " is also applied to certain copper-base alloys that contain no tin, as, for example, aluminum bronze and silicon bronze. Since the same commercial name frequently applies to widely varying compositions, care should be taken to specify the chemical composition of a commercial alloy.

Fabrication. Nearly all the copper-base alloys are readily machined. Some of the stronger alloys, such as aluminum-bronze and manganese-bronze, are tough and difficult to machine, but with proper tool angles and machine conditions it is entirely possible to machine even those. These alloys as a class are not readily welded by any of the com-

mercial methods. Because of their high heat conductivity they dissipate the heat so rapidly that it is difficult to make a proper weld. The classes that can most readily be welded are the yellow brasses, manganese-bronze, and the proprietory alloys, Everdur and Ambrac.

Corrosion. Certain alloys resist corrosion better than others, and under the heading " Remarks " in Tables II and III this condition is noted in some cases. As a class these alloys are considered non-corrosive with reference to atmospheric conditions, but they vary widely when exposed to chemical agents, or even to the same agent under different conditions. For this reason, it is difficult to predict resistance to corrosion. In nearly every instance a trial under service conditions is necessary where a new alloy is to be used. Laboratory tests are unreliable for comparing different types of material, although they are valuable as acceptance tests for material of the same type. Where corrosion resistance is of importance, the manufacturer of the alloy should be consulted as to its suitability under the proposed conditions, or tests made on samples of the alloy in question.

Sand-cast Copper-base Alloys. The common copper-base alloys containing more than 50 per cent copper are given in Table II which has been compiled from about twelve authorities. The composition and physical properties given are average and should not be used for specification limits. For many of these alloys, the physical properties will vary more owing to changes in casting and cooling conditions than to wide changes in composition. The relative value of these alloys for mechanical purposes varies with temperature, and information on this point should be secured before subjecting them to high-temperature use.

Wrought Copper-base Alloys. Table III gives the composition and physical properties of some of the common wrought copper-base alloys. The values given are average and should not be used for specification limits. Almost any physical properties between the figures for " hard " and " soft " may be obtained by appropriate working. Higher values for tensile strength or hardness may be obtained by a greater amount of working. The physical properties also vary with the temperature, and hence, if they are to be subjected to high-temperature use, information should be obtained from the manufacturers on this point. For copper-base bearing alloys, see p. 11-84.

ZINC AND ZINC-BASE ALLOYS

By W. M. Peirce

19. CHEMICAL AND PHYSICAL PROPERTIES

Chemical Characteristics. Zinc is a chemically active metal. Its chemical properties are the reason for its use in primary cells, for cyaniding and in the production of nascent hydrogen. It forms both basic and acid radicals, and is soluble both in acids and strong alkalies.

Physical Constants. The more important physical constants of zinc are given in Table I.

Metallography. The common impurities in zinc are lead, cadmium, and iron. See Table II, p. 11-54. Their importance varies individually with the use to which the metal is put. These metals, as well as copper, magnesium, and aluminum, which are the more common elements used in zinc alloys, are discussed below.

Lead, which does not enter into solid solution, has no great effect in unalloyed zinc. Its effect on the properties of certain zinc alloys, however, is enormous.

Cadmium, in the amounts present in commercial zinc, is completely in solid solution, and exerts an important hardening effect. It also raises the recrystallization temperature, and whereas pure zinc recrystallizes at so little above room temperature that it cannot be appreciably work hardened, zinc containing cadmium can be given a considerable degree of work hardening by cold rolling.

Iron has a limited solid solubility of the order of 0.001 to 0.003 per cent. Attention must be given to the iron content of zinc for rolling.

Copper is the alloying element most frequently added to zinc. It enters into solid solution in zinc to about the same extent (approximately 1 per cent), and with about the same effect, as cadmium, except that the copper-zinc alloys are more ductile and easier to roll.

Magnesium has a solid solubility of 0.01 or 0.02 per cent in zinc, but even these amounts exert a remarkable influence on its properties. When magnesium is added in the presence of copper, its effect is even more striking. Some of the most important zinc alloys contain both copper and magnesium.

Resonance	See Note 3	

NOTES. 1. Solid zinc (rolled) is about 3 per cent heavier than liquid zinc at the melting point.

2. Based on soft rolled zinc strip 99.99 per cent pure. Resistivity of strip zinc may vary 3 per cent, depending on the rolling treatment, and in commercial grades about the same amount, depending on the purity.

3. Rolled zinc has extremely low resonance, which permits its use in various sound apparatus.

Aluminum is the other important element used in zinc alloys. Its use is limited entirely to casting alloys, as usually zinc alloys containing aluminum are unstable when rolled. In the cast form, however, several per cent of aluminum can be used to improve greatly the physical properties, particularly the tensile and impact strength of zinc. The alloys, if properly formulated, are stable.

Corrosion

Atmospheric Corrosion. In pure distilled water zinc forms a loosely adherent film of hydroxide which affords little protection. This film, dried in the presence of oxygen and the traces of carbon dioxide always present in the atmosphere, forms a protective layer or film believed to be a zinc oxide-hydroxide-carbonate mixture. This is quite insoluble in rainwater, affords effective protection against further attack, and makes zinc a satisfactory roofing and flashing material. The presence of sulfur gases in industrial atmospheres increases the solubility of this film, accounting for the higher rate of weathering in industrial than in rural atmospheres.

Resistance to Organic Substances. Zinc is inert to such common organic substances as gasoline, kerosene, oil, and grease free from water. Soap and soap paste do not attack it, though in dilute soap solutions there is a tendency to form zinc soaps. Zinc is entirely inert toward anhydrous alcohol, but is oxidized by mixtures of alcohol and water. Sugar solutions in hard water do not attack zinc when totally immersed at room temperature, but distilled-water solutions at any temperature or hard-water solutions at elevated temperatures attack it.

Certain organic acids dissolve the atmospheric corrosion film on zinc, for example, acids formed by decomposition of red and white cedar at ordinary temperatures, and of other woods at higher temperatures (as in steam). Hence zinc and some other common metals cannot be safely used in contact with certain moist wood, or the drainage from them.

Toxicity. Excepting the salts of strong acids, which are corrosive, or zinc compounds containing other poisonous elements or radicals, the compounds of zinc are not strongly toxic. Zinc is a normal constituent in many foods and considerable excesses of zinc taken into the body are readily eliminated without ill effects. Excess zinc content in foods or beverages may cause unpleasant but not serious symptoms. Drinking water should not contain above 40 mg per liter.

Effect of Carbon Dioxide and Steam. Very high carbon dioxide concentrations appear to aid the solution of the corrosion film. Increased temperature may sometimes have such an effect. Live steam destroys the protective film and also attacks the metallic zinc at an increased rate. Hence unalloyed zinc is unsuitable for use when exposed to live steam.

Effect of Oxygen Concentration. See p. 11–07. Severe corrosion of zinc occasionally occurs in the presence of a water film without free access of oxygen to all portions of it. An example is a zinc roof, laid over an absorbent sheathing and building paper, on a building having high humidity inside. If the roof is unprotected from condensation on the under side, rapid corrosion of the zinc may occur. The preventive is building paper, saturated and coated on both sides with asphalt, under the metal roofing.

20. SLAB ZINC

Chemical Composition of Slab Zinc. According to the A.S.T.M. Standard Specifications for slab zinc (Spelter) (B6–33), the composition should conform to the maximum values of Table II.

Table II. Standard Specifications of Slab Zinc

	Grade	Maximum Allowable Per Cent of			Lead + Cadmium + Iron not to Exceed
		Lead	Cadmium	Iron	
1	Special high grade *†	0.010	0.005	0.005	0.010

6	Prime western	1.60	....	0.08	....

* All grades except prime western must be free from aluminum.
† Tentative standard.

Uses of Slab Zinc

Galvanizing. The process of coating iron or steel with zinc as a protection against corrosion is known as galvanizing, and the product is known as galvanized iron or steel. This use is the largest single outlet for metallic zinc. Zinc coatings are desirable not only because the zinc corrodes more slowly than iron but also because at cut edges or similar discontinuities in the coating, the zinc, being anodic to the iron, affords galvanic protection and the iron is not dissolved until the zinc has been completely removed by corrosion.

The suitability of galvanized coatings for use under any particular service conditions is governed by the factors discussed above under corrosion.

The life of zinc coatings, regardless of the method of application, has been shown to be directly proportional to the thickness or weight of the coating. The proportion of pure zinc to iron-zinc alloys in the coating does not have any significant effect.

Specifications and Tests for Galvanized Coatings. Galvanized coatings usually are specified as a given weight of zinc per unit area, for example, ounces of zinc per square foot of surface. For details of methods of determining the weight of the coating see Standard Methods of Determining Weight of Coating on Zinc Coated Articles, A.S.T.M. Specification A–90–33.

Specifications for most commercial products covering weight of coating and bend tests when required are available in A.S.T.M. Standards, 1933, Part I, Metals, pp. 278–312, and A.S.T.M. Tentative Standards, 1933, pp. 583–586.

On sheets, coating weights are given as weight per square foot of sheet, i.e., 2 sq ft of coated surface. Ordinary coatings on sheets range from 0.75 to 2.75 oz per sq ft of sheet coated on both sides. The weight of zinc per single covered surface would be one-half this amount. Zinc coatings on pipe, structural shapes, hardware, etc., generally range between 1.15 and 3.5 oz per sq ft of covered surface. The weight of coating on wire varies with the size of wire and process of coating, and, except in fine sizes, will range from 0.15 to 1.25 oz per sq ft of covered surface.

Methods of Application. Galvanized coatings are applied: (*a*) by dipping the article in molten zinc, (*b*) by electroplating, (*c*) by heating in contact with zinc dust.

Hot Dip Galvanizing. In the process, the iron or steel is cleaned by pickling, usually in hot sulfuric acid. A rinse and a dip in cold hydrochloric usually follow, but better practice involves removal of iron salts from the pickled material by vigorous rinsing and scrubbing if necessary, followed by dipping in 25 per cent zinc chloride (slightly acidulated). After partial drying, the material enters the bath of molten zinc, sometimes through a flux of zinc ammonium chloride. Wetting of the iron by the zinc and the formation of a solid layer of iron-zinc alloy on the iron surface occur in a matter of seconds. The longer the immersion, the thicker the alloy layers.

The material is withdrawn from the zinc bath through rolls kept clean by zinc ammonium chloride flux in the case of sheet or through a charcoal sand or asbestos wipe in the case of wire. The speed of withdrawal and character of the wipe influence the thickness of the layer of molten zinc adhering to the work.

The behavior of the coating on bending is influenced largely by the purity of the zinc, high-grade zinc being used where bending properties are important, as in the case of telephone wire. Factors in the operation tending to produce a thin uniform alloy layer also have an important beneficial effect on bending. A common practice is to wipe off practically all the molten zinc, leaving only the alloy layer which dusts rather than flakes on bending, the loss of coating being thus less conspicuous. Exposure tests have shown that a heavy coating which flakes lasts longer than a thin " tight wiped " coating which dusts at a bend.

A patent process known as " galvannealing," in commercial use, converts the pure zinc layer to alloy by heating, imparting some of the bending characteristics of tight wiped material and a type of surface somewhat similar to sherardizing.

Another patented process known as the " Crapo Process " involves special pretreatment of the iron surface before galvanizing to improve adherence.

Tin may be added to the zinc bath to produce a sheet with bright spangle (which has no merit except appearance). Aluminum may be added in hand dip galvanizing of pipe, shapes, and hardware to produce a smooth coating. The vapor of burning sulfur or ammonium chloride dust is sometimes blown over the surface of sheets to improve brightness.

Electrogalvanizing. Zinc coatings are also applied to wire, conduit, and hardware by electroplating. The only distinguishing feature of this process, as compared to other electroplating processes, lies in the attention given to methods of rapidly depositing heavy coatings (e.g., the patented Tainton Process), since the serviceability of the coatings depends on their thickness and the thickness ordinarily desirable is greater than in purely decorative plating.

This method of zinc coating has the merit of avoiding changes in the base steel due to heat and of not producing excessive deposits in recesses such as the base of threads which would affect dimensional tolerances.

Sherardizing. Zinc and iron alloy very readily, and coatings can therefore be produced by heating iron or steel in a closed vessel with zinc dust (sometimes termed blue powder) for several hours. The vapor pressure of the zinc is sufficient at the temperatures used, 600–700 deg fahr, to cause a reaction of zinc vapor with the iron, and this is probably supplemented by actual contact. (It has been demonstrated that alloying will occur by diffusion at only slightly elevated temperatures.) The resulting coating is almost entirely iron zinc alloy (richer in iron near the base metal) with some mechanically held zinc dust in the outer layers.

This process may result in some heat treatment of the base metal. The thickness of coating produced is quite uniform over all parts of the surface. Sherardized coatings like coatings of iron-zinc alloy produced by other methods afford an excellent base for paints or enamels. The coating itself is a matte gray and can be polished. Like other coatings consisting almost entirely of iron-zinc alloys, sherardized coatings dust rather than flake on bending. Also in common with such coatings the protection afforded by a given thickness is, under the average normal service conditions, equal to the protection afforded by an equal thickness of pure zinc.

The zinc dust used may be the by-product blue powder from spelter furnaces or may be expressly manufactured for the purpose, attention being given to a suitable particle size and metallic zinc content (the balance being largely ZnO).

Brass. See p. 11–40. The second largest use of zinc is in brass. This constitutes a separate field, and will not be discussed here except to state that, since lead is objectionable in brass for drawing operations, grades of zinc low in lead are largely used in brass manufacture.

Die Casting. The most rapidly growing use of zinc is for die casting. Suitable alloys for this process have been found to require zinc of exceptional purity, and the " Special High-grade " specification listed above is drawn primarily to define a suitable grade for use in zinc die-casting alloys. Freedom from lead, tin, and cadmium is the primary requirement.

By alloying with about 4 per cent aluminum, a few hundredths magnesium, and in some cases 1 to 3 per cent copper, alloys amenable to die casting, and having in the die-cast condition radically improved properties as compared with unalloyed zinc, are obtained.

These alloys and their properties are further described on p. 11–82.

Slush Casting. High grade slab zinc is used in slush castings, largely used for lighting fixtures and other ornamental parts. High grade unalloyed zinc is used as well as alloyed zinc containing small percentages of aluminum, and sometimes of copper.

21. ROLLED ZINC

Classification of Rolled Zinc. Rolled or wrought zinc is divided by the A.S.T.M. (see A.S.T.M. Standard Specifications for Rolled Zinc, B 69–29) into the following types:

Type A. Ribbon zinc and sheets or strips cut from ribbon zinc which has been rolled from a single bar in one continuous direction.

Type B. Sheet zinc or strips cut from sheet zinc that has been rolled by the pack rolling method.

Type C. Boiler and hull plates, which may be rolled either from a single bar or by the pack rolling method.

Zinc Gage. Table III compares the standard zinc gage and the American or Brown and Sharpe gage and the U. S. Standard gage. The use of this special zinc gage is discouraged and, in order to avoid errors, the actual thickness expressed in thousands of an inch is preferable.

Table III. Comparison of Zinc Gage and Other Gages

Mechanical Properties of Rolled Zinc. A standard specification (A.S.T.M., B 69–29) calls for temper and dynamic ductility (cupping) tests. These are considered the only ones sufficiently reproducible and valuable for specification purposes. *Temper* is measured by a testing machine which wraps a specimen tightly around a mandrel to which one end of the specimen is clamped. The degree to which the free end springs away from the mandrel is measured on an arbitrary scale, ranging from 0, representing no spring whatever, to 100, representing material that returns to its original straight condition. *Dynamic ductility* is determined by forming a series of cups by forcing a spherical-ended plunger into a test strip, the plunger being adjustably mounted in a drawing press to permit varying the depth of the cup. The maximum depth of the cup, in inches, which can be formed before visible " necking down " occurs is the dynamic ductility.

The three types of rolled zinc are classified according to temper as follows: Type A: dead soft, soft, half hard, and hard; Type B: commercial; Type C: no classification. It should be noted that the terms soft, dead soft, etc., serve to designate certain specific ranges of properties regardless of the combination of composition and rolling treatment by which the properties are obtained.

Where tensile tests are used the A.S.T.M. standard tensile specimen (see p. 5–84) for thin sheet metal is entirely suitable for zinc. A pulling speed as near to 0.25 in. per min as can be obtained on the testing machine should be used. Under these conditions, rolled zinc will have a " with-grain " tensile strength varying from 18,000 lb per sq in. for soft-temper high-grade zinc to 35,000 lb per sq in. for hard-temper prime western zinc. The elongation will vary from 5 per cent for the hardest to 65 per cent for the softest metal. The " across-grain " strength in every case will be a few thousand pounds higher and the elongation somewhat lower. By alloying, considerably higher tensile strengths can be obtained, although this is usually at the expense of ductility. The percentage elongation in the tensile test is of little significance since the rate of loading is far below the rate of deformation in commercial drawing or fabrication, and is no index to ductility in these operations.

The Modulus of Elasticity of zinc lies between 10,000,000 and 20,000,000, depending on the rolling treatment. Approximately 12,000,000 is a representative value for soft-rolled high-grade zinc.

The Shearing Strength of high-grade zinc plates is reported as 17,000 to 19,000 lb per sq in.

Static Tensile Tests. Of much greater importance than the ordinary tensile test, from a practical standpoint, is the static tensile or creep test which determines the resistance of various grades of zinc to elongation or flow at different temperatures under static tensile load. This information has been correlated with actual loading tests on corrugated zinc roofing sheets. (See Tables IV and V.)

Fabrication. The ductility of zinc falls off rapidly at temperatures below 70 deg fahr. All drawing and bending operations, therefore, should be performed at temperatures above that point. Frequently an operation which is just too severe to be successful at temperatures near the lower limit may be successfully accomplished by warming the

zinc and tools, for example to 100 deg fahr. In any type of extrusion, it is necessary to use an elevated temperature in order to operate with reasonable pressures.

For certain ornamental sheet metal work heavy gage zinc is hand formed at temperatures as high as 480 deg fahr. Shop methods in drawing zinc vary considerably from one plant to another, but in general, brass practice is followed with departures in detail depending upon the particular operation. It is, of course, unnecessary to anneal pure zinc between operations, and the work-hardening alloys require fewer annealings than brass.

Reductions in diameter from blank to the first cup should not exceed 45 per cent. A somewhat lower per cent reduction is usually preferable practice.

It is possible to reduce the wall thickness 25 to 33 per cent in redrawing operations in which the cup diameter is reduced 20 per cent.

There are many satisfactory lubricants for drawing zinc, the one chosen usually depending upon the succeeding operations. In using soap solutions it is usually necessary to wash the fabricated article within a short time to prevent spotting.

A vital factor in bending is the grain direction. Wherever possible, rolled zinc should be so used as to bring bends at right angles to the grain or rolling direction. When this can be done, proper bending is easy without sacrifice of hardness and stiffness. Zinc is successfully extruded into any of the forms commonly produced in this way. Tubing and rod have been produced, but in the United States development has been limited principally to the production of cups, buttons, nails, etc. In machining zinc, it is common practice to employ tools with a greater rake than normal for brass, and to use soapy water as a lubricant.

Welding of zinc requires some care, because of the low melting point and the tenacious character of the oxide. The best welding is accomplished with a gas flame, but zinc may also be spot-welded electrically. Zinc cannot be welded without seriously weakening areas adjacent to the weld by annealing. If strength is important, some cold-working operation to refine the grain should follow welding.

Zinc is easily soldered. A low soldering temperature is necessary to avoid excessive grain growth in areas adjacent to the joint. This is best secured by using a large iron hot enough to accomplish the soldering with a single pass. Half and half solder is generally used, although a low-melting-point solder is also of advantage. A solder composed of Pb 55 per cent, Sn 30 per cent and Cd 15 per cent is suitable for zinc. It has a low melting point and high tensile strength. Acidulated zinc chloride or killed hydrochloric acid makes an excellent flux, although much zinc is soldered without a flux.

ALUMINUM AND ALUMINUM ALLOYS

By Junius D. Edwards and Zay Jeffries

22. PROPERTIES AND COMMERCIAL FORMS

Aluminum is one of the lightest of the structurally used metals. In the period of less than 50 years during which aluminum has been commercially available, its annual production has increased from a few thousand pounds to more than 500,000,000 lb.

Bauxite, a hydrated oxide of aluminum, is the principal source of the metal, and is found widely distributed in many parts of the world. For the production of aluminum, the ore is refined by treatment with caustic soda, and pure aluminum hydrate is precipitated from the resulting solution. After calcination, the pure alumina (Al_2O_3) is sent to the electrolytic reduction works. Here it is dissolved in a bath of molten cryolite and electrolytically reduced to metallic aluminum. Any impurities in the alumina, such as oxides of iron and silicon, are reduced and appear in the aluminum. Commercially pure aluminum is generally understood to be 99 to 99.5 per cent pure, although grades up to 99.8 per cent or even higher are available. Aluminum having a purity of 99.98 per cent can be produced by electrolytic refining of the lower grades of metal.

Table I gives the properties of aluminum.

Table I. Properties of Aluminum

Commercial Forms. Pure aluminum is soft and ductile but can be hardened by cold working and alloying; certain of the alloys can also be hardened by heat treatment. Both pure aluminum and its alloys are available in wrought form, as plate, sheet, rod, wire, tubing, and rolled and extruded sections. It can also be worked by forging, drawing, stamping, spinning, and other metal-working methods. Alloys are available in cast form, produced by sand, permanent mold, or die-casting processes.

Corrosion-resistant Characteristics of Aluminum. Aluminum is resistant to most atmospheric influences, especially inland industrial atmospheres, but although it is relatively more resistant to seacoast atmospheres than many other commonly used metals, paint or other protection is generally advisable for permanent structures in such locations. As examples of the resistance of unpainted aluminum and its alloys to a variety of atmospheric conditions, may be cited the very satisfactory performance of relatively high-purity aluminum in transmission lines and outside bus-bar installations, of aluminum-silicon alloy castings used in many large buildings as spandrels and other ornamental parts, and of wrought products as window frames and store fronts. Aluminum is used to handle distilled water, many food products, fruit juices, milk, beer, and atmospheric nitric and glacial acetic acids. It is readily dissolved, however, by hydrochloric and hydrofluoric acids and caustic solutions.

This metal, in common with many other corrosion-resistant metals, owes its high resistance to the protective effect of the ever-present oxide coating. Aluminum of the highest purity, in general, possesses the highest corrosion resistance. The presence of most other metals, either as impurities or alloying elements, tends to lower corrosion resistance. Of the common alloying elements, manganese, chromium, and magnesium produce the most corrosion-resistant alloys. Silicon affects the corrosion resistance slightly, and yet, since it conveys other beneficial effects, such as good casting characteristics, it is either the major or one of the minor alloying constituents of some of the most corrosion-resistant alloys. Iron and copper lower the corrosion resistance in the order named, although properly heat-treated aluminum-copper alloys have a sufficiently high corrosion resistance to be used for many applications without paint protection.

The formation of a resistant film or coating under corrosive conditions consumes some of the aluminum and may result in complete perforation of thin sheet or foil, but in heavier sections the same amount of attack will have no appreciable effect on the mechanical integrity of the part. In aircraft, where the sections are of necessity very thin and the consequences of deterioration serious, the strong aluminum alloys are protected from corrosion by one of the several commercially available methods. For such service, the wrought Alclad products, consisting of a heat-treatable strong alloy core covered by a surface layer of high-purity aluminum, or corrosion-resistant alloy, offers an excellent combination of mechanical strength and corrosion resistance. The surface layer not only covers the strong alloy core and so protects it from corrosion, but also, because of its higher solution potential, offers an electrolytic protection over cut edges and abraded areas and also prevents penetration into the core, even under severely corrosive conditions. Ordinarily 17S rivets used to join Alclad sheet are likewise afforded considerable protection because of this electrolytic effect. Other non-heat-treatable Alclad products, employing the principle of a coating of higher solution potential than the core, are available. They resist destructive perforation to a remarkable extent.

Owing to the high solution potential of aluminum and its alloys, contact with many of the commonly used metals in the presence of a corrosive medium results in the rapid deterioration of the aluminum, with a corresponding protection of the metal of lower solution potential. For this reason, metallic contacts with other metals are generally avoided. Electrical insulation between the two dissimilar metals is of considerable help, although salts formed by the solution of the other metal are likely to be plated out on the aluminum surface and thus set up electrolytic action. In spite of the rapid action in severely corrosive media, little action is found to take place in ordinary atmosphere, unless there is an accumulation of a solution of relatively low electrical resistance. On the other hand, in some assemblies used in contact with strong electrolytes, it is advisable even to consider the relative solution potentials of various aluminum alloys which are in contact.

Bright surfaces produced by rolling or extrusion, or highly polished surfaces, tend to become darkened and slightly roughened through exposure to the weather, unless periodically cleaned. Similarly, regular cleaning of cooking utensils and similar articles will prevent pitting, which is often caused by the plating out of particles of heavy metals which have been dissolved in the liquids being handled.

23. ALUMINUM CASTINGS

Very little pure or commercially pure aluminum is fabricated directly into castings of commerce. The pure metal does not cast easily, nor are the properties of a casting made of pure aluminum attractive for most commercial purposes. The aluminum casting industry is therefore largely one of casting various aluminum alloys. There are three distinct casting arts; namely, sand casting, permanent mold casting, and pressure die casting. These arts are sufficiently different to warrant the inclusion of a list of alloys for each. The composition and properties of the more common alloys used for sand castings, permanent mold castings, and pressure die castings are given in Tables II, III, and IV, respectively. Aluminum alloy castings are so widely used at present that it is not possible to list the many specific uses here; nor is it possible to mention the particular combinations or properties leading to the selection of a particular alloy for a specific use.

Sand Castings are made by the ordinary methods of molding. The sand process is used for most large castings, such as crankcases for internal-combustion motors, oil pumps, manifolds, transmission housings, motor frames, architectural castings, etc. Green sand molds with either green or baked sand cores are used. The core binders are usually oil, pitch, or resin, the last two being used for soft and the first for hard cores. The crystallization shrinkage of aluminum alloys being high, ample gates and risers must be provided. Iron, aluminum, or copper chills are also used frequently to prevent cracks or shrinks. In making the molds, care must be taken to obtain the proper temper of the sand and uniform ramming. Aluminum does not " lay " well against a hard-rammed

Table II. Composition and Properties of Sand-cast Aluminum Alloys *

* Alloy numbers referred to are those of the Aluminum Co. of America. Prefixed letters denote changes in composition of standard alloy. Suffixed "T" and number designate heat-treated alloys.

† Properties obtained from standard 1/2-in. diameter test specimens, individually cast in permanent molds and tested without machining off surface.

‡ Hardness limits are based on casting Brinell tests. In the case of 122 and 142 alloys, the Brinell is that obtained on the heads of permanent mold pistons 1/2 in. or less in thickness, and at a point 1/2 in. from outer edge and 1/2 in. from gate. For heavier castings, semi-permanent and sand-cast pistons, the hardness decreases proportionately with increased section, the maximum decrease being approximately 20.

Table IV. Composition and Properties of Aluminum-base Die-casting Alloys

* The alloy designations correspond to numbers used in the investigation on aluminum-base die-casting alloys carried out under the jurisdiction of Committee B-6 on Die Cast Metals and Alloys (formerly Subcommittee XV on Die Cast Metals and Alloys of Committee B-2 on Non-Ferrous Metals and Alloys of the American Society for Testing Materials); the alloy numbers omitted correspond to alloy compositions which were investigated by the Committee, but which were not considered desirable for inclusion in these specifications. See *Proc. A.S.T.M.*, Vol. 29, Part I, p. 192, 1929.

mold. The metal must be stirred thoroughly to insure uniformity of composition. Melting is usually done in iron pots, non-metallic crucibles, or reverberatory furnaces. The metal should preferably be kept below about 1500 deg fahr during melting, and an oxidizing atmosphere is preferable to a reducing one. Unclean melting practice is largely responsible for so-called hard spots which usually consist of foreign matter entrapped in the liquid alloy. These hard spots may cause much trouble in machining. The pouring temperature should, in general, be the lowest one at which the mold can be filled without danger of misruns. Such practice will usually produce the strongest and most ductile as well as the most leak-proof castings. Low pouring temperature can often be secured by judicious arrangement of gates and risers.

Permanent Mold Castings are poured by gravity or other low pressure into metal molds. The permanent mold process imparts unusual properties to the metal as a result of the rapid chilling in the metal molds. Gates and risers are provided to insure compensation for crystallization shrinkage so that the permanent mold castings are sound and nonporous. They may be made very nearly to size and usually machine easily. Large numbers of permanent mold castings are used in cooking utensils, washing machines, vacuum sweepers, cylinder heads, and the like. It will be noted that certain permanent mold castings can be produced with a hardness up to 150 Brinell. The permanent mold process is conducive to the production of castings of high hardness, and moreover, such hardness may be combined with relatively great toughness. The benefits of the permanent mold process can be obtained to a marked degree and greater latitude of design enjoyed by using sand cores in conjunction with metal mold parts. Parts made in this way are called " semi-permanent mold " castings.

Pressure Die Castings are made in metal dies by forcing liquid metal quickly into the dies at high pressure, which is applied by means of a piston or with compressed air. The casting solidifies so rapidly that there is no opportunity for complete compensation for crystallization shrinkage or for elimination of all the entrapped air. Although the interior of the casting is sometimes quite porous, the outside shell is usually very sound and strong. Comparisons of tensile strengths of pressure die castings, as shown in Table IV, with other types of aluminum alloy castings indicate that the average strength of the die castings is high, notwithstanding a certain amount of porosity. Aluminum die castings may be made with thinner sections than those fabricated by other processes, and they may be made so nearly to size as to eliminate all or many of the machining operations.

Silicon is now perhaps the most important alloying element in aluminum-base die castings. It will be noted that all the alloys listed in Table IV have silicon specified. The combination of copper and silicon also occurs in five of the seven alloys.

Maximum and Minimum Weights of Castings. Aluminum sand castings weighing more than 7000 lb and as little as 1 oz have been made in production. So far as experience goes, there is no inherent reason for any limitation on the weight of a sand casting. In the permanent mold process, castings weighing as much as 750 lb each have been made and castings weighing less than $^1/_2$ lb have been made in production. The usual weight of permanent mold castings, however, is between 20 lb and $^1/_2$ lb. A 12-lb casting is considered large for a pressure die casting, and castings weighing as little as $^1/_{32}$ lb are made.

Section Thickness. The minimum section thickness for sand castings is usually kept at about $^1/_8$ in., that for permanent mold castings about $^3/_{32}$ in., and for pressure die castings $^1/_{16}$ in. There is no limit on the high side.

Finish. On large sand castings, $^3/_{16}$ to $^3/_4$ in. should be allowed for finish, depending on design, and on small bench work castings, $^1/_8$ in. For disk grinding, $^1/_{32}$ in. should be allowed. On permanent mold castings, for example, pistons up to 3-in. diameter, 0.075 in. on the diameter should be allowed. On pistons up to 5-in. diameter, about 0.10 in. should be allowed. Pressure die castings often require no finish if tolerances ±0.0025 in. per in. are permitted.

Tolerances on Dimensions and Weights. A tolerance of $^1/_{32}$ in. in thickness of sand castings, and ± 0.010 in. per in. on permanent mold castings, should be allowed. Plus or minus 5 per cent in weight with wood patterns and ± 3 per cent with metal patterns should be allowed on sand castings and ± 2 per cent on permanent mold castings. On pressure die castings a section tolerance of ± 0.0025 in. per in. should be allowed and a weight tolerance of ± 2 per cent.

Properties of Aluminum Alloy Castings at Elevated Temperatures. Commercial aluminum has a Brinell hardness number of only about 25 and a tensile strength of about 12,000 lb per sq in. at ordinary temperature, and its strength and hardness decrease progressively with rising temperature. Table V shows some of the tensile properties of certain of the aluminum alloys which are used commercially at elevated temperatures. So marked is the effect of alloying that one alloy has a strength at 600 deg fahr higher than that of commercial aluminum at ordinary temperature. The values shown, however, for the temperatures 400, 500, and 600 deg fahr are considerably lower than those usually associated with such temperatures. This results from the stabilization of the alloys at the temperature of test prior to the test itself. Except for the values given at 500 deg fahr for 132 alloy, the minimum time of exposure at the temperature of test prior to testing was 75 days. The profound effect on the material is indicated by the hardness values. These hardness tests were made at room temperature after the test piece had been stabilized

at the testing temperature. For example, in the 132 alloy, the room temperature hardness was changed from 130 to 54 by holding at 600 deg fahr for 75 days.

24. WROUGHT ALLOYS OF ALUMINUM

Alloy Composition and Nomenclature. The wrought alloys of aluminum may be grouped in two divisions, the first containing those alloys in which various tempers are produced by cold working, and the second containing those alloys which are subjected to heat treatment in order to obtain the desired mechanical properties. The latter are frequently called "the strong alloys," and, in general, their mechanical properties have higher values than those of the alloys in the first group.

Each of the wrought alloys is designated by a number, indicating the composition, followed by the letter " S," indicating that it is in the wrought condition or is capable of being wrought. The compositions of the commercial alloys are given in Table VI; other alloys have been used to a limited extent.

Temper Designations. To indicate an alloy in the soft or annealed condition, the alloy designation is followed by the letter " -O "; e.g., 2S–O, 17S–O. The hard temper is designated by " -H " (2S–H, 4S–H), and the intermediate cold-worked tempers by fractions before the " H " (2S–$^3/_4$H, 4S–$^1/_2$H).

In the strong alloys the letter " T " indicates that the material is in the fully heat-treated condition and has the maximum strength developed by heat treatment. This condition is obtained by a solution heat treatment, which consists of heating to the

proper temperature and quenching in cold water, followed by aging. Some of the strong alloys age at room temperature; others must be subjected to higher temperatures to cause precipitation of certain constituents (aging). These latter alloys are designated 25S–W, 51S–W, and 53S–W when they have been quenched but not subjected to the precipitation treatment, although 51S–W undergoes some spontaneous aging at room temperature.

In order to produce material with higher yield strengths than can be obtained by heat treatment alone, some of the alloys are cold worked after heat treatment, by an amount carefully controlled so as to retain suitable ductility in the resulting product. This produces material in the " RT " condition.

Alclad Products. In order to provide exceedingly high corrosion resistance, a composite material is produced in which this quality is imparted by means of a surface of high corrosion resistance, alloyed and integral with the strong alloy core. The thickness of the surface metal is so chosen as to retain the maximum physical properties consistent with adequate protection of the core.

Aluminum Foil. Aluminum sheet 0.005 in. and less in thickness is termed foil. The ductility and malleability of aluminum permits the rolling of foil commercially to gages as thin as 0.00025 in. Most extensively used thicknesses, however, are 0.0003 to 0.0007 in. For these extremely thin gages a special grade of pure metal is used. For certain uses, however, where additional strength is required, such as for diaphragms and shims, alloys of aluminum are used. The alloy foils, being less ductile, are usually of the gages of 0.001 in. and heavier.

The " film-forming " characteristic of aluminum has resulted in an extensive use of foil in electrolytic condensers for radio equipment, power factor condensers, etc. Aluminum foil is also used in foil and paper type condensers, in contacts for burglar alarm systems, as protecting tape for underground cables, etc. Its attractive appearance and non-toxic qualities have resulted in its being used extensively for wrapping food products and manufactured articles, such as photographic films and typewriter ribbons.

Effects of Cold Working on the Physical Properties of Aluminum and Its Alloys. The formulas given below are taken from R. L. Templin in The Aluminum Industry, Vol. II, Chap. 19, p. 396, and the American Institute of Mining and Metallurgical Engineers, Institute of Metals Division, p. 466, 1930.

Cold working is here defined as meaning the change in cross-sectional area of the metal which occurs as a result of rolling, forging, drawing, or extrusion at temperatures in the neighborhood of room temperature, that is, 60 to 80 deg fahr. In most cases the change in cross-sectional area of the metal amounts to a reduction in area. In the rolling of wide sheet, a reduction in cross-sectional area of the product may, without sensible error, be considered as resulting solely from the reduction in thickness of the product. When aluminum and its alloys are worked at temperatures above room temperature, the effects of cold working are less in proportion to the amount of working done than when they are worked at room temperature. Conversely, the working done at lower than room temperature becomes more effective than the same amount of work at room temperature.

In general, the cold working is expressed as the percentage change in the original cross-sectional area (commonly called " reduction ") as follows: $C = \frac{A - a}{A} \times 100$, wherein C = amount of cold working in percentage, A = initial area of the material in the properly annealed condition, a = area of the cold-worked material. For sheet, this formula becomes: $C = \frac{T - t}{T} \times 100$, wherein T = initial thickness of the material, and t = the final thickness. Aluminum sheet is usually rolled so as to conform to the Brown and Sharpe gage system.

The nominal amounts of cold working, together with the approximate B. & S. gage numbers' reduction for the various tempers, are given in Table VII.

Table VII. Relation of Cold Working to Temper

Temper of Metal	Approximate Amount of Cold Working *	Approximate B. & S. Gage Numbers' Reduction	
		Sheet	Wire
Soft	0	0	0
1/4 Hard	21	2	1
1/2 Hard	37	4	2
3/4 Hard	60	8	4
Hard	80	14	7

* Percentage reduction in cross-sectional area.

The effect of cold working on the tensile strength of aluminum and its alloys in the wrought condition is shown by the following formula: $T = T_0(1 + 0.9R)$, wherein T = tensile strength, lb per sq in., T_0 = tensile strength of the properly annealed material, R = reduction in area expressed as a decimal.

The yield strength of aluminum and its alloys is the stress corresponding to a limiting permanent set of 0.2 per cent. For properly annealed wrought metal this value will be approximately one-third of the ultimate tensile strength. For all the other tempers of a cold-worked product, the yield strength will vary from 80 to 95 per cent of the ultimate tensile strength.

The elognation value is affected to a considerable extent by both the size and shape of the test specimen, as well as by the ductility of the material. Cold working decreases the ductility and therefore the elongation.

The relation between the tensile strength and the Brinell hardness of wrought aluminum and its alloys may be expressed approximately by the formula:

$$BHN = T/575$$

Effects of Heat Treatment on the Physical Properties of Aluminum Alloys. The change in properties resulting from heat treatment of aluminum alloys is usually associated with a change in solubility of one or more of the alloying ingredients in aluminum with change in temperature. More than 5 per cent copper, for example, is soluble in solid aluminum just below the melting point of the eutectic, whereas at room temperature the solubility is well below 1 per cent. By heating aluminum alloys containing about 4 per cent or more of copper to a temperature slightly below the melting point of the eutectic, allowing the copper to dissolve in the aluminum at that temperature, and cooling quickly to a low temperature, the alloy becomes supersaturated in copper at the lower temperature. Such a treatment is known as a " solution heat treatment." In certain of the alloys, like 17S or duralumin, this supersaturated solid solution breaks down, at least in part, even at ordinary temperatures. This change, referred to as " aging," changes the physical properties. In certain of the alloys, because the changes produced at ordinary temperatures are insufficient for the requirements, elevated temperatures are used to effect the desired results. Such a treatment is known as the " precipitation heat treatment," or as " artificial aging." The general effect of aging is to increase hardness and strength of aluminum alloys, and the same is true of the precipitation heat treatment if it is not carried too far. This treatment, assuming prior solution heat treatment, is capable of producing a wide range of properties, without change in the composition of the alloy.

Since the alloys which age at room temperature do not acquire the full properties of the " T " condition until about four days have elapsed after quenching, the practice of forming immediately after quenching is frequently followed, particularly with strong alloys which are to be subjected to difficult forming operations. Room temperature aging can also be effectively retarded by holding the material at a low temperature after quenching. This can be accomplished by packing in ice or in frozen carbon dioxide (dry ice).

Heat treatment of aluminum alloys may be used to produce other effects, such as the removal of internal strains, stabilization of dimensions of parts used or processed at elevated temperatures, and change in particle size of constituents such as silicon, which may be present in amounts greater than can be dissolved in solid aluminum even at the eutectic temperature.

In carrying out the solution heat treatment, it is necessary to have close control of

Table VIII. Specific Gravity and Weight of Alloys

temperature. Thin pieces of wrought metal may be heated to the proper temperature and held there only a short time before cooling, with good results. This operation may be carried on in a hearth or pit furnace or in a bath of fused niter. Castings and large wrought pieces, however, must be held at the solution heat-treating temperature for considerable periods of time, and hence automatic control of temperature is a practical necessity of such operations. Cooling after the proper heating cycle may be done in cold or hot water, in oil, or in a blast of air.

The precipitation heat treatment may be effected by heating in pressure vessels with steam, or in baths such as oil, or in hearth or pit furnaces. The temperature should be well controlled for best results, and if an ordinary furnace is used, air circulation is desirable. The rate of cooling after the precipitation heating is not usually an important factor.

Specific Gravity. The specific gravity of aluminum alloys differs only slightly from that of the parent metal. The greatest increase is only about 3 per cent, and three of the alloys (51S, 52S, and 53S) are actually lighter than aluminum. The specific gravities are shown in Table VIII; the weights in pounds per cubic inch are obtained by multiplying the specific gravities by 0.03613.

Mechanical Properties. The mechanical properties of the wrought aluminum alloys are shown in Table IX. Although these properties are actually for sheet, they are generally applicable to all products except that the elongation values depend to some extent upon the size and shape of test specimen, and in certain products, such as heavy bar and plate, the amount of reduction may not be sufficient to permit development of the maximum properties of the alloy on subsequent heat treatment. All properties reported have been determined in accordance with the Standard Methods of Tension Testing of Metallic Materials (E8–33) prescribed by the American Society for Testing Materials.

Design Stresses for Aluminum Alloys. In Table X are given the stresses considered safe for ordinary structural design at temperatures below 100 deg fahr. Where temperatures above that point are to be considered, the values of Table X should be multiplied by the factors in Table XI.

Table X. Design Stresses for Aluminum Alloys

Values below are considered safe for ordinary structural design. When temperatures above 100° F are to be considered, multiply these values by factors of Table XI.

Alloy and Temper		Tension, lb per sq in.	Compression, lb per sq in.	Bearing, lb per sq in.	Shear, lb per sq in.

25. FABRICATION

Machining Aluminum. Aluminum and its alloys may be machined readily. Cutting tools for aluminum resemble in many respects those for cutting hard wood. The cutting edges must be ground to a sharp included angle, must be keen, and should be provided with smoothly finished surfaces. Such tools differ materially from brass-cutting tools. In many instances, satisfactory results may be obtained using tools ordinarily used for steel, provided they are sharp and in good condition. Steel tools for machining aluminum may be either high-carbon or high-speed types. Cemented tungsten carbide tools have been found indispensable, especially for machining aluminum alloys with high silicon content.

Forging. Forgings are produced from several of the strong aluminum alloys. The alloys are forged hot either under a hammer or in a forging press. For the general class of forgings including connecting-rods, aircraft propellers, and crankcases, the alloy 25S-T is used because of its superior hot working characteristics. Crankcases and nose pieces of more intricate design for radial aircraft engines are made from 51S-T since it is even more easily forged into the large, thin sections. For a more limited class of forgings 17S is also used. Forged pistons are commonly manufactured from 32S, which has a low coefficient of expansion, or from 18S. These alloys retain their physical properties at elevated temperatures better than some of the other aluminum alloys.

Welding. Aluminum and its alloys may be welded by the torch, arc, or electric resistance processes, by a technique that varies slightly from that applicable to steel. The equipment used in fusion welding is the same as that required for welding steel. In electric resistance welding, however, machines of greater electrical capacity and slightly different design are necessary.

A flux is used in the fusion welding processes to remove the oxide from the base metal and improve weld fusion. In metal arc welding this flux is most suitably supplied as a heavy coating on the electrode.

A 5 per cent silicon (95 per cent aluminum) alloy is used for metal arc electrodes and as a filler rod for torch welds in the strong aluminum alloys. Torch welds in common alloys (2S and 3S) are often made using a pure aluminum filler rod, especially where a polished surface is desired.

The heat of welding produces an annealing action in the common aluminum alloys and a complex—and somewhat deleterious—heat-treating effect in the strong alloys. For this reason a welded joint, except in fully annealed material, will not have mechanical properties equal to the unwelded material. In some cases, too, the heating has an adverse effect on the corrosion resistance. The metal arc will generally produce welds of greater strength than those made with the torch, but the process is not applicable to metal less than $^1/_{16}$ in. thick. Heat-treating the strong alloys after welding will improve the properties of the joint. Where the joint must develop maximum efficiency, torch welding and, in some cases, arc welding, cannot be considered equal to a well-designed mechanical type of joint.

Soldering. The soldering of aluminum presents a number of difficulties not met with in the soldering of other non-ferrous metals. The very tenacious oxide film on aluminum prevents wetting the metal when ordinary soldering technique is employed. Furthermore, many of the solders used in the past have not made corrosion-resistant joints when applied to aluminum. The situation has, however, been recently changed by development of a variety of solders and fluxes adapted to nearly all soldering requirements. By the use of the proper solder and the proper flux, and with a simple technique, aluminum parts can be joined in much the same way and for about the same type of service as solder is employed with other metals.

Finishing of Aluminum. Aluminum articles may be painted, lacquered, electroplated, oxide-coated, sand-blasted, given a frosted finish, given a satin finish by means of a wire scratch brush, or polished by suitable buffing wheels and polishing compounds.

For painting or lacquering, all that is required normally is a cleaning for grease and dirt by wiping the surface with mineral spirits or other solvent, though in the case of castings, improved adhesion may be obtained by means of a light sand blasting. Sheet or extruded shapes provide exceptionally good adhesion when they are given either an electrolytic or chemical oxide coating; the latter type of surface preparation is important in painting for protection against salt-water corrosion.

In electroplating aluminum, the surface is roughened by special etching procedures, which depend on the alloy being coated, and then plated with nickel. Any desired metal may then be plated over the nickel. For certain special applications, zinc or chromium may be applied directly to the aluminum surface. Zinc will electrochemically protect the aluminum, while chromium is of value in resisting abrasion or chemical attack by mild alkalies.

Electrolytic or anodic oxide coatings may be obtained on aluminum by making the article to be finished the positive electrode in a special electrolyte. This type of coating forms a hard, abrasion-resistant coating of superior protective value. It is usually white to light gray in appearance, but on the aluminum-silicon alloys it forms a dark gray coating, which is of artistic value, particularly on sand-blasted castings.

A frosted finish is usually obtained by etching the aluminum in a hot solution of sodium hydroxide (usually 2-5 per cent), followed by a treatment of strong nitric acid (usually 2 parts of concentrated acid to 1 part water). The nitric acid removes the colored film left on the surface by the caustic dip, but has little solvent action on the aluminum.

26. STRUCTURAL USES OF ALUMINUM ALLOYS

Although almost all the alloys mentioned in the preceding tables have been used structurally, certain ones are more important than others. These are listed below, together with a brief description of their uses.

3S Alloy. 3S is used in structural work where strength is not of primary importance or where welding is necessary. It is used for tank cars, storage containers, car and bus body plates, corrugated roofing, and the like. It is generally used in the hardest temper suitable to the necessary shop work.

4S Alloy. 4S, like 3S, is supplied in the annealed and in various cold-worked tempers. For any given temper, however, 4S has considerably higher tensile and yield strength than 3S. In the harder tempers the yield strength is comparable to that of the heat-treated alloys, although the ultimate strength is lower and the amount of forming which can be done is limited. Its uses are similar to those of 3S alloy.

52S Alloy. 52S combines mechanical properties comparable with those of 4S, with forming characteristics comparable with those of 3S alloy, and hence is developing a wide field of use. Rolled or extruded shapes of 52S, however, in common with those of 3S and 4S, cannot be cold worked sufficiently to obtain the properties of the harder tempers, the properties of such shapes usually being intermediate between those of the annealed and 1/4 H tempers. Largely because of this fact, 52S is used structurally mostly in the form of sheet and plate.

17S Alloy. Since 17S ages naturally at room temperatures following heat treatment, it does not have a stable as-quenched condition. 17S-T has tensile and yield strengths comparable with those of ordinary structural steel and is used for important strength members. When cold worked after heat treatment, the alloy is called 17S-RT and has higher properties as indicated in the foregoing tables.

51S Alloy. 51S in the as-quenched or " W " condition is very workable and hence is adapted to severe forming operations. 51S-W is used in body framing of railway cars and buses and in various welded constructions where 3S is not strong enough. As pointed out elsewhere, it can be artificially aged to 51S-T after forming, thereby gaining additional strength. 51S-T has the same yield strength as 17S-T, but its other mechanical properties are somewhat lower, as indicated in Table IX.

53S. Alloy. 53S is very similar to 51S, having slightly lower mechanical properties, somewhat greater ductility, and better resistance to corrosion, especially when compared with 51S-T. Its uses are similar to those of 51S alloy and, in addition, it is widely used for window sash, railings, store fronts, and various other architectural trim.

Casting Alloys. No. 12 alloy can be used structurally to about the same extent as cast iron. When a tight, leak-proof casting is needed, No. 43 is recommended.

Alloys 195-T6, 220-T4, and 356-T6 are heat-treated to obtain the maximum mechanical properties and are used to replace malleable-iron castings and, in some cases, steel castings. In choosing between these three alloys, it is advisable to consult the foundry to determine which is best suited to the specific conditions.

NICKEL AND NON-FERROUS NICKEL ALLOYS

By Robert Worthington

27. COMMERCIAL GRADES AND PHYSICAL PROPERTIES

Nickel is a white metal, commercially available as ingot and shot for the manufacture of alloys, anodes for electroplating, and in malleable mill products. The commercial grades of nickel produced in the United States and Canada are listed in Table I.

Malleable Nickel is available in castings and in the usual mill forms: plate, sheet, and strip; bar, rod, and wire; forgings; tubing. The metal is ductile and lends itself to ordinary fabricating operations, as drawing, stamping, spinning, machining. The strength of nickel is improved by cold-working, or by forging in the lower range of temperatures where the strains of working are not relieved, e.g., 1000-1200 deg fahr. Strengths ranging from 60,000 to 115,000 lb per sq in. are regularly furnished; spring wire carries strengths of 150,000 lb per sq in. with correspondingly low ductility.

Table I. Commercial Grades of Nickel Produced in the United States and Canada

Grades	Typical Composition							Uses
	Ni + Co	Fe	Cu	C	Si	Mn	S	
Malleable	99.00+	0.30	0.25	0.10	0.10	0.25	0.010	Rolling, forging, drawing.
Malleable, 5% manganese	94.00–95.50	0.40	0.25	0.15	0.10	4.25–5.25	0.010	Spark-plug wire, high-temperature applications,etc.
Malleable, 2% manganese	97.00–98.00	0.40	0.25	0.15	0.10	1.75–2.25	0.010	Electrical resistance wire; spark-plug wire.
Anodes; rolled and cast	99.00+	...	...	...	...	...	...	Electroplating.
Electrolytic, cathodes 27 by 36 in. and smaller cuttings therefrom	99.95	0.01–0.04	0.01–0.03	Trace	Trace	...	Trace	Highest-grade material for alloying in steel and nonferrous metals in electric, open-hearth, or crucible furnaces.
Ingot (10, 25, 50 lb) made by remelting electrolytic cathodes	99.55	0.15	0.15	0.06	0.08	...	0.010	For alloying of ferrous metals, particularly where this form is more adapted to the process involved.
Shot, made by remelting electrolytic cathodes	99.55	0.15	0.15	0.06	0.08	...	0.010	Principally used for crucible charges in ferrous and non-ferrous alloys involving small amounts of nickel.

Corrosion resistance accounts for the use of malleable nickel in caustic evaporators and in food-processing and chemical equipment; high temperature oxidation resistance

accounts for its use as automotive spark-plug wire and furnace equipment; appearance and toughness account for its use as coinage. Another important use, as elements in vacuum tubes, is based on several characteristics such as high melting point, fabricability, purity.

Physical and Mechanical Properties. **Physical and mechanical properties of nickel are given in Tables II and III, respectively. Table IV gives the technological properties of nickel.**

Table IV. Technologic Properties of Nickel

Box anneal	760	1400

Nickel-clad Steel is mild steel clad on one side with 10-20 per cent nickel. The bond is permanent under conditions of pressure, vacuum, temperature, and deformation in forming. The material is used for tanks, tank cars, and miscellaneous heavy plate construction.

28. ALLOYS OF NICKEL AND COPPER

Copper and Nickel in all proportions form solid solutions. The alloys are malleable, both hot and cold, throughout the entire range. As the nickel content increases, the alloys become stronger and tougher up to 70-80 per cent Ni. The alloys of the high copper end of the series, characterized by relative softness and high ductility, are easily and cheaply fabricated. Alloys low in nickel show a characteristic pink color, which disappears at 20 to 25 per cent nickel. Alloys with about 25 per cent nickel have a white color, such that nickel appears slightly yellow in comparison.

The nickel-copper alloys are hardened and strengthened by cold work, the high-nickel-content alloys to a considerably greater extent than the low-nickel. The tensile strength of spring temper Monel metal runs around 150,000 lb per sq in., whereas 80/20 cupro-nickel runs around 85,000 lb per sq in. Typical values of the physical and mechanical properties of copper-nickel alloys are given in Tables V and VI, respectively.

Monel Metal

Monel Metal * is a nickel-copper alloy of the following composition: Ni, 65–70 per cent; Cu, 26–30 per cent; Fe, to 3.0 per cent; Mn, to 1.5 per cent; Si, to 0.25 per cent; C, to 0.25 per cent. Spring wire sometimes carries a higher silicon (to 1.25 per cent) or manganese (to 2.5 per cent) content, and high-strength castings higher copper (to 34 per cent) and silicon (to 4 per cent) content.

Physical and Mechanical Properties. In appearance and in physical and mechanical properties Monel metal closely resembles malleable nickel. It is white, malleable, and ductile, both hot and cold, and corrosion resistant. The physical and mechanical properties of Monel metal are given in Tables VII and VIII, respectively. The effect of temperature on the tensile properties of hot-rolled Monel metal is given in Table IX.

"K" Monel Metal. A special grade of Monel metal, designated as "K" Monel metal, carries about 3.75 per cent aluminum. This modification is hardened and strengthened by heat-treatment, as well as by cold-working. The properties are given in Table X. Softening is effected by quenching in water from 1400–1500 deg fahr; hardening by slow furnace cooling from 1000–1100 deg fahr, with or without previous cold-working.

Fabrication. *Hot-working.* Monel metal responds to all hot-working operations within the temperature range of 1900 to 2100 deg fahr. With care, the temperature of the metal may be extended to 2150 deg fahr, but it loses all malleability at about 2200 deg fahr. Hot forging should not be attempted between 1200 and 1600 deg fahr, and only where

necessary for special conditions between 1600 and 1900 deg fahr. Sulfur-free fuel should be used for heating furnaces, and a definitely reducing atmosphere is desirable.

Table XI gives the temperature ranges for hot working of Monel metal.

Table XI. Technologic Properties of Monel Metal

Process	Deg Cent	Deg Fahr
Pouring (castings)................................	1540–1565	2804–2849
Forging..	1000–1175	1832–2147
Annealing:		
Open anneal....................................	925– 980	1697–1796
Box anneal......................................	750	1382

Cold-working. Monel metal is similar in many respects to mild steel in mechanical cold working, as in cupping, drawing, swaging, die forging, power hammering, bending, and forming. The elastic limit is higher; hence more power is required. Annealing for further cold work is accomplished by either box or open annealing methods. Sulfur-bearing atmosphere must be avoided and a reducing temperature is desirable.

Machining. Best results are obtained with cutting tools having slightly sharper cutting angles than required for steel. Cutting tools, where possible, are ground to a 15–20 deg rake back from the cutting edge. Self-opening die heads are necessary for successful thread chasing, and high-speed cutting tools are imperative. Sulfur-base oil, cut with a paraffin-base oil, is a better coolant than straight paraffin-base oil. For automatic work a free machining quality rod is available.

Welding. Monel metal welds readily by the several electric and gas methods. In arc welding, a special deoxidizing flux gives the best results. The flame, in gas welding, must be on the reducing side, close to neutral, and the work must be done rapidly and without rewelding. Fused boric acid is used as a flux.

Soldering. Soft solders, either high or low in tin, work well with Monel metal. Lead fillets are used for special purposes, and brazing and silver solders for strong joints where special corrosive substances are being handled.

Pickling. In commercial pickling, the oxide is first reduced by heating and cooling in a definitely reducing atmosphere, then the metal is submerged in a solution of 6 lb sodium nitrate, 3 lb sodium chloride, 1 gal concentrated sulfuric acid per 40 gal water, held at 180–200 deg fahr. Where reducing treatment cannot be applied, the metal is dipped in a hot moderately strong solution of hydrochloric acid and scrubbed with abrasive.

Uses. Because of its corrosion resistance and appearance, Monel metal is used for sheet-metal work of kitchens, restaurants, and soda fountains; architectural trim: and containers for handling acids, alkalies, salt solutions, food products, etc. Its strength and toughness make it useful for turbine blading, valves, marine propeller shafting, springs, etc.

Other Nickel-copper Alloys

Nickel 40-45 Per Cent. Alloys with 40–45 per cent nickel have a low temperature coefficient of electrical resistance, combined with relatively high resistivity (see Table V, 11–72) and thus are used for rheostats and resistances of all kinds which run at black heat. This alloy is used also for low-temperature heaters, bed warmers, etc.

The thermoelectric force developed between the 40–45 per cent nickel-copper alloy and either iron, copper, or nickel-chromium is high, and for that reason these combinations are used in thermocouples for pyrometric work.

Cupro-nickel Tubing. Copper-nickel alloys with 20 and 30 per cent nickel, both with and without zinc, are used as tubes for the more severe air impingement conditions of marine and stationary condensers handling sea water or corrosive inland waters at high velocity.

Coinage. The alloy with 25 per cent nickel is used for coinage by several countries, a use depending on appearance and toughness.

High Ductility Cupro-nickel. Copper-nickel alloys with 15–20 per cent nickel will stand excessive cold work in drawing and forming, without intermediate anneals. For this reason these alloys are used as bullet envelopes and deep drawings.

2-4 Per Cent Nickel. Small amounts of nickel improve the strength of copper in the elevated temperature range, and for that reason such alloys are used as heat interchanger tubes and particularly in locomotive work for stay rods and boiler and flue tubes.

29. ALLOYS OF COPPER, NICKEL, AND ZINC

Alloys of Copper, Nickel, and Zinc are known commercially as nickel-silver or german silver. It is usual to designate an alloy by the nickel content, e.g., 18 per cent nickel-silver.

In composition, the nickel-silvers range from about 10 to 25 per cent Ni and from 3 to 40 per cent Zn. In these ranges fall the common casting and cold-working compositions. Alloys with 10 per cent Ni or less and high Zn are regularly extruded. In some cases alloys with 10 to 15 per cent Ni are extruded, at least in simpler shapes. Alloys with Zn less than 10 per cent can be hot-worked, though not hot-extruded.

The strength of the nickel-silver alloys is improved only by cold working. Thus spring temper sheet and strip of an 18 per cent Ni and 27 per cent Zn alloy carries a tensile strength of 100,000 lb per sq in., and spring temper wire a tensile strength of 143,000 lb per sq in.

Cast and wrought alloys of nickel, copper, and zinc and their properties are given in Tables II, III, respectively, pp. 11–41 to 11–51.

30. ALLOYS OF NICKEL AND CHROMIUM

Nickel-chromium Alloys with 20 per cent or less of chromium have been used for years as elements in resistance heating devices, a use depending on both high resistivity and very good resistance to deterioration up to temperatures as high as 2100–2150 deg fahr. Data on these alloys are given in the section on conductor materials, pp. 11–92 to 11–101.

Nickel and chromium alloys, particularly when carrying iron, are used very extensively in high-temperature service aside from electrical resistance applications, and in handling corrosive substances. For nickel-chromium-iron alloys, see pp. 11–25 to 11–36.

MAGNESIUM AND MAGNESIUM ALLOYS

By John A. Gann

31. PROPERTIES AND USES OF MAGNESIUM

Magnesium is a silver-white metal and is the basis of the lightest structural alloys. It is produced by the electrolysis of molten anhydrous magnesium chloride. Domestic magnesium averages 99.94 per cent pure. Table I gives the properties of magnesium. A special product containing nominally 99.99 per cent magnesium is produced in small quantities by sublimation of the regular commercial grade. The more important uses are: (1) Chemical, based on its chemical reactivity when in a finely divided form or at high temperatures. These uses include pyrotechnics, flares, Grignard reaction, and desulfurization of nickel and nickel alloys. (2) Alloying ingredient: the addition of small amounts of magnesium to certain types of alloys gives marked improvement in physical properties, as in aluminum alloys and zinc die-casting alloys. (3) Structural material, as ultra-light alloys, castings, and wrought shapes. The structural stability and engineering properties of magnesium alloys adapt them to a wide variety of service conditions.

Btu per hr per sq ft per deg fahr per in	1102	....

* Unless otherwise noted, the magnesium used in the determination of many of the above properties had a purity of 99.9 to 99.99 per cent. Metal of approximately the same purity was probably used in the determination of the other properties, although the literature is silent on this point.

32. MAGNESIUM ALLOYS

Composition, and Physical and Mechanical Properties. Present (1936) commercial alloys, as Dowmetal, AM Alloys, and Bohnalite " X," contain between 88 and 99 per cent Mg. Tables II and III give the nominal compositions, uses, and physical and mechanical properties of these alloys.

Lightness is the most outstanding characteristic of magnesium alloys and is responsible for many of their present uses. Aluminum alloys are 1 $^{1}/_{2}$ times as heavy, cast iron and steel are approximately 4 times as heavy, and brass and bronze 5 times as heavy.

Strength characteristics, as tensile properties, toughness, and fatigue endurance, recommend magnesium alloys for a wide variety of applications. The cast alloys have properties substantially the same as those of cast aluminum alloys, when compared on an equal volume basis. On an equal weight basis, magnesium alloys have strength properties equal, or superior, to those of most other metals. (See Table IV.) Strength decreases with rise in temperature. In general, magnesium alloys are not recommended for use at temperatures above 400 deg fahr.

Available Forms. Magnesium alloys are available in a wide variety of cast and wrought forms. Sand castings vary in weight from a few ounces to approximately 700 lb. Die castings can be made in sizes having projected areas up to 100 sq in. and weighing up to 3 lb. Forgings range in size from small resonator horn disks to aircraft propellers. Sheet is available in sizes up to 20 ft long by 4 ft wide. Structural shapes, produced by extrusion, cover a complete range of sizes of round, square, and hexagonal bars, angles, I-beams, channels, and special sections.

Corrosion. Magnesium alloys are stable under ordinary exposure conditions, the surface gradually darkening with no decrease in strength. In heavy industrial areas, or in humid atmospheres along the seacoast, surface roughening may occur, and some protection may be desirable. Aqueous salt and acid solutions corrode magnesium alloys, with the exception of pure chromic acid, pure concentrated hydrofluoric acid, and alkali metal fluorides, chromates, and bichromates. The alloys are resistant to attack by most alkalies and many organic chemicals, including hydrocarbons, phenols, and oils.

§ Specific strength values are the normal strength values divided by the specific gravity.

Protection. Paints, varnishes, lacquers, and enamels of all types can be applied to magnesium alloys, although many paint materials, within a class, vary considerably in quality and service performance. Synthetic resin varnishes and enamels are the best all-round coatings, both for protection and high-grade finish. Baked finishes combine speed of finish with excellent adhesion, hardness, and toughness of film. Prior to painting, the metal should be cleaned free of dirt and grease, and then chrome-pickled. This consists of a short-time dip in a bath of 1.5 lb $Na_2Cr_2O_7$ and 1.5 pt concentrated HNO_3 per gallon of solution, followed by a thorough wash and rapid drying. Properly applied, this treatment produces a dull, iridescent bronze finish, combining a mechanical " tooth " and chemically inhibitive film, which greatly improves the adhesion and protective value of the paint coating.

Fabrication and Use

Foundry. Sand castings may be made in dry sand but are normally made in green sand to which has been added small amounts of fluorides, sulfur, boric acid, or other materials which inhibit the action of water vapor on the hot metal. Shrinkage factors are: $^3/_{16}$ in. per ft for castings of moderate size or with unrestrained shrinkage, $^5/_{32}$ in. per ft for large castings. Pattern equipment designed for aluminum work usually is satisfactory for magnesium alloys. Heat treatment effects pronounced improvement of the properties of most of the alloys, and is used where service conditions are severe. The properties of the as-cast metal are satisfactory for many industrial applications. Magnesium alloy die castings possess all the advantages of other types of die castings, plus light weight.

Machinability of magnesium alloys is superior to that of any other common metal. Both speed and depth of cut can be increased. Sharpness and proper clearance of cutting tools are essential for best results. The alloys finish exceptionally smooth with no tendency to tear or drag. Cutting compounds are recommended in certain high-speed operations, such as screw machine work.

Hot and Cold Working. Most plastic deformation operations on magnesium alloys are performed between 400 and 800 deg fahr. At these temperatures the alloys may be extruded, rolled, forged, and formed. Best results are obtained by working at moderate speeds and allowing generous bend radii. The alloys work-harden at or near room temperature more rapidly than many metals, and cold-working operations usually are limited to simple steps with small changes in shape or cross-section.

Joining. Magnesium alloy parts are joined by riveting or welding. Aluminum-alloy rivets, preferably containing no nickel or copper, should be used. Rivet holes should be $^1/_{64}$ to $^1/_{32}$ in. larger than shank diameter. The bearing strength of magnesium alloy sheet is approximately 50 per cent greater than its tensile strength. Galvanic corrosion in riveted assemblies is minimized by bitumastic paint or reinforced red lead between contacting, dissimilar metals.

Oxyacetylene, Electric Spot, and Seam Welding are feasible with magnesium alloys using technique similar to that used with aluminum. Acetylene welds have the strength of as-cast metal. A filler rod, of the same approximate composition as the base metal, and a flux are used. After welding, complete removal of flux is essential to prevent corrosion. It is removed by washing in hot water, followed by the chrome-pickle treatment (see above). Electric spot and seam welds are made on machines with water-cooled electrodes. Welds on $^1/_8$-in. sheet have a strength of approximately 1800 lb per spot, or 20,000 lb per linear foot of seam.

Uses. Magnesium alloys are standard materials of construction for many airplane parts, including crankcases, starting equipment, instrument housings, and landing and tail wheels. Sheet, plate, and structural shapes are used to increase the ratio of payload to dead load in trucks and trailers. Used in portable tools and equipment, these alloys reduce human fatigue, and in high-speed automotive equipment they improve operating efficiency.

TUNGSTEN

By Zay Jeffries

33. PROPERTIES AND USES OF TUNGSTEN

Tungsten, a metallic element, is very important, although the total amount produced seems insignificant as compared with some of the other metals. Because of several peculiar properties, tungsten is irreplaceable for some important uses.

Manufacture of Tungsten. Until 1904, pure tungsten had been produced only in the form of a powder or a non-coherent sponge. It was not used, except for alloying with other metals, until the invention of the tungsten incandescent lamp filament, in 1904, by Just and Hannaman. The filaments were of the squirted or pressed type, prepared by mixing tungsten powder with a binder, squirting the mixture through a die, and subsequently removing the binder or the greater portion of it by passing electric current through the filament, which also served to sinter or consolidate the tungsten into a coherent and fairly dense condition. Such filaments were brittle and fragile but were used in incandescent lamps until about 1911. In 1908, the General Electric Co. succeeded in producing ductile tungsten. Strong wrought tungsten, not ductile when cold, was also produced.

Tungsten ingots for working are pressed from dry powder and heated to a temperature near the melting point to consolidate. The resulting ingots are brittle when cold but somewhat malleable when hot.

In swaging an ingot from about 1/4 in. square, the work all being done at a high temperature, the rod is brittle cold and malleable hot until the swaged rod is about 50 mils diameter. At a size near 50 mils diameter, above or below as the working temperature is low or high respectively, the swaged rod becomes ductile cold.

Physical and Mechanical Properties. The properties of tungsten are: atomic weight, 184.0; melting point, 3382 deg cent (highest of all metals and among the elements exceeded only by carbon); coefficient of linear expansion, 0.000,004,44 per deg cent at 27 deg cent (Worthing); electrical resistivity at 0 deg cent, 0.000,004,91 ohm-cm for pure single crystal wire, 0.000,005,05 for ordinary polycrystalline wire; at 20 deg cent, 0.000,005,50. Very fine wire as drawn may have a value as high as 0.000,008, which is reduced to about 0.000,006 or somewhat less by heating to a high temperature. The average temperature coefficient of resistivity between 0 and 100 deg cent is about 0.0047 per deg. Resistance at 2100 deg cent is about 12 times and at 2400 deg cent about 15 times the resistance at room temperature. Modulus of elasticity is 40,000 kg per sq mm or about 57,000,000 lb per sq in. Poisson's ratio is 0.17, independent of temperature. The thermal conductivity is 1.17 watts per sq cm per deg cent per cm at 2000 deg cent, 1.66 at 0 deg cent, 2.32 at −190 deg cent, and 34.3 at −252 deg cent. It is weakly paramagnetic. The electronic work function is 4.54 volts. Tungsten crystallizes with a body-centered cubic space lattice, the length of a side of the unit cube being 3.155 Angstrom units and the nearest approach of atom centers 2.732 Angstrom units. Fine tungsten wire is stronger than any other material known. The remarkable improvement in tensile strength by working is shown in Table I.

Table I. Tensile Strength of Tungsten

Kind of Material	Diameter, mils	Tensile Strength, lb per sq in.	Kind of Material	Diameter, mils	Tensile Strength, lb per sq in.
Sintered tungsten ingot	200 × 250	18,000	Drawn wire.......	5.78	366,000
Swaged rod...........	216	50,000	" "	5.50	378,000
" "	125	107,000	" "	3.96	483,000
" "	80	176,000	" "	1.14	590,000
" "	26	215,000	" "	1.00	650,000
Drawn wire...........	18	264,000	" "	0.50	700,000
" "	7.23	340,000			

Drawn tungsten can be treated to a higher temperature than any other metal without removing the effects of working (strain hardening). A 25-mil drawn wire had a tensile strength of 101,000 lb per sq in. at 890 deg cent, a value not equaled by any other metal.

Drawn tungsten wire has some peculiar properties. When ductilized by the swaging and drawing process, it is typically ductile. That is, it can be drawn further cold, but it is not typically malleable; it splits into many fibers when hammered on an anvil. When ordinary drawn metals are heated so as to cause the strain-hardened grains to recrystallize, the ductility, largely lost because of the drawing, is restored. Ductile tungsten so treated becomes brittle at ordinary temperature, and to make it again ductile it must be further worked hot, but below the recrystallization temperature

Corrosion. Tungsten metal in the powdered state is black when finely divided and gray when coarse. In air at ordinary temperatures, the coherent and dense metal slowly oxidizes on the surface until a thin film of oxide stops further action. It is rapidly dissolved by fused alkali nitrates and nitrites and slowly attacked by hot aqua regia or strong hydrogen peroxide.

Tungsten is scarcely attacked by hydrochloric, nitric, or sulfuric acids owing to the formation of a protective film or tungstic acid. It is rapidly dissolved by hydrofluoric acid containing nitric acid, giving a clear solution. When heated above a red heat it oxidizes fairly rapidly. Exposed at high temperatures to carbon monoxide or hydrocarbon gases two tungsten carbides (reported to be WC and W_2C) form.

Cemented Carbides. Tungsten is the most important element in the so-called cemented carbides now used extensively for cutting tools, wire drawing and other dies, and wearing parts of machinery. The cemented tungsten carbide is made by producing very fine tungsten carbide powder approximating the composition of WC. This is mixed with metallic cobalt from about 3 to 20 per cent by weight according to the hardness and wearing properties desired, and sintered at a temperature far below the melting point of the tungsten carbide. This material has remarkable cutting and wear-resisting properties. It is relatively expensive as compared with the common cutting tools, and tools are therefore usually made by attaching a small tip of the cemented carbide to a steel shank by copper brazing. In a similar manner the drawing dies are usually made by mounting a relatively small piece of the cemented carbide in a steel casing. Other carbides such as tantalum carbide and titanium carbide have been used to add to the tungsten carbide, principally for the purpose of enhancing the steel-cutting qualities.

Uses. Wrought and ductile tungsten are now used for many purposes. Drawn wire has supplanted the pressed filaments for incandescent lamps. Tungsten is also used for talking-machine needles, filaments for radio and rectifier tubes, electric furnace resistors, and lamp filament supports. The wrought tungsten has been made in rods up to about $^3/_4$-in. diameter, and in sheet. Wrought tungsten is used principally for x-ray targets and contacts for internal-combustion ignition appliances such as Delco.

By far the greater part of the tungsten produced is used in making alloy steel, principally into high-speed steel, which contains about 18 per cent tungsten, and into magnet steel. The use of small percentages of tungsten in some structural steels seems assured. Tungsten is added to steel either in the form of tungsten powder or preferably as ferrotungsten containing at least 75 per cent tungsten.

MOLYBDENUM

By Zay Jeffries

34. PROPERTIES AND USES OF MOLYBDENUM

Molybdenum is a hard, silvery-white metallic element. Its use as a metal followed that of tungsten. It was prepared by squirting into small wires which were used for filament supports in incandescent lamps. It is still used for this purpose but the wires are drawn.

Manufacture. Wrought and drawn molybdenum were developed by the General Electric Co. about 1908. Wire is made by hot drawing, at least in the early stages of drawing. The ingots are prepared by pressing powdered metal and consolidating below the melting point. These are brittle when cold and must be worked hot. After the hot working has progressed to a certain point, the rod becomes ductile cold.

Physical and Mechanical Properties. Some of the properties of molybdenum are: atomic weight, 96.0; density, 10.21 g per cu cm; coefficient of linear expansion, 0.000,005,00 per deg cent at 27 deg cent (Worthing); electrical resistivity at 0 deg cent, 0.000,005,08 ohm–cm; at 2000 deg cent, 0.000,006,15; average temperature coefficient of resistivity between 0 and 100 deg cent, 0.0047; thermal conductivity is 1.43 watts per sq cm per deg cent per cm at 0 deg cent. It is weakly paramagnetic. The electronic work function is 4.41 volts. Molybdenum crystallizes with a body-centered cubic space lattice, the length of a side of the unit cube being 3.142 Angstrom and the nearest approach of atom centers 2.720 Angstrom.

Table I gives typical mechanical properties of molybdenum wire, 25 mils diameter, treated in various ways.

Table I. Mechanical Properties of Molybdenum

Description	Tensile Strength, lb per sq in.	Elongation in 2 in., per cent	Reduction of Area, per cent
Swaged and drawn hot (1000–1300° C) from 25 to 125 mils	148,000	4.7	68
Swaged and drawn hot (black heat–800°) from 25 to 125 mils	154,000	5.7	65
Annealed to produce large grains	42,500	3.15	None
Annealed to produce very small grain size	125,000	20.0	66

Brittle molybdenum can be ductilized like tungsten by working below the recrystallization temperature. Unlike tungsten, drawn wire can be recrystallized with an increase in ductility if the annealing temperature is low, say 1050 deg cent, so as to produce a fine-grained structure. Higher annealing temperatures produce larger grains, causing a diminution in cold ductility.

Corrosion. In air at ordinary temperatures, dense and coherent molybdenum, like tungsten, slowly oxidizes superficially, the action stopping with the formation of a protective film of oxide. At red heat, the oxidation proceeds rapidly with the formation and volatilization of molybdenum trioxide. It is attacked or dissolved by nearly all reagents which attack tungsten. It is soluble in nitric acid, sulfuric acid, and hydrogen peroxide.

Uses. Molybdenum is used mostly as an alloying element in steel. Although it imparts characteristics to steel somewhat similar to those imparted by tungsten, the two metals are not interchangeable, volume for volume. Molybdenum has never been as successful in high-speed steel as tungsten. It is used chiefly in structural steels for automobiles in amounts less than 1 per cent. The wrought metal is used for x-ray targets, the wavelength being quite suitable for the study of crystal structure.

DIE-CASTING ALLOYS

By J. C. Fox

35. TYPES OF DIE-CASTING ALLOYS

Die-casting alloys may be classified into six main groups:

1. Tin-base alloys: tin, alloyed with copper, antimony, and lead.
2. Lead-base alloys: lead, alloyed with antimony or antimony and tin.
3. Zinc-base alloys: zinc, alloyed with aluminum, magnesium, and/or copper.
4. Aluminum-base alloys: aluminum, alloyed with copper, nickel, silicon, iron, and manganese.
5. Copper-base alloys: the brasses and bronzes, copper, alloyed with zinc, tin, lead, aluminum, nickel, manganese, etc.
6. Magnesium-base alloys: magnesium, alloyed with aluminium, manganese and nickel.

Tin-base Alloys. Table I gives the composition of typical tin-base alloys used in die casting.

Alloy No. 1, of Table I, is the highest quality "babbitt" mixture corresponding to S.A.E. specification No. 10 Babbitt. It is used for main shaft and connecting-rod bearings in the automotive and aircraft industries. No. 2 also is used for bearings and other applications requiring a high-class tin-base alloy. It fulfils S.A.E. specification No. 11. No. 3 is a special automotive bearing composition. No. 4 (S.A.E. Specification No. 12), because of the lead content, is of lower cost than the others.

Table I. Typical Tin-base Die-casting Alloys

Alloy No.	Copper, per cent	Antimony, per cent	Lead, per cent	Tin, per cent
1	4.50	4.50	......	90.0
2	6.0	8.0	......	86.0
3	7.75	7.75	1.75*	82.75
4	3.0	10.50	25.0	61.50

Although tin-base alloys are used mostly for automotive bearings, they also are used in parts of soda fountains, milking machines, syrup pumps, and similar apparatus where resistance to the action of acids, alkalies, and moisture is essential. They are also used to some extent for surgical instruments, dental appliances, etc., because of their resistance to corrosion.

Lead-base Alloys. The compositions of typical lead-base alloys used in die castings are given in Table II.

Lead-base alloys are used where a cheap non-corrosive metal is required and where strength, hardness, and other mechanical properties are unimportant. Parts which must resist strong mineral acids as in the chemical industry are made of lead-base die alloys. X-ray apparatus parts are made of lead-base alloys, because of the opacity of lead to the x-rays. The high density or unit weight of lead is another factor in its use.

Table II. Typical Lead-base Die-casting Alloys

Alloy No.	Antimony, per cent	Tin, per cent	Lead, per cent
5	5	..	95
6	10	..	90
7	17	..	83
8	15	5	80

Zinc-base Alloys. The zinc-base die-casting alloys in most common use today are those conforming to the A.S.T.M. Tentative Standard B86–34T and the S.A.E. Standards 921 and 903.* Chemical composition limits for these alloys are given in Table III.

Table III. Composition of Zinc-base Die-casting Alloys

Composition	A.S.T.M. Alloy XXI S.A.E. Alloy 921	A.S.T.M. Alloy XXIII S.A.E. Alloy 903
Copper, per cent	2.50–3.50	0.10 max.
Aluminum, per cent	3.50–4.30	3.50–4.30
Magnesium, per cent	0.02–0.10	0.03–0.08
Iron (max.), per cent	0.100	0.100
Lead (max.), per cent	0.007	0.007
Cadmium (max), per cent	0.005	0.005
Tin, per cent	0.005	0.005
Zinc	Remainder	Remainder

The percentages of lead, tin, and cadmium given in this table should not be exceeded if stability of properties, dimensions, and corrosion resistance are to be expected. This makes necessary the use of the highest purity metals: zinc of the 99.99+ per cent purity grade; electrolytic copper; 99+ per cent aluminum; 99.9+ per cent magnesium. Precaution must also be taken to insure against contamination with injurious metals in the melting and casting operations.

The A.S.T.M. and S.A.E. Standards call for the minima of physical properties of die-castings of these alloys, as given in Table IV.

Table IV. Minimum Physical Properties of Zinc-base Die-casting Alloys

Property	Alloy XXI	Alloy XXIII
Tensile strength, lb per sq in	44,000	35,000
Charpy impact, ft-lb	6.0	12
Elongation in 2 in., per cent	2.0	3

Average physical and mechanical properties of these two alloys, as determined from die-cast test bars, made in accordance with the A.S.T.M. specifications, are given in Table V. Though the A.S.T.M. Alloy XXI possesses higher tensile strength and hardness than the Alloy XXIII, the latter alloy, because of its greater dimensional stability, and higher impact strength which remains unchanged even under the severest conditions of use, is usually favored for applications requiring strict maintenance of properties and dimensions.

Table V. Physical and Mechanical Properties of Zinc-base Die-casting Alloys

Property		Alloy XXIII
Density, g per cu cm	6.7	6.64
Melting point, deg fahr	734°	728°
Specific heat, g-cal per g per deg cent	0.10	0.10
Thermal conductivity, g-cal per sec per sq cm per deg cent per cm	0.25	0.27
Thermal expansion per deg cent	$27.7 \times 10^{-}$	27.4×10^{-6}
Electrical conductivity, mho-cm at 25 deg cent	144,000	155,000
Tensile strength, lb per sq in	48,000	40,000
Elongation in 2 in., per cent	5	5
Compressive strength, lb per sq in	93,000	60,000
Shearing strength, lb per sq in	45,800	31,000
Transverse deflection, in	0.22	0.27
Brinell hardness number	83	74
Charpy impact strength, ft-lb (1/4" × 1/4" bar)	19	20

Pressure die-castings made from these alloys have high strength, high ductility, resistance to impact, and good corrosion resistance, and they are easily machined. Practically every type of commercial finish may be satisfactorily applied. Zinc-base die-castings are widely used for automotive parts, household and office appliances, and miscellaneous objects such as toys, novelties, and ornaments.

Aluminum-base Alloys, see p. 11–60.

Copper-base Alloys. Until recently (1932), commercial die-casting practice was limited to the casting of alloys of comparatively low melting points. Progress developed along the line of higher melting points. Tin and lead alloys of casting temperatures up to 650 deg fahr were first used, followed by zinc-base alloys with casting temperatures up to 800 deg fahr, in turn followed by aluminum-base alloys with casting temperatures up to 1300 deg fahr. Difficulties in the manufacture of die castings multiply rapidly with the rise in the melting points of the alloys. The life of the die decreases with ascending casting temperatures. The Doehler Die Casting Co. perfected (1931) a process for the pressure die casting of copper-base alloys. Typical die-casting alloys of this group are given in Table VI. Mechanical properties of these alloys are given in Table VII.

---

* These alloys also conform to the "Zamak" series of the New Jersey Zinc Co. (U. S. Patents 1596761, 1779525, 1852441.)

Table VI. Nominal Composition of Copper-base Die-casting Alloys

Composition	Alloy 1	Alloy 2	Alloy 3
Copper, per cent	57.0-59.0	63.0-66.0	80.0-81.5
Zinc, per cent	40.0-42.0	32.0-34.0	13.5-15.0
Tin, per cent	0.5-1.50	....	....
Silicon, per cent	....	0.75-1.25	4.0-5.0
Lead, per cent	....	....	....
Nickel, per cent	....	....	....
Manganese, per cent	....	....	....

Table VII. Mechanical Properties of Copper-base Die-casting Alloys

Property	Alloy 1	Alloy 2	Alloy 3
Tensile strength, lb per sq in	55,000-65,000	65,000-75,000	85,000-95,000
Yield point, lb per sq in	35,000-40,000	35,000-40,000	65,000-70,000
Elongation in 2 in., per cent	15-20	15-20	10-15
Brinell hardness	120-130	110-120	160-180

Magnesium Base Alloy (see also p. 11-76). Although at present only a few magnesium-base alloy die-castings are being produced, it is interesting to note that a subcommittee of committee B-6-A.S.T.M. is functioning on this type of alloy. This committee has prepared tentative specifications (A.S.T.M. Tentative Standard B94-36T) covering "Alloy 12" as follows:

Aluminum, per cent	10.0 ± 1.0
Silicon, per cent	0.5 ± 0.5
Manganese, min. per cent	0.10
Copper, max. per cent	0.05
Nickel, max. per cent	0.03
Magnesium, per cent	Remainder

BEARING METALS

By Christopher H. Bierbaum

36. PROPERTIES AND USES OF BEARING METALS

Bearing Metals are alloys composed of two or more metals in proportions in which they do not enter into a solid solution. They consist of relatively hard and soft microscopic particles or crystals intimately mixed. The function of the hard particles or bearing crystals is to support the load and resist the wear at times when actual metallic contact exists between the bearing surfaces. The softer particles, in a measure, owing to their plasticity, allow the harder particles to adjust themselves to the surface requirements of the journal. The softer particles also wear down lower than the harder particles and thus form slight depressions on the apparently smooth bearing surface. These depressions retain some of the lubricant and thereby effect a residuary lubrication, sufficient to prevent scoring or cutting during metallic contact. The property of a metal to retain lubrication upon a "run-in" bearing surface characterizes it as a bearing metal, and its capacity for doing so largely determines its value as such. A bearing metal, therefore, may be defined as an alloy that is capable of retaining a lubricant upon a bearing surface. Heretofore a run-in bearing surface could be produced only under service conditions, wherein it was necessary that all the disturbed metal on the surface, incident to tooling, should first be worn off; this was tedious and often caused bearing surface inaccuracies before a run-in condition was obtained. Recently (1928), however, a high state of perfection of diamond tooling has enabled the production of bearing surfaces that approach insensibly close to those run-in in service.

This effects a twofold economy: it reduces the time for fitting and running-in; and it enormously prolongs the life of bearings. Nevertheless, journal and bearing should mutually polish each other. Bearing and journal therefore should bear some relation to each other, e.g., their hardest particles, for best results, should be of the same order of hardness. These requirements would not be imperative, were the journal to possess infinite hardness and the cylindrical surface to be ideally true. A highly accurate, ground and polished journal surface of chromium plate, nitrided nitralloy steel, or hardened tooled steel closely approaches this ideal state. The mating member, nevertheless, should have the microstructure of a bearing metal.

It is essential that, with two surfaces bearing together, one, say the journal, should have the highest possible microscopic homogeneity, and the other a heterogeneity corresponding to that of a bearing metal.

Babbitt Metals. The alloys in Table I are from A.S.T.M., 1933 Standards, Part 1, p. 845. These alloys cover the field very completely and can be recommended for the uses outlined below:

No. 1 is suited for crankpin service in steam and internal-combustion engines. It should be well confined in its backing or be used as a thin layer sweated onto bronze or steel. It is the least likely to crack and the most plastic of the tin-base alloys.

No. 2 is suited for substantially the same service as No. 1. It has, however, a higher bearing value, and is less likely to pound out. Like No. 1, it is especially suited for sweating on, owing to its high tin content.

No. 3 is the hardest babbitt and has the highest bearing value. When allowed to cool and solidify very slowly, it develops the $SnCu_4$ crystal, which is the hardest copper-tin constituent; it should therefore never be mated with the softest steels. It is ideal for the highest service requirements when well seated and not subjected to loose pounding.

No. 4 alloy has excellent bearing value for engine main bearings and general machinery, machine tools, and the like. It will withstand severe punishment and give general satisfaction. It is the most economical tin-base babbitt.

Nos. 5 and 6 are intermediate alloys, neither tin nor lead base. They are alloys in which the soft matrix contains the tin-lead eutectic, for which reason they become mushy at a relatively low temperature. They are not to be recommended for either service or economy, as compared with Nos. 4 and 7.

No. 7 is the most economical of the lead-base alloys. Its entire tin content is combined with antimony, giving a high percentage of bearing crystal; for that reason it is very serviceable. It is even suitable for use in many places where the high-tin babbitts are now specified.

Nos. 8, 9, and 10 are all lead-base babbitts belonging to the same general class. Their bearing value decreases with a decrease of tin content. They are serviceable with relatively light loads; with good workmanship they stand high speeds and are suitable for mating with the softer steels.

Nos. 11 and 12 are antimonial lead alloys and constitute the cheapest grade of babbitt. They should be used for the lightest service only, such as line shafting and less important bearings; they are suited to mate with the softest steels.

Bronze Alloys. Up to the present time (1936) a vast number of bronze bearing formulas have been evolved, many of them even of doubtful value. The whole range of engineering work, however, can be covered satisfactorily by a comparatively small number of alloys. Those given in Table II are an approved list, from which the engineer can select a bearing for any and all requirements encountered in practice. This table is the result of selections and rejections of bearing formulas, during a period of more than 39 years, in an effort to reduce this entire field of alloys to an efficient minimum number.

The phosphorus content of a bronze, be it a trace or an amount not in excess of 0.25 per cent, has no appreciable effect, either upon the physical properties or bearing value of the resulting bronze; it is important, however, that deoxidation with phosphorus be effected. Hence, deoxidation with phosphorus should be specified and a trace of it required in the resulting alloy.

Considerable work and research have been done on casting bearing bronzes centrifugally; so far, however (1936), there is no proved advantage either as to physical properties or bearing value of any centrifugally cast material. The advantages claimed are entirely due to the chill effect incident to the process, and the question is one of economic production. Chilling, however, can best be controlled in stationary molds.

The importance of high-class workmanship cannot be overestimated, especially with the harder bearing metals and their harder mating journals. Grinding or lapping is ideal for the production of accurate surfaces, but, owing to the microconstituents of bearing metals, great care should be taken not to leave grinding particles embedded in the softer constituents of the bearing surface.

* The compression test specimens were cylinders 1 1/2 in. long and 1/2 in. in diameter, machined from chill castings 2 in. long and 3/4 in. in diameter. The Brinell tests were made on the bottom face of parallel machined specimens cast in a 2-in. diameter by 5/8-in. deep steel mold at room temperature.

† Permissible variations in percentages of the desired elements are as follows:

Percentage of element specified.......	not over 2	2-5 in.	5-10 in.	over 10
Permissible variation, units of per cent.	0.25	0.50	0.75	1.0

‡ The values for yield point were taken from stress-deformation curves at a deformation of 0.125 per cent reduction of gage length.

§ Johnson's apparent elastic limit is taken as the unit stress at the point where the slope of the tangent to the curve is 1 1/2 times its slope at the origin.

‖ The ultimate strength values were taken as the unit load necessary to produce a deformation of 25 per cent of the length of the specimen.

¶ These values are the average Brinell number of three impressions on each alloy using a 10-mm ball and a 500-kg load applied for 30 sec.

Two distinct tendencies during the last 15 years (1936), for the improvement of bearing service, apply to both bearing alloys and their steel journals: a large number of the more suitable alloys are now being produced, not only as sand cast, but also in a preferred chill cast condition; and there is a very general tendency to increase the hardness of journals

* Sand cast † Chill cast. ‡ Deoxidized with phosphorus.

and shafts. Both conditions have aided materially in improving serviceability of bearings. It therefore has become a more exacting engineering problem to specify the most efficient combinations of bearings and journals. For this reason rather full comments are made on the following list of bronzes and their application.

Furthermore, the mere selection of the proper alloy for any particular service does not insure that the bearing will be satisfactory. Many factors, including design, quality of workmanship, accuracy of fitting, clearance, oil grooving, etc., still enter the problem.

Alloy T-1 is a high-quality, worm gear bronze. As such it may be designated an international standard. It should not be used with very soft or low-carbon steel. In the sand-cast condition it is specified as: S.A.E., 65; A.S.T.M., B22-21 – grade D; A.R.E.A., grade D. Chill casting increases its physical properties. In this condition it has the widest application for motor car, truck, and bus worm gear drives. It also is widely applied in worm gear speed reducers. For best service it should mate with hardened steel, accurately finished and well polished.

Alloy T-2 is a high-grade gear bronze. Its lead content does not detract from its physical properties, yet is sufficient to permit tooling to be done with greater accuracy than on T-1. It is suitable for elevator worm gear, worm gear speed reducers, spur gears meshing with small steel pinions, where quiet running and the wearing quality of a bronze is essential, feed nuts for working tools, and like service. When sand cast it is specified as S.A.E., 63. Chill casting increases its physical properties, making it an exceptionally high-grade bearing bronze for very high speeds, as in steam turbine worm wheels. With fair workmanship, at lower speeds it will support relatively heavy loads.

Alloy T-3, an intermediate bronze between T-1 and T-7, is a favorite composition for machine tool bearings. It is well adapted for worm gears where the softer steels are used, and also is suitable for steel mill bronze inserts and segmental bearing sections, feed nuts, bushings, and general machinery bearings. Its lead content permits easy and accurate tooling. Chill casting increases the physical properties, especially compressive strength, making it more serviceable for use with heavier loads.

Alloy T-4 is a new nickel-phosphor-bronze. It has the lowest coefficient of thermal expansion of all the copper-tin bearing and phosphor bronzes. It is suitable for heavy punishment when the bearing surface of its mating member is either hardened steel, nitrided nitralloy, or chromium plated, accurately finished and polished, and is also suitable for valve stem guides for internal-combustion engines. The lead content gives it an accurate tooling quality. Chill casting increases its density and refines the grain. It then has wide application for the highest requirements of worm wheel service and speed reducers, both in the largest and smallest sizes. It is favored for small worm wheels in portable tools. For hard bronzes in Diesel engines and like service, if combined with corresponding workmanship and mating material, it is unsurpassed.

Alloy T-5 is especially adapted to service requiring high compressive strength. It is suitable for low-speed and heavy-pressure journals, not exceeding 1500 lb per sq in. It is well adapted for thrust bearings, thrust washers, and step bearings, pivot bearings, dies, and trunnions, and is suitable for bascule and lift bridges. With light loads and accurate workmanship it will support an exceedingly high speed. It is specified as: A.S.T.M., B22-21, grade B; and A.R.E.A., grade B.

Alloy T-6 is adapted to very heavy duty on thrust and pivot bearings for lift and swing bridges and the like, with very high pressures and comparatively low speeds. For this purpose it is second only to Alloy T-11. It should be used only against hardened-steel surfaces. Accurately fitted, it will withstand bearing pressures in excess of 1500 lb per sq in. It is specified as: Federal Specification Board, Q-Q-B-691, composition 10; U. S. Navy, 46-B22, grade 4; U. S. Army Ordnance Dept., 57-702, grade 10; A.S.T.M., B22-21, grade A; A.R.E.A., grade A.

Alloy T-7 is a leaded phosphor-bronze, an old standard for general machine construction, suitable for crosshead and crankpin bearings and for general machinery, lathes, grinders, etc., for relatively high speeds and journals, not heat-treated. When sand cast, it is specified as: U. S. Navy, 46-B22, grade 2; U. S. Army Ordnance Dept., 57-70B, grade 8; S.A.E., 64. Chill casting increases its physical properties materially, causing a finer and more perfect distribution of the lead with a general refinement of grain, making a superior bearing metal for severe punishment.

Alloy T-8 is a relatively high-lead bronze suitable for brass and copper rolling mill neck bearings and bushings, where the spindles are of soft steel and the speed relatively high. In general, it is adapted for the intermediate or softer grades of steel journals, with intermediate or light pressures and relatively high speeds. It is substantially the famous Penn. R. R. alloy known as Ex. B metal. When sand cast it is specified as: U. S. Navy, 46-B22, grade 1; U. S. Army Ordnance Dept., 57-70B, grade 7; S.A.E., 67. Chill casting increases its physical properties materially, owing to the finer distribution of the lead and a general grain refinement, with the result that in the chilled condition this alloy is capable of resisting greater punishment with higher bearing and wearing qualities.

Alloy T–9 is a relatively high-lead bronze. It is serviceable for bearings where the danger of melting babbitts exists. It fills a field where the harder babbitts are otherwise especially serviceable. On account of its lead content and resulting plasticity, it is serviceable with poor workmanship and a soft steel mating member, in that the copper-tin crystal is hard enough to produce a mutual polishing effect between the bearing and its journal.

Alloy T–10 is a very high-lead alloy, representing the probable limit of usefulness of high lead content. Its composition and serviceability are substantially those of the old plastic bronzes. It is suitable for poor workmanship, and competes with the intermediate and cheaper grades of babbitt, having the advantage of not melting out when heating.

Alloy T-11, Lumen bronze, is a unique hard zinc-base alloy. Its capacity for holding an oil film after it has once been established is unequaled by any other alloy. It is hard and unyielding, and therefore requires care in fitting. It is especially serviceable for use where high compressive strength is required, and has an enviable record for all kinds of bridge bearings, for pivots, thrust collars, bascule trunnion bushings, and bearings in draw, swing, and lift bridges. It is suitable for turntable pivots, cold neck rolling mill table bearings, crane bearings, etc. In electrical and in general machine tool service it has phenomenally long life, and is well suited for fractional-horsepower motors. It must not be subjected to excessive pounding and impact.

Thermal Expansion of Bearing Bronzes. Table III gives the linear coefficient of thermal expansion for the bearing bronzes. It supplies exact data for computing expansions and clearance of bearings at different temperatures. The expansion of these alloys is rather irregular, and therefore, it is necessary that these data be given in each case for several temperature intervals.

WELDING, BRAZING, AND SOLDERING MATERIALS

By Bradley Stoughton and D. F. Miner

37. METAL JOINING

Joining Metallic Bodies. If two metals are brought into such close contact that there is actual union of the interatomic bonds, they will be completely joined. Thus, if two pieces of a very soft metal like lead or gold be pressed together for a considerable period of time at atmospheric temperature, mutual diffusion will produce a firm bond between the space lattices. In the case of iron, however, the pieces of metal must be heated to a point where they are very soft (actually near the melting point) and forced together, care being taken that no oxide of iron intervenes in the joint. The process of welding wrought iron is very old, but has now been much improved by electric methods of heating. Another means of accomplishing the same result is to bring melted metal in contact with the pieces to be joined. The processes of soldering, brazing, and " burning on " are examples of this method.

Pressure Processes

Hammer Welding is the original and old-fashioned method, slow in operation and low in efficiency.*

Electric Welding without Full Fusion. This includes butt (or " flash"), spot, seam, and percussive welding. All these are rapid and high in efficiency.*

Pressure after Heating by the "Thermit" Reaction. This is also high in efficiency.*

Fusion Processes

In all fusion processes, the structure of the deposited metal has the characteristics of cast metal which has not been worked. Its properties will depend on what metal (or alloy) is deposited. It may be strong, or it may be ductile, but it never can be both as strong and as ductile as the same metal after rolling or forging.

Soldering. Deposited metal has very low melting point and very low strength.

Brazing or Bronzing. Deposited metal has low melting point and low strength.

Fusion of " Welding Rod " by Burning Gas. (*a*) Oxy-hydrogen gas, or else city gas with oxygen. These gases serve for welding with lead, brass, bronze, etc., but do not give high enough temperature for fusing steel welding rods and others of high melting point. Usually the welding-rod alloys which have high melting points have also higher strength. (*b*) Oxy-acetylene gas. Gives temperatures up to 3500 deg cent.

Fusion of Welding Rod by Electric Arc. (*c*) " Carbon arc," i.e., using a carbon electrode for the arc. (*d*) " Metal arc," i.e., using the welding rod itself as an electrode. (*e*) " Shielded arc." The electric arc is surrounded with a gas which keeps the deposited as well as the heated metal from becoming oxidized.

Fusion by Combination of Gas and Electric Arcs. (*f*) Atomic hydrogen arc welding. Especially valuable for small-sized work; easy to operate; oxidation of metals is avoided; gives higher temperature than the ordinary electric arc.

Fusion by the " Thermit " Reaction. This process is especially adapted to very large welds, and to repair work in place, such as welding stern posts of ships and side frames on locomotives without dismantling the broken machine.

General Discussion of Joining

A joint may be made which is 100 per cent as strong as the parent metal, but two very important considerations must here be noted:

1. If the metal is heated to get it plastic, its properties may be injured by the high temperature necessary, because all metals are injured within certain ranges which are peculiar to the metals concerned.
2. When metals freeze and cool slowly, they assume a coarse grain size which gives less strength and less ductility than the same metal with smaller grain size.

Expertness in welding takes into account these two circumstances, and also two more:

3. The molten pool must be free from oxide, dirt, gases, and other foreign matter.
4. In planning the operation, provision must be made for taking care of the expansion and contraction stresses which are set up in the structure.

38. ARC WELDING ELECTRODE MATERIALS

Bare Wire Electrodes.

Representative Composition of Wire

C max	Mn max	S max	Si max	P max
0.18	0.60	0.04	0.04	0.04

So-called bare wire usually has a residual coating of iron oxide (sulcoat) resulting from acid left from the pickling operation and a thin coating of lime applied after pickling. These materials are purposely applied, and they serve to stabilize the arc.

Weld metal deposited with bare wires has the following average properties:

Ultimate tensile strength	50,000–60,000 lb per sq in.
Elongation in 2 in. (weld metal test piece)	5–10 per cent
Free bend elongation	15 per cent
Density	7.60–7.65 g per cu cm
The usual sizes of wire cover the range	$^1/_8$ in. to $^5/_{16}$ in.

---

* By efficiency is meant the strength, as well as the ductility, of the joint, as compared to the same two properties of the pieces welded.

Coated Wire Electrodes. Where easier manipulation, better arc stability, and better control of melting rate are desired, lightly coated electrodes are widely used. These coatings, approximately 0.002 to 0.005 in. thick, applied by dipping, dusting, or wiping, usually consist of metal oxides and carbonates. The physical properties of the deposited metal are practically the same as for bare electrodes.

Covered Wire Electrodes. Heavy coatings (10 to 25 per cent of wire diameter) are applied by extrusion or other methods to electrodes to be used where better physical properties of the weld are desired. These coatings improve the strength, ductility, density, and resistance to corrosion by excluding oxygen and nitrogen from the arc stream and pool of molten metal. They also serve to maintain the composition of the metal, replacing elements lost in melting of the wire. The resistance to corrosion of metal thus deposited is often greater than the structural plate on which it is used, whereas bare electrode metal rusts very easily.

Heavy coatings fall into two classes: (*a*) inorganic coatings which contain primarily metal oxides and silicates, and (*b*) organic coatings which contain as high as 30 per cent carbohydrates, the remainder being inorganic, slag-forming constituents. Some successful coatings are combinations of the two types. The quality of a weld depends as much on the skill of the welder as upon the particular brand of covered electrode he uses. Weld wire deposited with covered wire electrodes has the following average properties:

Ultimate tensile strength	60,000-75,000 lb per sq in.
Elongation in 2 in. (weld metal test piece)	25-35 per cent
Free bend elongation	30-50 per cent
Density	7.80-7.85 g per cu cm

39. SOLDERING

Solders. Many special solders are on the market, which have complex compositions and exhibit some advantages for special work. The most generally used materials are of two types: (*a*) lead and tin solders, and (*b*) silver solders. Where high operating temperatures are to be encountered, or high-strength joints are required, silver solder should be used in preference to the lead and tin solders. Silver solder can be used on metals other than copper and is recommended for stainless steel. Brazing alloys containing copper and phosphorus are used successfully for copper and copper alloys, the cost being less than that of silver solder.

Lead-tin Solders. Table I (from A.S.T.M. Standard Specifications B32–21) gives the composition and melting points of several lead-tin alloys used for solder metal and commercially known as soft solder. Melting points of lead and tin are included for comparison. The A.S.T.M. specifies that those designated by an A (Class A) shall be made of new or virgin metal while those designated by a B (Class B) shall be made from at least one-half virgin metals, the balance being recovered or secondary metals. For galvanized iron and zinc only Class A solders should be used.

It is to be noted that the alloys are completely solid below the lower point given, designated " melting point," and completely liquid only above the higher point given, designated " complete liquefaction point." In the range of temperature between these two points the alloys are partly solid and partly liquid. In Grade 1 the amount of solid portion is so small, in the range given, that it is practically unnoticeable. In Grade 4 the proportion of solid and fluid metal in the range given makes this alloy suitable for use as a wiping solder. The choice of the class and grade of solder for any specified purpose depends on the material in connection with which it is to be used and the method of applying. It is recommended that the grade of solder metal be selected which contains the least amount of time required to give suitable flowing and adhesive qualities for the work in hand.

Silver Solders. Table II gives the composition, melting point, flow point, and color of eight grades of silver-copper-zinc alloys used for brazing purposes and commercially known as silver solders (from A.S.T.M. Standard Specifications B 73–29).

Solders of Grades 1, 2, and 3 are suitable for brazing purposes which require a solder that flows more readily than the ordinary copper-zinc brazing solders. Grades 4 and 5 flow freely at a still lower temperature and are recommended for use where strong joints are required, and where heating to a sufficiently high temperature to flow Grades 1, 2, or 3 would be injurious to the article being soldered. Grades 6, 7, and 8 are high-grade silver solders and are recommended for special cases where a high degree of malleability and ductility is required.

Soldering Fluxes are rated according to activity. The neutral fluxes, particularly rosin or rosin in alcohol, are not corrosive and are used where corrosive action is to be avoided

Table I. Composition and Melting Points of Lead-tin Solders

* The addition, not to exceed 0.50 per cent, of cadmium to assist in fabricating Grades 1, 2 shall not be considered as a harmful impurity.

or where washing is not practicable. They are mild in cleaning action, however, and difficult to use on oxidized surfaces.

The more active fluxes usually contain zinc chloride, ammonium chloride, or both, either in a water solution or in a petrolatum paste. Various proportions of these materials are used, depending on how much cleaning action is required. To prevent corrosion, the joints should be washed in hot water after soldering. Powdered borax is the most widely used flux for silver solder and brazing alloys.

ELECTRICAL CONDUCTOR MATERIALS

By H. C. Knutson and D. F. Miner

The terms conductor and insulator are only relative. There is no sharp dividing line between them. For practical purposes, however, conducting materials are those selected to carry current in an electrical circuit and insulating materials are those chosen to restrict the current in the conductor to desired paths.

Conductors are mostly all metals, but there is a wide difference in conductivity (as much as 70 to 1 ratio in metals). They are usually separated into:

(*a*) Good conductors such as copper, aluminum, silver.

(*b*) Poor conductors (resistors) such as iron; alloys of nickel, iron, copper, and chromium; and carbon products.

40. COPPER CONDUCTORS

Conductivity of Copper. The Bureau of Standards (1914) made measurements of a large number of representative samples of copper and established standard values of resis-

tivity and temperature coefficients, which have been adopted by the International Electrotechnical Commission.

The following rules of the International Electrotechnical Commission have been adopted by the American Institute of Electrical Engineers.

The following shall be taken as normal values for standard annealed copper:

1. At a temperature of 20 deg cent the resistance of a wire of standard annealed copper 1 meter in length and of a uniform section of 1 sq mm is $^1/_{58}$ ohm = 0.017241. . . . . ohm.

2. At a temperature of 20 deg cent the density of standard annealed copper is 8.89 grams per cubic centimeter.

3. At a temperature of 20 deg cent the constant " mass " temperature coefficient of resistance of standard annealed copper, measured between two potential points rigidly fixed to the wire, is 0.00393 = 1/254.45 . . . . per deg cent.

*** Resistance at the stated temperatures of a wire whose length is 1000 ft at 20 deg cent**

† Length at 20 deg cent of a wire whose resistance is 1 ohm at the stated temperatures.

4. As a consequence it follows from (1) and (2) that, at a temperature of 20 deg cent, the resistance of a wire of standard annealed copper of uniform section, 1 meter in length and weighing 1 gram, is $(^1/_{58}) \times 8.89 = 0.15328$ ohm.

Paragraphs 1 and 4 define what are sometimes called "volume resistivity" and "mass resistivity," respectively. These may be expressed in other units as follows: Volume resistivity = 1.7241 microhm-cm (or microhms in a centimeter cube) at 20 deg cent = 0.67879 microhm-in. at 20 deg cent and mass resistivity = 875.20 ohms (mile, pound) at 20 deg cent.

The new value is known as the International Annealed Copper Standard, and is equivalent to

0.017241 ohm (meter, mm^2) at 20 deg cent.

The units of mass resistivity and volume resistivity are interrelated through the density; this was taken as 8.89 grams per cu cm at 20 deg cent by the International Electrotechnical Commission. The International Annealed Copper Standard, in various units of mass resistivity and volume resistivity is:

0.15328	ohm (meter, gram) at 20 deg cent
875.20	ohms (mile, pound) at 20 deg cent
0.017241	ohm (meter, mm^2) at 20 deg cent
1.7241	microhm-cm at 20 deg cent
0.67879	microhm-in. at 20 deg cent
10.371	ohms (mil, ft) at 20 deg cent

* Copper wires and cables of 98 per cent conductivity. For aluminum wire the allowable carrying capacities shall be taken as 84 per cent of those given in the table for the respective sizes of copper wire with the same kind of covering.

† The allowable carrying capacities of No. 18 and No. 16 are 10 and 15 amp, respectively, when in cords for portable heaters, types HC and HPD.

Per Cent Conductivity of a material is computed on the basis of 100 per cent conductivity corresponding to the resistivity of the International Annealed Copper Standard at 20 deg cent, e.g., 0.15328 ohm (meter, gram).

Wire Tables. The values in Table I (abridged from Smithsonian Physical Tables) are for annealed copper of standard resistivity. For copper of other resistivity, a suitable correction factor must be applied. Hard-drawn copper may be taken as having about 2.7 per cent greater resistivity than annealed copper.

Tables II and III give the A.S.T.M. Standard Specifications for tensile strength, elongation, and maximum resistivity for various grades of copper wire.

Table IV gives the allowable continuous-current-carrying capacities of copper wires and and cables of 98 per cent conductivity, according to the National Electrical Code. For aluminum wire the allowable carrying capacities shall be taken as 84 per cent of those given given in the table for the respective sizes of copper wire, with the same kind of covering.

Temperature Coefficient of Resistivity of Copper. The temperature coefficient for the International Annealed Copper Standard is $\alpha_{20} = 0.00393$, and $\alpha_0 = 0.00427$ at 20 and 0 deg cent, respectively. The temperature coefficient of copper is proportional to the conductivity, so that where the conductivity is known the temperature coefficient may be calculated, and vice versa. A consequence of this relation is that the change of *resistivity* per degree is constant, independent of the sample of copper and of the temperature of reference. This resistivity-temperature constant, for volume resistivity and centigrade degrees, is 0.00681 microhm-cm, and for mass resistivity is 0.000597 ohm (meter, gram). Table V gives the temperature coefficients (α_{t_1}) of copper having various percentages of standard conductivity. These are for use in the formula

$$R_t = R_{t_1}\,[1 + \alpha_{t_1}(t - t_1)],$$

where R_t is the resistance at the temperature t, and R_{t_1} is the resistance at the " initial temperature " t_1. Table V was calculated by means of the following formula, which holds for any per cent conductivity, n, within commercial ranges, and for centigrade temperatures. (n is considered to be expressed decimally: e.g., if per cent conductivity = 99 per cent, n = 0.99).

$$\alpha_{t_1} = \cfrac{1}{\cfrac{1}{n\,(0.00393)} + (t_1 - 20)}$$

Table V. Temperature Coefficients of Copper for Different Initial Temperatures (Centigrade) and Different Conductivities

Ohms (meter, gram) at 20° C	Per Cent Conductivity	a_0	a_{15}	a_{20}	a_{25}	a_{30}	a_{50}

41. ALUMINUM CONDUCTORS

Conductivity of Aluminum. The A.I.E.E. standard of conductivity for hard-drawn aluminum wire is 60.97 per cent of the International Annealed Copper Standard. On this scale the conductivity of commercial hard-drawn copper is usually taken at 97 per cent.

The electrical conductivity of annealed high purity (99.97 per cent) aluminum is 64.6 per cent, based on the International Annealed Copper Standard. The electrical conductivity is lowered by the addition of alloying elements, the reduction varying with the nature of the element and the amount added. Heat treatment and mechanical working also influence this property to a marked degree. See Table VI.

Wire Tables. Table VII for aluminum wire (from Smithsonian Physical Tables) is based on a figure for the conductivity of aluminum published by the U.S. Bureau of Standards, which is the result of many thousands of determinations by the Aluminum Co. of America. A volume resistivity of 2.828 microhm-cm and a density of 2.70 may be

Table VI. Electrical Conductivity

(Approximate Values)

Metal	Conductivity, Per Cent of International Annealed Copper Standard
Aluminum (99.97 per cent)	64.6
Aluminum conductors (hard drawn)	61.
2S-O	57.
3S-O	50.
3S-H	40.
17S-T	30.
51S-T	45.

considered to be good average values for commercial hard-drawn aluminum. These values give:

Conductivity at 0° C, cgs electromagnetic units	38.36×10^{-6}
Mass resistivity, ohms (meter, gram) at 20° C	0.0764
" " " (mile, pound) at 20° C	436.0
Mass per cent conductivity relative to copper	200.7
Volume resistivity, microhm-cm at 20° C	2.828
" " microhm-in. at 20° C	1.113
Volume per cent conductivity relative to copper	61.0
Density, g per cu cm	2.70
Density, lb per cu in	0.0975

For current-carrying capacity of aluminum wires, see Table IV.

Temperature Coefficient of Resistivity. The 20 deg cent temperature coefficient of 61 per cent conductivity annealed aluminum wire is 0.00403 per deg cent, corresponding to a 0 deg cent coefficient of 0.00444. Grassi found that the temperature coefficient of aluminum is proportional to its per cent conductivity (as is also true of copper).

	Copper	Aluminum
Cross-section	1	1.61
Diameter	1	1.27
Weight	1	0.488
Breaking strength	1	0.64

Use of Aluminum Conductors. The largest use of aluminum conductors is for power transmission through cables having a high-strength steel reinforcing core. At very high potentials, such as 100,000 volts, aluminum conductors possess a marked advantage over copper in the lower corona loss due to their greater diameter for the same conductance. Aluminum cable steel reinforced (A.C.S.R.) is used for the messenger cables of overhead catenary railway lines. It is also used in the smaller sizes for signal circuits and for telephone lines supported on the same structures with power lines, where its high strength permits the use of as long spans as the transmission conductors. Large all-aluminum cables have frequently been installed for railway feeders where they carry heavy currents at relatively low voltages. Particularly in large conductors the use of aluminum effects a great saving in weight.

Aluminum may be used in bus-bar construction, both on switchboards and for the general transmission of power. The current rating of aluminum bus-bars may be conveniently taken as 80 per cent of the accepted values for copper of equal cross-section and similar shape.

Aluminum is used for the rotor windings of squirrel-cage induction motors and also for field windings in certain types of motors and high-speed turbo-generators. The windings must, however, either occupy more space or be operated at a higher temperature. The remarkable property of insulating aluminum wire by means of an electrolytically applied oxide film is of service in constructing windings for electrical machinery where space is limited, or where a heat-resistant insulation is necessary. The difficulty of making a satisfactory and permanent joint to other portions of the circuit, which may be of copper, has retarded the widespread use of aluminum conductors in machines.

42. METALLIC RESISTOR MATERIALS

A large number of alloy wires used for resistance purposes are on the market. They cover a wide range of resistivities, operating temperature limits, physical properties, temperature coefficient of resistance, etc. For detailed description of these products the catalogs of manufacturers should be consulted. In general, the trade-name products can be grouped in approximately ten classes of alloys. Table VIII, naming a few products under each class name, gives the approximate composition and electrical characteristics of resistance wires commonly used. Tables of current-carrying capacities at various chosen operating temperatures are available in the manufacturers' catalogs.

Table VIII. Electrical Resistance Materials *

43. CARBON

Carbon Brushes

Types. The chief use of carbon in electrical manufacturing is for current collection. Carbon brushes form an important part of the electrical circuit in commutator machines, and many types have been developed to afford most satisfactory operation of motors and generators. The many grades of brushes on the market may be classified generally into five grades known as, (1) carbon graphite, (2) electro-graphite, (3) natural graphite, (4) resin bonded, (5) metal graphite.

Composition and Manufacture. The three purest forms of carbon are diamond, petroleum coke, and lampblack. The last two substances are extensively used in the manufacture of carbon brushes and other carbon products. Petroleum coke is the residue left on the side of a still after the refining of crude oil. For brush use, this green petroleum coke is first purified by subjecting it to an intense heat in a calcining furnace, and then ground to a fine powder, 200 mesh or finer. Lampblack is made by the incomplete combustion of oil or gas, depending upon the type of black desired.

The graphite brushes of highest grade are made by transforming pure carbon brushes to graphite by subjecting the material to an intense heat in an electric furnace.

The method of making carbon graphite and graphite brushes is as follows: (1) Calcined petroleum coke, lampblack, graphite, or other flours are mixed with a pitch or other binder in steam heated mixers. (2) After thoroughly mixing, material for molded brushes is permitted to cool and again reground and pulverized, after which the fine powder mix is molded under hydraulic pressure into plates. (3) The molded carbon graphite plates are then baked at various temperatures. (4) This completes the manufacturing process for carbon graphite and for natural graphite plates from which brushes of these two classes are cut. (5) In the case of electro-graphite material the carbon graphite plates are given an additional high-temperature treatment in an electric furnace which removes all impurities and in addition changes some of the carbon into graphite. From these plates are cut electro-graphite brushes.

Metal graphite grades are made by mixing fine-mesh copper, lead, zinc, tin, or other materials with graphite. This material is mixed, molded, and baked in a manner similar to carbon graphite material.

Resin bonded brushes contain a certain amount of resin of high electrical resistance such as a condensation product resulting from the reaction of formaldehyde upon phenol.

Properties. Plain carbon graphite brushes will carry between 35–50 amp per sq in., whereas the grade having the highest content of graphite will carry about 70 amp per sq in. continuously. High metal content grades are rated at 125–150 amp per sq in. but will carry 450–500 amp per sq in. momentarily without undue heating. The higher the metal content of brush material, the higher the current-carrying capacity of that material.

Table IX gives the U.S. Navy specifications for carbon brushes.

Table IX. Specifications for Carbon Brushes *

(U. S. Navy)

	Grade A	Grade B	Grade D	Grade E
Specific resistance at 30° C, ohm-in.	0.00176 to 0.0021	0.0015 to 0.0019	0.0006 to 0.0012	0.000005 to 0.000025
Specific resistance at 250° C, ohm-in.	0.0013 to 0.0017	0.0011 to 0.0015	0.0004 to 0.0010	....

Per cent graphite	....	....	....	20 to 30

* A Grade C, formerly included in these specifications, has been discontinued by the Navy.

Uses. 1. Carbon graphite brushes are survivals of the original types and are used mostly on machines of older design where a cleaning action on the commutator is required. They are not suitable for high speeds and heavy currents.

2. Electro-graphite brushes have largely superseded the carbon graphite type. They have lower friction, higher current capacity, less ash, lower abrasive effect, and greater mechanical strength.

3. Natural graphite brushes are an improvement over the carbon graphite type where abrasive action is beneficial but where low friction is required for higher-speed operation.

4. Resin bonded brushes have a laminated structure whose distinctive characteristic is that the resistance across these laminations is from 5 to 8 times the resistance parallel to the laminations. This is effective in reducing short-circuit current in the face of the brush. They are particularly suited to machines with high commutating voltage.

5. Metal graphite brushes have replaced the early leaf copper types. They are used where high current capacity and low contact drop are important, as in electroplating generators or slip rings on a-c machines

Carbon Contact Material

Carbon and combinations of carbon and metal are often used as contact materials where current is frequently interrupted. The object is usually to provide terminals which will not melt and weld together, as metal contacts sometimes do. Relays, contactors, and various control devices use buttons or studs of this type, making contact with moving parts of metal, usually brass or copper. Where high conductivity is required, copper graphite or silver graphite material is used. These are similar to metal graphite brush material, giving non-sticking contacts with low contact drop and some degree of lubrication. Silver graphite, although more expensive, gives lower contact drop after long service than does copper graphite. It is therefore used in low-energy circuits, such as relays, where reliable operation, even after long periods of idleness, is important.

MAGNETIC MATERIALS

By J. B. Seastone

44. COMMERCIAL TYPES

Classes of Commercial Magnetic Materials. Magnetic materials may be divided into four groups for the sake of convenience of description, namely: (*A*) the *non-retentive* or magnetically " soft " materials; (*B*) *retentive* or magnetically " hard " materials; (*C*) those *special magnetic materials* having properties suited only to certain special applications; and (*D*) the *non-magnetic ferrous* alloys.

The Non-retentive or Magnetically " Soft " Materials are by far the most important, on the basis of the amount used. Materials falling in this class range from cast iron, which is one of the poorest, to Hipernik, which is one of the best, and include also cast steel, ordinary low-carbon sheet or plate, ingot iron, and the electrical (silicon) sheet materials. These materials are, in general, characterized by low coercive force, comparatively low hysteresis loss, relatively high permeability, and, usually, a fairly high saturation induction. They are used in the electromagnetic circuits of electrical apparatus.

The Retentive or Magnetically " Hard " Materials find application in the permanent magnets of meters and relays, sound-reproducing units, magnetos, and other equipment where a steady magnetic field is required and where it is not convenient to obtain this field electromagnetically. These materials are characterized by high coercive force, comparatively high hysteresis loss, and, usually, low permeability.

Special Alloys include those materials having special temperature-permeability relations, used in compensating for changes in flux in a magnetic circuit due to temperature changes; materials having unusually good properties only at low inductions; materials especially suited to operation at very high flux densities; and those materials which can be used at very high frequencies.

Non-magnetic Steels. Steel in the austenitic state is practically non-magnetic, having a permeability 1 to 2 per cent greater than air. It has been found that certain alloying elements, notably manganese, nickel, and carbon, lower the critical point so that steel can be made austenitic at room temperatures. In order to make a non-magnetic steel of reasonable cost and good machinability, certain compositions have been found most favorable. A typical non-magnetic steel composition contains 0.20 to 0.40 carbon, 10.0 to 11.5 manganese, 6.0 to 7.5 nickel.

45. NON-RETENTIVE MATERIALS

Effect of Impurities. Generally speaking, the magnetic properties of iron and its alloys are adversely affected by the presence of impurities. Carbon, sulfur, and oxygen tend to increase the hysteresis loss and to lower the permeability at all inductions. Manganese, phosphorus, and copper have little effect if present in small quantities, but, with the exception of cobalt, all additions to pure iron tend to lower the saturation induction and the permeability at high flux densities. Silicon, aluminum, and arsenic tend to decrease the hysteresis loss and to improve the permeability at moderate and low flux densities, largely because of the elimination of oxygen and other impurities, but even these elements impair the permeability at high flux densities. Silicon is also of considerable value because it increases the resistivity of the alloy, and, therefore, reduces the eddy current losses. (Aluminum and arsenic act in the same way, but are seldom used.)

Effect of Mechanical Strain. A strain beyond the elastic limit tends to increase the hysteresis loss and reduce the permeability of magnetic materials. This effect is apt to be

† Values for electrical sheet steels furnished in part by American Rolling Mill Co., Middletown, Ohio.

‡ 78 per cent nickel.

§ 50 per cent nickel.

¶ The guaranteed maximum loss at 10,000 gausses, 60 cycles, in 29 gage, is used to designate the grade of electrical sheet steel.

roughly proportional to the amount of distortion or strain, and usually the best magnetic materials are the most sensitive to mechanical abuse. Shearing or punching strains will increase the 10 kilogausses, 60-cycle loss of a $1\,{}^{3}/_{16}$-in. wide strip of silicon steel 10 or 15 per cent and will decrease the permeability at this induction more than 30 per cent. This effect is greater the thicker the material, and is apt to be more marked on the softer grades. The percentage effect of shearing or punching is an inverse function of the width of the piece sheared. It may be very large in the case of narrow sections such as are found in the teeth of small motors.

Stresses within the elastic limit will change the magnetic characteristics of materials. These changes may improve or impair the magnetic properties, depending on the kind and the amount of the stress, the induction at which the test is made, and the kind of material. Changes in magnetic conditions are likewise reflected in changes in the length, or, if confined, in the stress on such materials. These effects are usually small, but may become significant at low inductions or for very high-quality materials.

Effect of Direction of Grain. Electrical sheet or strip steels are apt to show an appreciable change in properties depending on the direction of the flux in the material relative to the final rolling direction. Usual sheet or strip material will show 10 per cent or 15 per cent higher loss when test strips are cut perpendicular to the direction of final rolling than when they are cut parallel to this direction, and the " cross-grain " samples will have 20 to 30 per cent lower permeability. Samples sheared at 45 degrees to the direction of rolling usually show loss and permeability characteristics not far different from the " straight-grain " specimens.

Effect of Temperature. The magnetic properties of iron and iron-silicon alloys are only slightly affected by ordinary temperature changes. In general, the permeability at low and moderate flux densities is improved, and the hysteresis loss is reduced, as the

NOTE. To find the approximate iron loss at any induction or frequency, multiply the loss, at 60 cycles, 10,000 gausses, by the factor shown in the table. Values are most accurate for about a 4 per cent silicon steel, are reasonably exact for lower silicon steels, and may be used to give approximate values for Hipernik.

Table III (Part 2). Approximate Frequency and Induction Core Loss Factors for 29 Gage (0.014 in.) Material

Induction, gausses	Frequency					Induction, lines per sq in.
	400 Cycles	640 Cycles	1000 Cycles	1600 Cycles	2500 Cycles

NOTE. To find the approximate iron loss at any induction or frequency, multiply the loss, at 60 cycles, 10,000 gausses, by the factor shown in the table. Values are most accurate for about a 4 per cent silicon steel, are reasonably exact for lower silicon steels, and may be used to give approximate values for Hipernik.

temperature is raised. These changes are greater at low flux densities but may usually be neglected in the commercial application of materials over ordinary temperature ranges. Iron and silicon-iron alloys become non-magnetic at about 750 deg cent, and the magnetic properties are in general more seriously impaired as temperatures of about 500 deg cent are exceeded. The magnetic properties of materials are sometimes impaired after being being held for some time at temperatures of the order of 100 deg cent. This " aging " effect used to be of considerable importance, but electrical steels produced today are not seriously affected.

Effect of Heat Treatment. It is usually possible to effect a marked improvement in the magnetic properties of materials by a proper heat treatment or annealing cycle. This heat treatment usually involves heating the material to a suitable temperature, holding at this temperature for a short time, and cooling slowly to several hundred degrees centigrade. The best annealing temperature, if only the release of punching strains is desired, will usually be about 725 deg cent. The punchings can be held at this temperature for several hours, and cooled at a rate of about 30 deg cent per hr. It is important that every precaution be taken to exclude oxidizing or carburizing gases from the material while it is above 600 deg cent. This is effected by either placing the material to be annealed under a tightly sealed metal box, or, if an electric furnace is used, by supplying an inert or reducing atmosphere to the annealing chamber.

If the material to be annealed has been given no other annealing treatment, the maximum temperature will range between 750 and 900 deg cent for such materials as cast iron,

Table IV. Loss of Electrical Sheets as a Function of Gage for Commercial Grades in Common Use

The grade is designated by the guaranteed maximum iron loss when tested at 10,000 gausses, 60 cycles, A.S.T.M. Method

cast steel, ordinary structural or low-carbon steel, " pure " iron, and low-silicon steel. High-silicon steel is annealed at temperatures ranging above 1000 deg cent, and Hipernik at temperatures above 1200 deg cent. The importance of proper atmospheric control increases as the annealing temperature is raised.

Curves and Data on Commercial Non-retentive Magnetic Materials. In using data on commercial magnetic materials it is important to remember that the magnetic properties of all such materials are apt to vary considerably, depending upon chemistry, kind and amount of mechanical work done on the material, heat treatment, and factors at present beyond control. It is impossible to give exact figures representing the various magnetic characteristics, and the values presented will be those corresponding to the average of good practice. In general, the range over which the values will fluctuate will be smaller for the materials of higher magnetic quality. Silicon steel sheets, for example, show variations in standard iron loss of less than 10 per cent, although permeability figures for this class of material will vary over a considerably wider range. In general, both hysteresis losses, and low and moderate flux density permeabilities, will vary over a considerably wider range than the permeabilities at high values of magnetizing force.

Although electrical sheets are usually marketed under the trade names of the various manufacturers, the number of grades and the loss characteristics of these grades have been fairly well standardized (the " radio " grades are essentially the same as the standard). Accordingly, the figure corresponding to the 29 gage (0.014) iron loss, expressed in watts per pound when tested at 10,000 gausses and 60 cycles, has been used to designate the grade of electrical sheet material.

Table V. Apparent Incremental Permeability Standard E and I Laminations

Length of magnetic circuit = 5.6 in. Two lap joints. 29 gage material, 0.66 grade

	D-c Magnetizing Force, in Oersteds

Steady magnetizing force = 10.0 oersteds	62	63	65	70	100	310

Data from Westinghouse Electric tests. Ring samples, no air gaps. 60-cycle a-c tests with no air gaps have checked these figures closely.

46. RETENTIVE MATERIALS

General Considerations. The magnetic properties and the application of the various retentive or permanent magnet materials, depend, in the main, on four factors, namely: (1) the physical dimensions of the magnetic current, (2) the heat treatment of the material. (3) the subsequent " stabilization," and (4) small variations in composition.

1. The relative lengths of the retentive material, of the air gap, and, if present of the non-retentive material, together with the cost and weight or size considerations, will determine, in general, the choice of magnetic material. If the air gap must be relatively large, or if weight or size are important considerations, materials having high coercive force will be used.

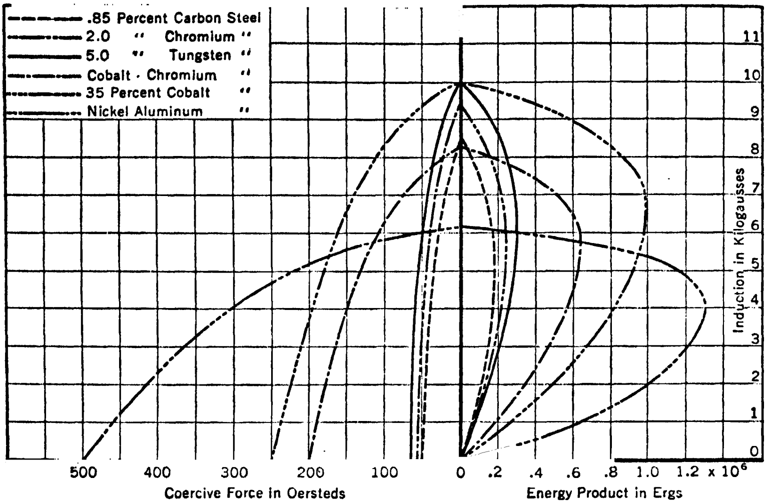

FIG. 1

2. The desired magnetic properties of these materials are not developed, as a rule, until a final heat treatment has been given. Usually, precautions must be taken to avoid cracking, excessive oxidation, decarburization, or overheating; the temperatures must be rather closely controlled; and it is ordinarily desirable to keep these materials at high temperatures as short a time as is practicable. Permanent magnet materials are ordinarily quite difficult to forge or machine.

Table VII. Properties of Permanent Magnet Materials, Approximate Values

Characteristic	0.85 Per Cent Carbon Steel	2.0 Per Cent Chromium Steel	5.0 Per Cent Tungsten Steel	Cobalt Chromium Steel	Cobalt Steel	Nickel Aluminum Steel

* Cooled in air.

† Cannot be forged or machined, may be ground, and casts fairly well.

‡ Heat to 1200 deg cent, quench, and age 4 hr at 700 deg cent.

§ Annealing impairs the magnetic properties of this material and should be avoided. If necessary for machining hold at 830 deg cent for 1 hr, cool 30 deg cent per hr to 600 deg cent, cool in air.

¶ Carbon fairly critical.

‖ The manganese is not essential, but increases the coercive force from 350 to 500, and lowers the residual induction from 7500 to 6000.

** Heat rapidly to 1160 deg cent, cool in air, heat slowly to 725 deg cent, cool in air, heat to 1000 deg cent, cool in moving air to 300 deg cent, and quench in oil, according to Darwins, Ltd., Sheffield, England.

3. After the material has been heat-treated and magnetized it is frequently necessary to put the material in such condition that very little or no further change in magnetic properties will occur. This may be accomplished, but only by sacrificing a part of the initially available magnetic energy, by one or all of three methods.

(*a*) Prolonged " aging " at a slightly elevated temperature, usually about 100 deg cent for about 10 hours.

(*b*) Subjecting the material to mechanical shock or vibration, as by dropping it several feet to a hard surface.

(*c*) Applying a small negative, or alternating, demagnetizing force, as by introducing a slightly larger air gap than will later be used in the magnetic circuit.

4. Small amounts of various impurities will sometimes produce changes in the magnetic properties of retentive materials. Small percentages of sulfur, phosphorus, or oxygen are believed to be harmful, and loss of carbon in heat treatment may damage some grades considerably.

Data on Commercial Retentive Materials. Hysteresis loops are shown in Fig. 1. General data on permanent magnet materials are shown in Table VII.

47. SPECIAL MAGNETIC MATERIALS

Low-induction Materials. There are several magnetic materials which have remarkable magnetic characteristics at very low flux densities. These materials include those known as (1) " Conpernik " and (2) " Perminvar."

(1) *Conpernik* is characterized by a constant permeability of a little over 1000 at flux densities up to several hundred gausses, and by a very low hysteresis loss at those low inductions. The composition of Conpernik is the same as that of Hipernik, and the unusual properties are secured by a low-temperature heat treatment. The hysteresis loss of Conpernik is about 1.6×10^{-2} erg per cu cm per cycle at an induction of 100 gausses. The material may be used to advantage in several ways, for example, in producing reactors with a reactance to resistance ratio well over 150, at frequencies of about 500 cycles. In order to keep eddy current losses low, it is generally used in 0.005-in. thickness.

(2) *Perminvar*, characterized by somewhat similar properties, is an alloy of iron, nickel, and cobalt, in one of several proportions. The magnetic properties are developed by special heat treatment.

High-induction Materials. An alloy of iron and cobalt, preferably in the ratio of 65 per cent iron to 35 per cent cobalt, has remarkable properties at very high inductions. The saturation induction is about 12 per cent higher than that of pure iron, or a little over 24,000 gausses, and at magnetizing forces between 50 and 200 oersteds the inductions are about 25 per cent higher than for iron. The material is used only for special applications because of its relatively high cost.

Temperature Effects. (1) Alloys of copper and nickel, in the proportions of 70 per cent copper to 30 per cent nickel with the addition of small amounts of manganese and silicon, and alloys of iron and nickel in the ratio of 3 to 1 respectively, will show substantial and approximately linear changes in permeability with temperature, and are used as shunts for compensating the magnetic circuits of electrical instruments for changes in temperature.

(2) An alloy of iron and nickel, with about 35 per cent nickel (Invar composition), will become non-magnetic at a slightly elevated temperature and is used in magnetic-thermal relays.

High-frequency Materials. Powdered iron or powdered permalloy, with the particles of magnetic material insulated from each other, and the whole compressed into a solid mass, may be used for the cores of radio reactors, or in other applications where the frequency is very high. Such materials usually have low permeabilities (initial permeabilities of the order of 25) and high resistivity, one material having a resistivity of about 50 ohm-cm.

MISCELLANEOUS MATERIALS

48. MISCELLANEOUS METALLIC MATERIALS

Duriron is a corrosion-resisting material made by the Duriron Co., Dayton, Ohio, consisting of Si, 14.50 per cent; Mn, 0.35 per cent; C, 0.80 to 0.85 per cent; Fe, balance. The following are given as its physical properties: specific gravity, 7.0; weight per cubic inch, 0.253 lb; melting range, 2275 to 2375 deg fahr; coefficient of expansion, 0.000,015,65 per deg fahr from room temperature to the melting point, and 0.000,004 per deg fahr from room temperature to 212 deg fahr; electrical resistivity, microhm-cm at 32 deg fahr, 63.3; thermal conductivity (silver = 1.000), 125; Shore scleroscope hardness, 49–51; contraction allowance in casting, 1/4 in. per ft. The makers give the tensile strength as 15,000 to 20,000 lb per sq in., and the compressive strength as 95,000 lb per sq in. Duriron will not soften or materially alter its shape at temperatures below 2000 deg fahr, nor does it oxidize at temperatures below 1500 deg fahr.

Corrosiron is a cast-iron alloy, containing about 14.25 per cent silicon and other metalloids in small quantities. It melts at about 2400 deg fahr and weighs 0.263 lb per cu in. It is brittle with long flat crystals. A bar 1 by 2 in., 24 in. long, has a transverse strength of about 1200 lb, with the load applied at the center, the deflection being about 0.16 in. Shrinkage is about 3/16 in. per ft. In designing, flat surfaces should be avoided, all corners rounded, and sections of metal kept as even as possible.

Corrosiron is used in the construction of pipes, valves, pipe fittings, acid pumps, pans, etc. It is made by the Pacific Foundry Co., San Francisco.

Copper-aluminum-iron Bronze. Tests on copper-aluminum-iron bronze as an acid-resisting material, made at the Univ. of Wisconsin, were reported by O. L. Kowalke (*Chem. & Met. Engg.*, Jan. 7, 1920). Two bronzes of the following composition were tested:

	Copper	Aluminum	Iron Alloy	Specific Gravity
Bronze A	87.0	9.8	3.14	7.71
Bronze B	85.6	10.81	3.57	7.58

Bronze A is resistant particularly to sulfuric, lactic, phosphoric, tartaric and acetic acids and to caustic soda. Nitric acid attacks it readily, and hydrochloric acid and aqua ammonia both attack it too readily for commercial purposes. Bronze B is more resistant to sulfuric acid than Bronze A. It is less resistant to hydrochloric acid and more resistant to aqua ammonia than Bronze A, and is also attacked readily by nitric acid.

The corrosion of forged specimens of Bronze A in 35 per cent sulfuric acid was only about one-half that of cast or rolled specimens.

Illium (*Product. Engg.*, November, 1932). Illium is an alloy of nickel, chromium, and copper, developed by the Burgess-Parr Co., with the following average physical characteristics: tensile strength, 6000 lb per sq in.; elastic limit, 50,000 lb per sq in.; hardness, Brinell, 170–200; melting point, 2372 deg fahr; specific gravity, 8.3; weight per cubic inch, 0.3 lb; specific heat, 0.105 g-cal per g per deg cent; coefficient of expansion per deg cent (20–300 deg), 0.000,013,5; electrical resistance, 121.9 microhm-cm; contraction in casting, 5/16 in. per ft. Illium is readily machined, being slightly harder than cast steel, and may be welded to itself or other metals by acetylene or electric arc. It is resistant to the following: *acids*: acetic, butyric, citric, formic, hydrocyanic, lactic, nitric, oleic, oxalic, phosphoric, picric, sulfuric; *salts*: ammonium chlorate and sulfate, copper sulfate, ferric chloride, mercuric chloride, potassium alum, silver nitrate, sodium chloride and hydroxide, hypochlorite, and nitrite; *organic substances*: acid mine water, apple vinegar, carbolic acid, formaldehyde, fruit juices, malt vinegar; *miscellaneous*: bleaching powder, bromide solution, carbonated water, hydrogen sulfide, sulfur dioxide.

Fusible Alloys. A variety of compositions containing tin, lead, and bismuth or cadmium are used when a low melting point is required; some of these alloys are given in Table I.

Table I. Composition of Fusible Alloys

Alloys	Melting Point deg fahr	Composition, per cent			
		Pb	Sn	Cd	Bi
Lipowitz	140	26	13	10	51
Wood's	158	26	13	12	49
Rose's	230	28	22	..	50
50 per cent plumbers' solder	358	50	50	..	..
Pure tin	450	..	100	..	..

CEMENT, CONCRETE, LIME, MORTAR, AND PLASTER

By Theodore Crane

1. CEMENT

Cement. In engineering literature the term cement is understood to mean the finely pulverized product obtained by the burning of a suitable mixture of argillaceous and calcareous materials, or by an artificial mixture of such materials after burning, which will possess the property of hardening into a solid mass when mixed with water. The essential ingredients in the manufacture of cement are calcium carbonate ($CaCO_3$), silica (SiO_2), and alumina (Al_2O_3); the last two, combined in various proportions, constitute the argillaceous material. The characteristic property of cement is that of hardening by the addition of water, and therefore its ability to harden when excluded from the air.

The cements used in engineering and building construction in this country are portland, natural, puzzolan, and calcium aluminate cements.

Portland Cement is the finely pulverized product resulting from the calcination to incipient fusion of an intimate, artificial mixture of properly proportioned argillaceous and calcareous materials with no addition subsequent to calcination excepting water and calcined or uncalcined gypsum. It has a definite chemical composition varying within comparatively narrow limits. There are three distinct stages in the process of its manufacture: (1) the preparation of the correct mixture by the selection, proportioning, mixing, and grinding of the ingredients; (2) the burning of the mixture to a clinker; and (3) the pulverizing of the burned clinker to a fine powder.

Portland cement is almost universally used for reinforced-concrete construction. It is a highly uniform product sold under the standard specifications of the A.S.T.M.

Standard Specifications for Portland Cement. (A.S.T.M. Standards C 9-30.)

Chemical Properties. The following limits shall not be exceeded:

Loss on ignition, per cent	4.00
Insoluble residue, per cent	0.85
Sulfuric anhydride (SO_3), per cent	2.00
Magnesia (MgO), per cent	5.00

Physical Properties. 1. The residue on a standard No. 200 sieve shall not exceed 22 per cent by weight.

2. A pat of neat cement * shall remain firm and hard, and show no signs of distortion, cracking, checking, or disintegration in the steam test for soundness.

3. The cement shall not develop initial set in less than 45 minutes when the Vicat needle is used or 60 minutes when the Gillmore needle is used. Final set shall be attained within 10 hours.

4. The average tensile strength in pounds per square inch of not less than three standard mortar briquets composed of one part cement and three parts standard sand by weight, shall be equal to or higher than the following:

Age at Test, days	Storage of Briquets	Tensile Strength, lb per sq in.
7	1 day in moist air, 6 days in water	275
28	1 day in moist air, 27 days in water	350

5. The average tensile strength of standard mortar at 28 days shall be higher than the strength at 7 days.

Natural Cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature below fusion. The proportions of lime and clay in the raw material may vary between much wider limits than in portland cement. Natural cement does not develop its strength as quickly nor is it as strong as portland cement.

---

* Neat cement is portland cement mixed with water and no aggregate added. See A.S.T.M. Standard C77-32 for method of preparation of pat.

Natural cement, mixed with three parts of sand, is widely used for laying brick, stone, or terra-cotta as it produces, without the addition of lime, a plastic mortar amply strong for masonry requirements. It is suitable for concrete placed in massive foundations and similar work where high structural strength is not required, and is also blended with portland cement to increase the workability of the latter.

Standard Specifications for Natural Cement. A.S.T.M. Standard C 10-09. 1. The residue on a standard No. 100 sieve shall not exceed 10 per cent, and on a standard No. 200 sieve shall not exceed 30 per cent, by weight.

2. Pats of neat cement about 3 in. in diameter, $1/2$ in. thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(a) A pat shall then be kept in air at normal temperature.

(b) Another pat shall be kept in water maintained as near 70 deg fahr as practicable.

These pats shall be observed at intervals for at least 28 days, and, to pass the tests satisfactorily, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

3. The cement shall not develop initial set in less than 10 minutes, using the Vicat needle. Final set shall be attained in not less than 30 minutes nor more than 3 hours, using the Vicat needle.

4. The minimum requirements for tensile strength for briquets 1 sq in. in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Neat Cement

Age	Strength
24 hours in moist air	75 lb
7 days (1 day in moist air, 6 days in water)	150 lb
28 days (1 day in moist air, 27 days in water)	250 lb

One part cement, three parts standard Ottawa Sand

7 days (1 day in moist air, 6 days in water)	50 lb
28 days (1 day in moist air, 27 days in water)	125 lb

Pending the revision of this specification, the neat cement tests have been practically eliminated from standard practice. Furthermore, the facilities for grinding natural cement have been so improved, since this standard was written, that the residue permitted on the No. 200 sieve may be reduced to 12 per cent by weight.

Puzzolan Cement is the finely pulverized product resulting from grinding a mechanical mixture of fused argillaceous material and hydrated lime. The argillaceous substance may consist of natural puzzolaric material, such as volcanic ash, trass or allied igneous material, or of an artificial material such as water-granulated blast-furnace slag.

The American puzzolan cements are manufactured from blast-furnace slag, granulated at the furnace by spraying with water, after which the cinder is very finely ground. The best grades of puzzolan will pass approximately 98 per cent through a No. 200 sieve. The chief use of puzzolan cement in this country is for non-staining mortars employed in laying fine masonry, particularly limestone and marble. It is also blended to some extent with portland cement for use in massive construction to reduce the amount of heat generated by hydration.

Lafarge and other grappier cements, by-products produced during the calcination of hydraulic lime, are no longer employed to any extent in this country. They were formerly imported from Europe and used in non-staining mortars. At present the white portlands, certain natural cements, and high-grade puzzolan cements have taken their place.

High, Early-strength Cements are now being widely used for work which requires speed or where cold-weather conditions demand costly protection during the curing period. There are: (1) The calcium-aluminate cements, in a class by themselves, producing a 28-day strength in 24 hours. These cements have a high resistance to corrosive sulfate solutions which makes them particularly suitable for work exposed to sea water and ground water containing calcium, magnesium, or sodium sulfates. They are also used as a binder for refractory materials. (2) A large number of high, early-strength portland cements which, when used in normal quantities, produce a 28-day strength at about 72 hours. Both these types of cements are more expensive than standard portlands. When used, they should be specified by name, and an abstract of the manufacturer's recommendations for their use should be written into the specifications.

2. CONCRETE

Concrete is a physicochemical mixture of cement and water combined with a fine and coarse aggregate. The hardening of the cement-water paste, resulting from the chemical reaction between the water and cement, binds together the particles comprising the aggregates. It requires only about 2 1/2 gal of water to hydrate 1 bag of cement, but it is necessary to use two or three times this amount for the purpose of obtaining a sufficiently plastic mixture to permit proper placement of the concrete. A certain amount of water, therefore, remains uncombined and distributed within the paste, causing minute water voids in the concrete, which tend to reduce its structural strength, impermeability, and resistance to exposure. The strength and other desirable qualities of concrete, as far as proportioning is concerned, depend upon the cement-water ratio and not upon the relative amounts of aggregate and cement, except in so far as the latter affect the cost and the workability of the concrete.

Designing a concrete mixture, therefore, comprises: (1) the selection of suitable materials meeting the requirements of good practice which are described in the Standard Specifications of the A.S.T.M.; (2) selecting a water-cement ratio which will produce concrete of the desired strength and resistance to exposure; (3) determining the most suitable quantities and combinations of aggregates which will give the necessary workability when mixed with cement and water of the chosen proportions.

Cement. Standard and high-early-strength portland cements, meeting the standard specifications of the A.S.T.M., should be used for all reinforced-concrete work except that calcium-aluminate cement may be used where rapid hardening is essential. Natural and puzzolan cements, with or without a blending of portland, are suitable for massive construction, but are not used to any extent for reinforced-concrete work. American cements are sold by the barrel (4 bags each weighing 94 lb and assumed to contain 1 cu ft) and delivered in jute or paper bags, except that for very large operations bulk delivery is employed.

Aggregates. Crushed stone or screened gravel are the principal materials used for coarse aggregates. Trap, granite, limestone, or quartz gravel are satisfactory; soft limestones, sandstones, and shale should be avoided. Quartz sand is almost universally used as a fine aggregate, although crushed cinders, crushed slag, and various light-weight materials are employed for special purposes.

The following is a summary of the Joint Standard Building Code * specification for concrete aggregates: They shall consist of natural sands and gravels, crushed rock, crushed air-cooled blast-furnace slag, or other inert material having clean, uncoated grains of strong and durable minerals; they must not contain more than 3 per cent soft, friable, thin, flaky, elongated, or laminated particles; or more than 1 1/2 per cent shale; or more than 2 per cent silt and crusher dust finer than No. 100 standard sieve (percentages to be based on the weight of the combined aggregate as used in the concrete). When all three groups of these deleterious substances are present in the aggregates, the combined amounts shall not exceed 5 per cent by weight of the combined aggregate. Aggregates shall not contain strong alkali or organic material which gives a color darker than standard when tested by the A.S.T.M. standards for organic impurities in sands for concrete (Serial Designation: C40-33).

The maximum size of the aggregate should not be larger than 1/5 of the narrowest dimension between forms of the member for which the concrete is to be used nor more than 3/4 of the minimum clear spacing between reinforcing bars. Maximum size here means the clear space between sides of the smallest square opening through which 95 per cent (by weight) of the material can pass.

Fine Aggregate. Fine aggregate should consist of uniformly graded sand, or the screenings of crushed stone or gravel. Material that appears satisfactory upon cursory inspection should have: (1) a colorimetric test to determine the amount of alkali or organic material, (2) a decantation test to determine the amount of silt, (3) a sieve analysis to determine the grading of the sand: particles should vary from fine (at least 5 per cent passing a 50-mesh sieve) up to a 1/4-in. maximum. These tests are described in detail in the A.S.T.M. standards.

Mortar specimens, composed of the sand and cement to be used, should be made and tested for both tension and compression. The results at both the 7- and 28-day periods should at least equal tests on similar specimens of the same proportion and consistency, using graded Ottawa sand having a fineness modulus of 2.40 ± 0.10 mixed with the same cement.

---

* Published by the American Concrete Institute.

Coarse Aggregate. Coarse aggregate should consist of crushed stone or gravel retained on a screen with $^1/_4$-in. holes. It should be graded from the smallest to the largest particles. Though the strength and economy of concrete are favored by a larger, rather than a smaller, size of aggregate, some fine particles are necessary for workability, and the necessity of proper placement definitely limits the maximum size for any particular type of work. If the aggregate is not well graded from fine to coarse, the concrete will be harsh and subject to honeycomb. For most reinforced concrete in building construction, a size passing a 1-in. square opening is customary. For narrow walls or thin sections, as the ribs composing the structural members of a ribbed floor system, $^5/_8$-in. stone or gravel is desirable. A 2-in. or even 3-in. size may be used for thick walls, piers, or other massive work.

Admixtures are substances other than cement, aggregates, and water added to concrete mixtures to improve their quality. They may be used as integral waterproofing, to shorten the time of setting, to protect against the action of frost, to harden surfaces exposed to abrasion, or to increase workability. For waterproofing of concrete, see p. 12–10.

The use of admixtures to shorten the normal period required for hydration of the cement is generally accepted practice where job conditions demand the earliest possible employment of the structure. Certain chemicals, as calcium chloride, may be bought in the open market and safely added to the mixing water, and many proprietary compounds also will not injure the quality of the concrete. Such products should be specified by name, and the maker's recommendations for use should be included in the specifications.

Admixtures should not be relied upon to protect concrete against frost, except as insurance against a slight and temporary fall of temperature below freezing. Under such conditions, an accelerating compound may be used to shorten the period of extreme vulnerability, as the effect of freezing is most disastrous before the concrete has taken initial set. The use of admixtures to harden concrete surfaces is confined almost exclusively to interior floor finishes. Many excellent proprietary compounds are available. They should be specified by name, and the maker's recommendations written into the specifications.

Increased workability may be obtained: (1) by increasing the proportion of cement in the mixture; (2) by adding plasticizing agents, as hydrated lime or celite. Although many compounds are available, some of which are of material benefit, it is always desirable to proportion the concrete ingredients with the utmost care and to use a well-graded aggregate.

Water. The water used in mixing concrete should be free from oil, acid, alkali, or organic matter. The use of sea water for mixing is generally prohibited.

Proportionment. The amount of each ingredient is measured by volume or weight. Any appropriate method may be used for measurement, provided that accuracy is obtained. The concrete is designated by the proportion of each of the ingredients in the following order: cement, sand, stone or gravel. For example, a 1 : 2 : 4 mixture is one consisting of 1 part of cement, 2 parts of fine aggregate, and 4 parts of coarse aggregate. One bag of cement (94 lb) is considered to equal 1 cu ft.

Since the prime requisite for making good concrete is the strict control of the water-cement ratio, provided that the mixture is sufficiently plastic to insure proper placement without the danger of honeycomb, the proportion of cement paste to aggregate may be varied for the several portions of the work provided that the ultimate strength, assumed in the structural design, is held constant for all mixtures by strictly adhering to the water-cement ratio.

For example, massive work such as abutments or gravity retaining walls may have a mixture such as 1 : 3 : 5 or 1 : 3 : 6, whereas, for comparatively thin, heavily reinforced sections, such as the structural elements of a floor system, where greater workability is required, a mixture of 1 : 2 $^1/_2$: 3 $^1/_2$ or 1 : 1 $^1/_2$: 3 would be used. The proportions of aggregates to cement, however, should always be such as to produce a plastic mass that will work readily into the corners and angles of the forms and around the reinforcement without excessive puddling; there should be no segregation of materials, nor should free water collect upon newly poured surfaces. In general, the combined aggregate should be such that when separated by a $^1/_4$-in. sieve, the volume retained on the sieve is approximately 40 per cent of the total, nor should the amount of coarse material be such as to produce a harsh mixture. When forms are removed, the faces and corners of all members should appear smooth and free from honeycomb. In no case should the water-cement ratio exceed the limit given in Table I corresponding to the strength assumed in the design. The value upon which the working stresses are based is the ultimate compressive strength in pounds per square inch developed at an age of 28 days by standard cylinders prepared and tested according to the A.S.T.M. standards. During the progress of the work, at least one specimen of concrete should be tested for each 100 cu yd. If the strength of such samples falls below that assumed in the design, the engineer should require the application of heat and moisture to increase the strength of the concrete to the required minimum.

As it is often impracticable to await the result of a 28-day test, samples may be tested at an age of 7 days and the following equation applied:

$$\text{Probable 28-day strength} = f + 30\sqrt{f}$$

f = ultimate compressive strength at an age of 7 days.

Table I, taken from the Joint Standard Building Code, gives the assumed 28-day strength of various concrete mixtures. The water-cement ratios to be used for different degrees of exposure of concrete are presented in Table II. In Table III are listed trial mixtures for various water-cement ratios. The mixes are intended as a guide only. The first batch should be made with measured water content and the proportions thereafter adjusted to produce the desired workability, maintaining the specific water-cement ratio.

Table I. Assumed Strength of Concrete Mixtures (From Joint Standard Building Code)

Water-cement Ratio *	Plastic Concrete		Moderately Wet Concrete	
	Approximate Mixture †	Assumed 28-day Compressive Strength, lb per sq in.	Approximate Mixture †	Assumed 28-day Compressive Strength, lb per sq in.
$8\frac{1}{4}$	1 : 7	1500	1 : $6\frac{1}{2}$	1500
$7\frac{1}{2}$	1 : 6	2000	1 : $5\frac{1}{2}$	2000
$6\frac{3}{4}$	1 : $5\frac{1}{4}$	2500	1 : $4\frac{3}{4}$	2500
6	1 : $4\frac{1}{2}$	3000	1 : 4	3000

NOTE.—In interpreting this table, surface water contained in the aggregate must be included as part of the mixing water in computing the water-cement ratio.

* U. S. gallon per 94-lb sack of cement.

† Volume of portland cement to sum of separate volumes of fine and coarse aggregate, measured dry.

Table II. Classes of Concrete for Different Degrees of Exposure

Type of Structure	Degree of Exposure	U. S. Gallon of Water * per Sack of Cement
Walls, dams, piers, and other structures exposed to sea or alkali waters.	Extreme	$5\frac{1}{2}$
Walls, dams, piers, reservoir linings, etc., exposed to alternate wetting and drying in fresh water in northern climate. Watertight structures. Sewers, pressure pipe, tanks, piles, athletic stadia, pavements, all thin structural members exposed to severe weather and frost action.	Severe	6
Walls, dams, piers, reservoir linings exposed to fresh water in southern climate. Exterior columns and beams of reinforced-concrete buildings. Basement walls. Thin structural members of all types exposed to moderate weather and frost action.	Moderate	$6\frac{3}{4}$
Ordinary enclosed structural members. Heavy piers and retaining walls in moderate exposure. Mass concrete, footings, etc., protected from alternate wetting and drying and from severe weather conditions.	Protected	$7\frac{1}{2}$

* These quantities should not be exceeded even when resultant strength is higher than required for structural stability. Free water or moisture carried by the aggregate must be included as part of the mixing water.

Moisture Contained in Aggregates. The absorption of most aggregates can be neglected as it is very small except for porous sandstones. All aggregates, however, particularly the fine aggregates, retain more or less water in the form of surface moisture. As this becomes part of the mixing water, the amount should be determined and the quantity deducted from that otherwise required for the chosen water-cement ratio. An approximation from $\frac{1}{4}$ to $\frac{1}{2}$ gal of water per cu ft may be assumed for fine aggregates varying from moist to moderately wet. Very wet sand may contain from $\frac{3}{4}$ to 1 gal per cu ft. Coarse aggregates retain less—from $\frac{1}{8}$ to $\frac{1}{4}$ gal. Accurate determination may be made by weighing a sample of the damp material, drying, and reweighing. The loss in weight is then converted to gallons of water per cubic foot of aggregate. Storage piles will retain a constant moisture content for two or three days, under settled weather conditions. Determination of water should, therefore, be made at such intervals or after a rain.

Table III. Trial Mixtures for Various Water-cement Ratios

Water-cement Ratio, gallons per sack *	Slump, in.	Trial Mix, Dry Compact Volumes for Maximum Size of Aggregate †	
		1-in. Aggregate	2-in. Aggregate

* Water-cement ratios include moisture contained in the aggregate.

† Proportions are given by volume, aggregate dry and compact. For approximate proportions by weight add 15 per cent to proportions of aggregate shown in the table. If aggregates are measured in a damp and loose condition, they occupy a greater volume than when dry and compact. Amount should be determined by test. Approximate average value for sand 20 per cent, for coarse aggregate, 6 per cent.

Some aggregates, especially sand, increase in volume when wet. Fine sands may increase as much as 40 per cent on adding only 5 per cent by weight of water. To correct for bulking, the bulked aggregate should be increased a sufficient amount to obtain the desired volume based upon a dry, compact condition. The weight of a given volume, measured damp and loose, compared to the volume produced by the same weight dry and compact, gives the necessary factor for the correct field mix to correspond to the proportions stated in the specifications.

Slump Test. An approximate method of determining the relative consistency of concrete is that known as the slump test. Samples of concrete, taken at the mixer, are placed in a metal mold, which is the frustum of a cone, base 8 in. in diameter, upper surface 4 in. in diameter, height 12 in. The mold is filled in a specified manner and immediately removed by being raised vertically. The distance which the plastic concrete subsides from the 12-in. level is the "slump." For similar materials mixed under the same conditions this test gives a very fair indication of the consistency of the concrete. It should not be used to compare consistencies of batches made with aggregates of other than the same grading. See Table III.

Mixing. Concrete should be mixed in a standard type batch mixer or, for small operations, on a water-tight platform. Mixing should continue until all materials are thoroughly distributed and the mass is uniform in color and homogeneous, i.e., for at least 1 min and preferably for 2 min after all materials have been placed in the mixer. Each batch should be carefully voided from the mixer before recharging. All equipment used to mix or convey concrete should be thoroughly cleaned at completion of the day's run. Remixing partially hardened concrete with an additional amount of water, or water and cement, should not be permitted. Aggregates may be measured in loading hoppers or in calibrated buggies or wheel barrows. Automatic water control is desirable provided that the water contained in the aggregates can be accurately checked; in any case, a water-measuring device should be installed controlling the supply from the storage tank to the mixer.

Conveying. Concrete should be handled from the mixer to the place of deposit as rapidly as practicable. Any means such as two-wheel buggies, wheel barrows, trucks, chutes, or belt conveyors may be employed provided that the concrete is delivered to the point of final deposit in a thoroughly homogeneous condition and before the cement has commenced to harden.

Depositing. Before concrete is placed in excavated areas all water should, if possible be removed and under no consideration should a flow of water be permitted around the newly deposited material. Before concrete is placed within wood or steel forms, ice, snow, shavings, or other débris should be removed. When building structural floors composed of clay block or cement tile, against which concrete is poured, the tile or block should be thoroughly wet with water except in freezing weather.

Concrete should be deposited evenly in the forms, in uniform layers. When constructing walls, a depth of 1 or 2 ft should be carried in a continuous operation entirely around the building or around the unit that is being constructed. Columns and pilasters should be poured in one operation and the concrete allowed to settle for at least 2 hours before pouring superimposed elements. Floor construction should commence with the beams and girders, into which the concrete should be poured directly; if concrete is dumped on the floor forms and allowed to flow into the beams, segregation will result. Where chutes are used, the concrete should be received in a hopper and redistributed by buggy or wheel barrow.

Concrete should not be dropped from a height of more than 5 ft without the aid of a pipe or elephant-trunk. It should be placed as nearly as practicable in its final position to avoid rehandling, and it should be thoroughly compacted by spading or puddling so as to expel entrained air as well as to insure complete filling of the forms and thorough embedment of the reinforcement. Excessive spading against exterior surfaces should, however, be avoided, as such tends to cause a layer of laitance next to the forms. Either internal or external vibration is helpful for compacting the concrete in thin walls or sections which it is difficult to spade.

Construction joints should be located so as to least impair the strength of the structure. Where horizontal joints are made, the hardened surface should be cleaned and roughened before additional concrete is deposited. Beams, girders, brackets, and column capitals should be considered as part of the floor system and placed monolithically with the floor slab. Construction joints in floors should be located near the middle of the spans, slabs, beams or girders, unless a beam intersects a girder at this point, in which case the joints in the girders should be offset a distance equal to twice the width of the beam, and provision should be made for shear by use of inclined reinforcement.

Concrete should not be deposited during freezing weather without special precautions being taken, as freezing of the water before setting exerts a disruptive force which causes disintegration. Although concrete which has been frozen immediately after placement may, upon subsequent thawing, eventually gain its designed strength, good practice demands protection, as alternate thawing and freezing will completely destroy the best concrete.

On cold-weather operations, the materials should be sufficiently heated to produce a temperature in the concrete at the time of deposit between 50 deg fahr and 100 deg fahr. Sheet-iron pipe, buried in the aggregates and fired with wood, is the usual method for heating small quantities of aggregates. Large quantities may be heated by a network of steam pipes underlying the storage piles. Foundations and slabs resting upon the ground may then be sufficiently protected by covering with canvases or, at extreme temperatures, by canvases covered with earth. For multi-story buildings, it is necessary to enclose the entire structure for a height of several stories with canvases, the interior being heated to a temperature of at least 50 deg fahr for a period of not less than 72 hours by means of steam, or salamanders burning coke.

Curing. After concrete has obtained its initial set, the proper hardening requires the presence of heat and moisture. Surfaces such as sidewalks, pavements, and floors should be kept moist for a period of 10 days after laying. Such treatment greatly increases the strength, durability, and resistance to abrasion. Surfaces may be covered with damp sand, or soft-wood shavings, the day after they are laid, and kept damp by frequent sprinklings. Vertical surfaces such as walls and columns should be sprinkled twice daily for a period of one to two weeks after stripping, according to the length of time which the forms have remained in place. Thin sections and ornamental work should also be protected by burlap or canvases from the effect of hot sun or drying winds. It should be remembered that a concrete designed for a certain 28-day strength, which it would acquire if cured at a temperature of 70 deg fahr, will attain only about 82 per cent of that strength when cured at a period of 50 deg fahr, and that a temperature just above freezing might well result, at the end of 28 days, in a strength hardly more than one-half of that which an average 70 deg fahr temperature would have produced.

Forms may be made of steel, wood, or composition boards, as may be most practicable for the type of work. They should conform to the lines and dimensions of the member as described on the drawings; they should be substantially constructed and sufficiently tight to prevent leakage of mortar. Temporary openings should be provided to facilitate cleaning débris from the bottoms of columns, piers, and similar members. Forms should be so removed as to insure the complete safety of the structure. The surfaces of forms should be oiled or wet before placing concrete. Oils should not be used against surfaces which are to receive plaster, nor should water be used in freezing weather.

In order to permit the erection of multi-story buildings with one set of forms, stripping is performed panel by panel, reshoring immediately. The entire floor system is then supported by shores for a period of two or three weeks from the time that concrete is deposited. Under such conditions the following periods may be accepted as a guide in determining the approximate time that the forms for the various members should remain in place upon buildings which are conservatively designed and which are not subjected to excessive construction loads, provided, however, that the concrete is such as will develop, under good curing conditions, a compressive strength of 2000 lb per sq in. at an age of 28 days, and that the temperature of the surrounding air during the entire curing period has not fallen below 50 deg fahr.

Beam and Girder Construction: Columns, 1 day provided that girders are shored to prevent any appreciable load being transferred to columns; girders, 3 days provided that each girder is immediately reposted so that only one member at a time is left unsupported; beams, 4 days provided that the same procedure is followed as for girders; panels up to 7-ft span, any time after the beam forms are removed.

Girderless Construction: Columns as noted above; drops, 3 days provided that slabs are reshored to prevent any appreciable load being transferred to the unsupported sections; slabs, up to 20-ft span, 4 days provided that each slab is immediately reposted and permanent 6 by 6 in. shores left beneath the center of each bay and not disturbed at the time of stripping.

Wall Forms: The forms of low, non-bearing walls can often be removed one or two days after pouring. It is only necessary that the concrete be sufficiently hard to support its own weight and permit the shock and jar of stripping without crumbling or spalling.

If concrete has been subjected to low temperatures, it may have the appearance of adequate strength when actually frozen. If forms are removed, the structure or the part affected is likely to fall when thawed. Although the use of a blow-torch may prove the existence of frost in the concrete, a more reliable method is to obtain a sample of the material in question and to place it in warm water for a few hours. If frozen and not hardened, the concrete on the surface of the sample will disintegrate.

High Early-strength Concrete. Increased strength at early ages may be obtained either by the use of additional cement or by special cements made for this purpose. For example, a compression strength of 2000 lb per sq in. may be obtained at age 3 days by limiting the water to $4^1/_2$ gal per sack of cement and curing at a temperature of 70 deg fahr; a 1000-lb compression strength may be obtained at the same age by using 6 gal of water per sack and curing at the same temperature. It should be remembered that, if the curing temperature is lower, less water should be used per sack of cement. For example, if the temperature is 40 deg fahr, a little less than 5 gal of water would correspond to a strength of 1000 lb at age 3 days. As the water-cement ratios are reduced, the amount of cement required for any given quantity of aggregate must be increased to make the concrete sufficiently plastic or workable. Increasing the time of mixing also increases the strength of the concrete, if other conditions remain constant. This increase is quite rapid up to 2 min.

Many special portland cements are made to give high early strength, without increasing the amount per batch that normally would be required for standard construction. The calcium aluminate cements have also found wide application, although considerably more expensive. They may be used to obtain at age 24 hours a strength normally to be expected from a standard portland cement at age 28 days.

Light-weight Concrete. Stone concrete weighs approximately 144 lb per cu ft. A lighter material is often desirable for short-span floor slabs and roof slabs, which may be designed with concrete of low stress value. This is obtained by using light-weight aggregates of burnt clays, or by proprietary methods that produce light-weight concrete by aeration. Cinder concrete weighs about 120 lb per cu ft; burnt clay aggregate concrete, 100 lb per cu ft; aeration methods are controlled to meet any specification for weight down to approximately 40 lb per cu ft.

Colored Concrete. Only mineral pigments should be employed to color concrete. Several makers produce a wide range of colors especially designed for portland cement mortars. The weight of pigment ordinarily should not exceed 5 per cent of that of the cement; 10 per cent should be an absolute limit, as a greater amount is likely to cause deterioration of surfaces exposed to abrasion or weathering. Much smaller percentages of certain colors, as lampblack, injure the quality of the concrete. Only thoroughly accredited material should be used, and the effect upon the cement should be established by actual test. Common practice is to buy the powdered pigment, proportion by weight, and mix dry with the cement; but better results are obtained when the cement and pigment are ground together. It is recommended that cement and pigment be blended at the mill and not on the job.

Finishing Concrete Surfaces. Concrete surfaces may be finished by painting, rubbing with abrasive material, scrubbing to expose the aggregate, or tooling as for natural

stone. It is necessary to remove all nails, wires, and bolts, or to cut them off a sufficient distance back of the surface to permit the application of protecting mortar, 1 in. thick, properly keyed into the surrounding concrete, and to repair stone pockets, honeycomb, or seams where laitance has settled. Such sections should be cut out, cleaned, wet, and pointed with a mortar of the same proportions as used in the concrete. When cutting out defective work, a $^1/_2$-in. shoulder should be left around the edges of the recess to avoid thin coatings of mortar spreading out over sound concrete, as these will invariably crack off.

A cheap method of finishing concrete surfaces not subject to abrasion is the application of a cement wash composed of 1 part white cement, 1 part finely screened sand, and 5 per cent hydrated lime, measured by volume of the cement. There are also many excellent proprietary paints for use on concrete surfaces. Such coatings resist the action of lime in the concrete and cover the same range of colors as that found in ordinary oil paints. Chemical solutions, some of which are colorless, may also be used to harden floor surfaces and prevent dusting; chief among these are the sodium silicate, aluminum sulfate, and zinc sulfate treatments.

A method of finishing vertical surfaces widely used on industrial buildings is to rub or grind with No. 20 Carborundum stone and plain water. The surfaces are rubbed until a thin paste develops, which is later removed by washing and brushing. Best results are obtained if the surfaces can be rubbed when the concrete is not more than 2 days old; if of greater age, a cement wash may be applied during rubbing to assist in the grinding. Excess material should invariably be removed later by brushing and washing.

The exposed aggregate finish is obtained by scrubbing concrete surfaces when only 1 or 2 days old with fiber or wire brushes and clean water. If the surfaces are too hard to be affected by this treatment, a solution of hydrochloric acid may be used. When the aggregates have been exposed, the surface should be thoroughly washed. This method is satisfactory for panels or other limited areas, but it is not suitable for extended work on monolithic buildings, owing to the difficulty of treating all surfaces at the same age, which is necessary for uniform results.

If thoroughly hardened before treatment, concrete may be finished by bush hammering, crandaling, or other methods employed for the finishing of natural stones. Tooling may be done by hand, compressed air, or electricity.

Quantities of Materials. Handbook tables, giving volumes of cement, sand, and coarse aggregates required for 1 cu yd of concrete of specified proportions, may serve as a rough guide, but may be somewhat misleading on account of the various gradings of the aggregates. An accurate determination of the quantities required for any given mixture can be made on the principle that the volume of concrete produced by any combination of materials, so long as the mixture is plastic, equals the sum of the absolute volumes of the cement, aggregates, and water. The absolute volume of a loose material is the actual total volume of solid matter comprising the particles.

Absolute volume = Unit weight ÷ (Apparent specific gravity × Unit weight of water).

Unit weight of the aggregate is determined for surface dry material; 1 cu ft of water is roughly 62.5 lb; 1 sack of cement = 1 cu ft = 94 lb; apparent specific gravity of cement = 3.1; specific gravity of aggregate = 2.65.

Assume that a batch consists of 1 sack of cement; 2.2 cu ft of dry, fine aggregate, at 110 lb per cu ft; 3.6 cu ft of dry, coarse aggregate at 100 lb per cu ft; and 7 gal of water. Then:

Cement = 1 cu ft @ 94/(3.1 × 62.5) = 0.49 cu ft abs vol
Fine aggregate = 2.2 cu ft @ 110/(2.65 × 62.5) = 1.46 " " " "
Coarse aggregate = 3.6 cu ft @ 100/(2.65 × 62.5) = 2.18 " " " "
Volume of water = 7.0/7.5 = 0.93 " " " "

Total volume of concrete produced 5.06 cu ft

For these conditions, 1 sack of cement produces 5.06 cu ft of concrete, neglecting absorption or losses in manipulation. The cement required for 1 cu yd of concrete is 27/5.06 = 5.34 sacks, or 1.33 bbl. The amount of fine aggregate is (5.34 × 2.2)/27 = 0.43 cu yd; the amount of coarse aggregate is (5.34 × 3.6)/27 = 0.71 cu yd.

For unusual materials, as blast-furnace slag or light-weight aggregates, the exact apparent specific gravity should be used. The value 2.65 is sufficiently accurate for sand, gravel, and limestone. The average value for granite is about 2.70, and for traprock 2.95.

Waterproofing Concrete. Concrete may be made practically impervious to water under moderate pressures if (1) the water-cement ratio is reduced to 5 $^1/_2$ or 6 gal per bag of cement; (2) the cement content is increased to give proper workability, i.e., the amount of combined aggregate, measured separately, reduced to between 3 $^1/_2$ and 5 parts by volume of the cement (aggregates measured dry and compact); if vibration is employed, a stiffer and consequently cheaper concrete can be used; (3) the aggregates, both fine and coarse, are carefully graded to obtain a minimum void content; (4) the methods of mixing, transporting, and depositing conform to good practice as defined in preceding paragraphs; (5) the concrete is cured under moist and warm conditions for a period of at least 10 days after placement.

The concrete comprising small units should be deposited as far as practicable in one continuous operation; when construction joints are necessary the old and new work should be joined by keys and the bond insured by roughing the surfaces already cast and slushing with a rich mortar before continuing work. If contraction joints are required by the design, they should be carefully placed so as to eliminate any possibility of the passage of water.

Concrete may also be waterproofed by either the membranous or surface coat method. The former consists of 3 to 5 layers of fabric laid in hot pitch or asphalt mastic, usually applied on the exterior and protected by a single course of brick or a heavy coating of cement mortar. The surface coat method generally consists of two coats of carefully proportioned cement mortar applied to the interior surface, which has previously been roughened and dampened to insure bond. Both methods require care in design and expert application, as their value depends upon obtaining a continuous, unbroken envelope on all surfaces exposed to hydrostatic pressure.

3. LIME

Quicklime is a calcined material, the major part of which is calcium oxide in natural association with a lesser amount of magnesium oxide, capable of slaking in water. Quicklime can never be used as such for structural purposes; it must always be slaked first. Quicklime is sold in several forms, such as crushed, granular, ground, lump, pebble, and pulverized lime. In many localities, well-supervised commercial plants have been established for the preparation of lime putty. Slaked and aged under proper conditions, it is delivered to the work as required.

Chemical Composition of Quicklime. (A.S.T.M. Tentative Specifications C5–34T.) All classes of quicklime shall conform to the following requirements as to chemical composition, calculated to the non-volatile basis:

	Calcium Lime	Magnesium Lime
Calcium oxide, min, per cent	75	..
Magnesium oxide, min, per cent	..	20
Calcium and magnesium oxides, min, per cent	95	95
Silica, alumina, and oxide of iron, max, per cent	5	5
Carbon dioxide, max, per cent:		
If sample is taken at the point of manufacture	3	3
If sample is taken at any other place	10	10

Classification of Quicklime According to Slaking Time. (A.S.T.M. Tentative Specifications C5–34T, Appendix 2.) In a bucket put two or three lumps of lime about the size of one's fist, or, if the lime is granular, an equivalent amount. Add sufficient water to just barely cover the lime, and note how long it takes for slaking to begin. Slaking has begun when pieces split off from the lumps or when the lumps crumble. Water of the same temperature should be used for the test and field practice.

If slaking begins in less than 5 min, the lime is quick slaking; from 5 to 30 min, medium slaking; after 30 min, slow slaking.

Slaking of Quicklime. For quick-slaking lime, the lime should always be added to the water. Sufficient water should be used at first to cover all the lime completely. The mass should be hoed thoroughly and quickly at the slightest appearance of escaping steam and enough water should be added to stop the steaming.

For medium-slaking lime, enough water should be added to the lime to about half submerge it. Occasional hoeing may be necessary if steam starts to escape. A little water may be added now and then if necessary to prevent the putty from becoming dry and crumbly. No more water than is required should be added, and not too much at a time.

For slow-slaking lime, sufficient water should be added to the lime to moisten it thoroughly, and the mass should be allowed to stand until the reaction has started. Water may then be added in such small quantities that the mass is not cooled. Hoeing should not be begun until the slaking is practically complete. Hot water is preferable in cold weather, or the mortar box may be covered so as to prevent loss of heat.

Preparation of Lime Putty or Paste. The time required for aging lime putty varies for different limes. The process should continue until all particles have been completely hydrated. In no case should the putty be used until thoroughly cold. The following procedure applies, under average conditions, to the preparation of lime putty after slaking. If desired, a part or all of the sand may be added immediately after slaking, but the present practice, except on small operations, is to postpone the addition of sand until the mortar is desired for use.

(*a*) Plaster White Coat. After the action has ceased, the putty should be run through a No. 10 sieve and stored in bins for a minimum of 2 weeks, except for quick-slaking pulverized limes which may be used 24 hours after slaking is completed.

(*b*) Plaster Brown Coat. After the action has ceased, the putty should be run through a No. 8 sieve and stored in bins for 2 weeks except as noted above. When desired for use, 1 part of lime putty is combined with 3 parts of sand by volume, together with the required quantity of hair or fiber, the whole being thoroughly mixed in a drum type of mixer.

(*c*) Plaster Scratch Coat. The procedure is the same as for the brown coat except that the proportions should be 1 part of lime putty to 2 parts of sand by volume.

(*d*) Mason's Mortar. After the action has ceased, the putty should be stored until cold, the length of time depending upon the character of the lime, and mixed in the appropriate proportions as given for lime or cement-lime mortars.

Hydrated Lime is a dry powder obtained by treating quicklime with enough water to satisfy its chemical affinity under the conditions of hydration. It consists essentially of calcium hydroxide or a mixture of calcium hydroxide and magnesium oxide and magnesium hydroxide. It is more convenient, particularly for masonry mortars, but does not give a plasticity equal to that of well slaked quicklime and is less economical where the volume of work warrants the slaking of lime at the site.

Classes of Hydrated Lime. A.S.T.M. Tentative Specification C6-34T covers the following two classes of limes: mason's hydrated lime, used for scratch or brown coat of plaster, for stucco, for mortar, and for addition to portland cement concrete; and finishing hydrated lime, used for any of the purposes enumerated above under mason's hydrated lime, and in addition, as an ingredient in the final or white coat of plaster. Finishing plaster shall have a plasticity figure of not less than 200, as determined in accordance with method given in A.S.T.M. Tentative Specification C110-34T.

Air-slaked Lime. Quicklime slakes when exposed to the air, by absorbing moisture from the atmosphere; and lime that is thoroughly air-slaked is as good as that slaked in the usual way. In general, however, air-slaked lime is not thoroughly slaked, and is therefore unsuitable for construction purposes inasmuch as it contains injurious amounts of oxides and carbonates in addition to the hydroxides of calcium and magnesium.

4. MORTAR

General Requirements. All materials should conform to the latest standard specifications of the A.S.T.M. Sand should be thoroughly screened, well graded from fine to coarse, the width of the joints determining the maximum size of particle, which is usually that passing a screen with 8 meshes to the linear inch. Except for this limitation on size, sands used for mortars should conform to the requirements given above for fine aggregates. Mineral pigments, thoroughly incorporated with the cement before mixing the other ingredients, may be employed to obtain the desired color, but the amounts used should be limited as specified for concrete work. Integral waterproofing compounds, hardeners, or accelerators may also be incorporated where conditions warrant their use. Such admixtures should be used in strict conformity with the manufacturers' recommendations.

All dry materials should be thoroughly mixed before the addition of water. The amount of water is controlled by the requirements of the work. In general, the consistency for laying brick, stone, and tile should be such as to facilitate thorough embedment of the masonry units and yet stiff enough to permit proper pointing and to furnish support for superimposed courses. Mortar applied as a finish over floor slabs, or fills, should be placed with merely enough water to permit screeding. This is not only for the purpose of permitting more speedy finishing, but also to increase the abrasive resistance and diminish dusting of the wearing surface. The consistency of mortar applied as stucco, to the exteriors or interiors of wall surfaces, is determined by the requirements of application and surface texture.

Portland Cement Mortar, mixed in the proportion of 1 part cement to 2 $^1/_2$ or 3 parts of sand, is customarily used for the surfacing of concrete slabs such as sidewalks and floors. Wherever possible, such finishes should be placed monolithically with the base course; hard, metallic surfaces may be obtained by the use of various admixtures, the mortar being surfaced with a steel trowel. For exterior work, exposed to the elements, a steel trowel finish is not only inappropriate but causes disintegration; sidewalks, for example, should be finished by means of a wood float. Cement mortars, usually containing integral waterproofing compounds, are also used in the surface-coat method of waterproofing and occasionally in place of lime plaster for interior finishes where a particularly hard surface is required.

Lime Mortar, generally composed of 1 part of either hydrated lime or lime paste and 3 parts of sand by volume, is now seldom used except for plastering purposes as noted below.

Portland Cement—Lime Mortar, composed of 1 part portland cement, an equal volume of either hydrated lime or lime paste, and 5 or 6 parts of sand, makes a satisfactory mortar for all ordinary masonry purposes. The use of portland cement and sand in the proportions of about 1:3, with the addition of only 10 or 15 per cent of lime by volume, is good practice only for masonry structures subjected to heavy loads where strength is a prime requisite. In the field of building construction, where it is necessary to construct weather-tight walls, the addition of a quantity of lime equal in volume to that of the portland cement produces a much more plastic mortar and one which will greatly facilitate the proper laying of masonry units.

Natural Cement Mortar, mixed in the proportion of 1 part cement to 3 parts of sand, is suitable for all types of masonry used in building construction, as the natural cements produce, without the addition of lime, a more plastic mortar than that obtained with portland cement.

Puzzolan Cement—Lime Mortar, mixed in the proportions of 1 part of puzzolan cement, 1 part lime paste, and 6 parts of sand, produces an excellent mortar which is also widely used for masonry.

Non-staining Mortar. Owing to the fact that many of our light-colored building stones, such as marble and limestone, are discolored when brought into contact with ordinary portland cement, it is necessary to use a so-called non-staining cement for such work. At present there are several white portland cements, natural cements, and puzzolan cements which are specially manufactured to meet this requirement. These cements may be used with varying amounts of hydrated lime or, preferably, in order to gain greater plasticity, lime paste. To avoid the possibility of efflorescence only the better grades of cement and lime should be used.

Table IV. Quantities of Material for 1000 Cu Ft of Mortar

Mortar	Lump Lime, 180-lb. bbl, number of bbl	Hydrated Lime, 50-lb Sacks, number of sacks	Cement, 94-lb Sacks, number of sacks	Sand, cu yd
Lime mortar:				
1 : 2 1/2	57	350	....	37
1 : 3	47	292	....	37
Cement-lime mortar:				
1 : 1 : 6	24	146	130	37
Cement mortar:				
1 : 2	16	92	442	34
1 : 3	12	69	331	39
1 : 4	10	55	264	41

(Based on use of good-quality lime. Lime quantities are approximate and will vary with the grade of lime and the size of particles composing the sand. In cement-mortars, 1/10 of the cement by weight is replaced by dry hydrated lime or its equivalent in lump-lime paste.)

5. PLASTER

Plasters are made from gypsum, which is composed of 1 part calcium sulfate and 2 parts of chemically combined water of crystallization. Gypsum plaster is produced by the calcination or dehydration of gypsum at a temperature which varies from 325 deg fahr to 350 deg fahr. At this temperature calcination removes approximately 1 1/2 parts of the chemically combined water, resulting in calcined gypsum or plaster of Paris. When gypsum is dehydrated by complete calcination at high temperatures, it is called calcined gypsum. Hard-finish plasters such as Keene's cement are made from this material by the addition of a catalyzer, such as alum.

Portland Cement Plaster is made from limestone and clay, which have been heated to a temperature above 1200 deg cent, and then ground to a fine powder and mixed with a small amount of gypsum to retard its setting time. Lime plaster is made by mixing quicklime, which is obtained by heating limestone to a temperature above 900 deg cent. Plaster used for finishing coats may be a specially prepared gypsum plaster or a mixture of lime plaster and calcined gypsum.

Neat Gypsum Plaster is composed of calcined gypsum, fibered or unfibered, and materials to control the working quality and setting time. Gypsum ready-sanded plaster is sanded at the mill in the proper proportions of calcined gypsum and sand, water being added only on the job. Gypsum bond plaster is a specially prepared gypsum plaster for use on concrete surfaces, it is not sanded. Gypsum wood fibered plaster, containing usually between 1 and 2 per cent of wood fiber, and other gypsum plasters to which sand is added, should be mixed as follows:

First or scratch coat on wood, metal or gypsum lath: 1 part plaster to 2 parts of sand by weight.

First or scratch coat on clay tile, gypsum tile, or brick, and for all second or browning coats: 1 part plaster to 3 parts of sand by weight.

The final coat may be a sand float finish, employing ready-sanded plaster, or texture work with color as desired. The universally used hard white finish is produced by combining approximately 1 part of gypsum gaging plaster with 3 parts of lime putty by volume, or 1 part of lime putty with 1 part of Keene's cement by volume where a more resistant surface is desired. Only gypsum mortar should be used for setting precast gypsum units, and when gypsum construction is plastered, gypsum plaster should be employed. Gypsum mortar is composed of 1 part of unfibered gypsum neat plaster and not more than 3 parts of clean, well-graded sand by weight.

STONE, BRICK, AND TERRA-COTTA

By Jasper O. Draffin

6. STONE *

Classification. Building stones are classified according to origin (igneous, sedimentary and metamorphic), and subdivided according to mineral and chemical composition, texture and structure, and geologic age. The most common granular crystalline-igneous rocks are granites, diorites, and gabbros or diabases; the more common dense varieties of volcanic origin are rhyolite, andesite, and basalt. Igneous rocks that have conspicuous crystals disseminated through a fine-grained to dense ground mass are called porphyrics (e.g., granite-porphyry, rhyolite-porphyry). Sedimentary rocks include conglomerates (consolidated gravel), sandstones and many quartzites, shales (consolidated clays), limestones, and dolomites. The more common metamorphic rocks are gneisses, schists, slates, some quartzites, and marbles.

Igneous Rocks. The most abundant of the granular crystalline rocks is *granite*, which consists mainly of feldspars and quartz with minor quantities of mica or hornblende, and minute quantities of certain other minerals. Commercially, however, other granular igneous rocks, like *diorite* and *gabbro*, which consist mainly of soda-lime feldspar and hornblende or pyroxene, are referred to as " black granite." These rocks are commonly massive, although closely spaced fractures or joints parallel to the surfaces of some quarries resemble a bedded or stratified structure. *Gneisses* (granular metamorphic rocks similar to granites in mineral composition but distinguished by a foliated arrangement of mineral grains) are also called granite commercially. Granites as a whole are composed mainly of hard minerals that are extremely resistant to chemical weathering and are so firmly welded together by crystallization under great pressure that they make by far the strongest stone in common use. Granites that contain unusually large percentages of mica are comparatively soft, but are resistant to weathering if free from alteration. Gray and light-red granites are generally more durable, as they consist of minerals which are more resistant to weathering. True granite generally has the advantage of breaking with regularity and is readily formed into simple shapes, but is so much harder and tougher than most sedimentary rocks that the elaborate finishing of blocks is comparatively expensive; however, in structures of monumental character and those subjected to severe conditions of physical and chemical weathering it may be ultimate economy to use granite.

Sedimentary Rocks. *Limestone* is widely distributed and is more widely used for building and crushing that any other kind of stone. It includes many varieties, which differ in color, composition, and adaptability for engineering and building purposes. Many limestones are dull gray or bluish gray and unattractive from an architectural standpoint.

---

* Largely from G. F. Loughlin.

Some of these are massive and suitable for crushing, and sufficiently free from impurities to be used in metallurgical and chemical industries; but others contain so many shaly streaks and are so impure that they are of no value unless situated where they can be used with other material in the manufacture of portland cement. The famous Indiana oölitic limestone, which contributes more than half of the building stone quarried annually in the United States, is a light buff to gray, porous, granular stone, similar to sandstone in mode of origin, although its " sand " grains are practically all minute shells or shell fragments. It is very easily quarried and worked, and is adapted for architectural and engineering uses where chemical weathering is not too severe.

Most limestones and marbles consist mainly of the mineral calcite which is slightly soluble in rainwater and in other waters or vapors containing acids and certain salts, especially ferric sulfate. Dolomite stone, or high magnesium limestone, which consists mainly of the mineral dolomite, is similarly affected but much more slowly. The effect of this corrosion is to roughen the surfaces of unevenly grained stones and gradually to remove small details of finish; but the rate of corrosion on the most exposed parts of buildings in the larger eastern cities of the United States is only about 1 in. in 600 to 800 years. It is much faster where attack by acid waters is more concentrated and continuous. The texture of limestones and dolomites varies from very porous to impervious, and their strength and resistance to weathering vary accordingly; but resistance to freezing depends not so much upon the degree of porosity as upon the size and distribution of the pores and the presence of impurities, especially certain varieties of clay minerals, that readily absorb and give off water with changing climatic conditions.

Sandstones vary greatly in color, texture, and usefulness. Their more common colors include light gray, buff, pink, red, and brown. Siliceous sandstones consist almost entirely of quartz grains cemented by silica, and the impervious variety of this composition, called quartzite, is extremely hard and difficult to work; but it is used especially in the manufacture of silica brick and occasionally as crushed stone and building stone. Calcareous sandstones contain calcite (calcium carbonate) as the principal cementing material; like limestones they are noticeably affected by severe or prolonged chemical weathering. Argillaceous sandstone contains clayey material as its chief cementing constituent; it is subject to relatively rapid disintegration, especially if certain of the clay minerals are concentrated along layers. Ferruginous sandstone contains considerable red, brown, or yellow iron oxide in its matrix. Its durability depends mainly upon whether the stone is otherwise siliceous, calcareous, or argillaceous.

Metamorphic Rocks are igneous and sedimentary rocks which have been acted upon by heat, water, or pressure, or combinations of these agents, to the extent that the original rock structures have been altered. Gneiss, marble, slate, and schist are the more common varieties; they are generally characterized by a foliated or laminated appearance, and some have pronounced cleavage planes. Marble occurs in all colors from pure white to black and is used chiefly for buildings, especially as interior finish; slate is employed for roofing purposes, the common colors being " slate," red, green, and purple. Mica and hornblende schists sometimes occur in such thin layers that they are of little value except for low-grade rubble or riprap, but the thicker layers of the more compact varieties are used for masonry and for concrete aggregate.

Strength of Stone. The strength varies according to the kind of stone, type of stress, and the locality where the stone is found. Table I gives average values for the principal varieties employed in engineering and architectural construction.

Table I. Average Strength of Stone

(U. S. Bureau of Standards, *Tech. Paper*, 349)

Kind	Range of Strength Properties, lb per sq in.				Modulus of Elasticity, millions of pounds per square inch
	Compression	Tension	Modulus of Rupture	Shear	
Granite	10,000–40,000	600–1000	1300–2400	2000–4300	5.7– 9.6
Syenite	14,000–28,000	....	....	....	....
Diorite	16,000–35,000	....	....	....	....
Quartzite	16,000–45,000	....	....	....	....
Limestone	2,500–28,400	280– 890	600–2200	1200–3000	3.0–10.4
Marble	8,000–27,000	400–2300	600–3500	1300–6500	7.2–14.5
Basalt	28,000–67,000	....	....	....	....
Serpentine	11,000–28,000	800–1600	....	2600–5000	4.8– 9.6
Sandstone	5,000–20,000	280– 500	500–1000	300–3000	1.9– 7.7
Slate	7,000–31,000	3000–4300	4000–9000	2000–3600	9.0–15.0

Durability of stone is a relative term and depends upon the climate, character of atmosphere, and amount of exposure of the stone in the structure. On the basis of a degree of disintegration so great that repairs are necessary because the building becomes unsightly, the U. S. Bureau of Standards (*Tech. Paper*, 123, 1919) gives the following estimates for the life of stone:

Coarse brownstone	5 to 15 years
Laminated fine brownstone	20 to 50 years
Compact fine brownstone	100 to 200 years
Bluestone	Untried, probably centuries
Nova Scotia stone	Untried, probably 50 to 200 years
Ohio sandstone, best siliceous variety	Perhaps 1 to many centuries
Limestone, coarse fossiliferous	20 to 40 years
Limestone, fine oölitic (French)	30 to 40 years
Marble, coarse dolomitic	40 years
Marble, fine	50 to 200 years
Granite	75 to 200 years
Gneiss	50 years to many centuries

7. BRICK

Brick. Until about 1900 the word brick always meant a prism of burned clay; but at about that date bricks composed of sand and lime were put upon the market, and at present many such brick are used annually, although their number is very small in comparison with that of ordinary clay brick. Ordinarily the word brick means a burned-clay brick, and a brick composed of sand and lime is called a sand-lime brick.

Clay Brick is made by submitting clay which has been prepared properly and molded into shape to a temperature which converts it into a semi-vitrified mass. Building brick are usually made from surface clay, and paving brick from shale (a fine-grained and indurated clay), since shale gives a tougher, denser, and stronger brick.

Classification of Clay Brick according to Method of Molding. *Soft-mud brick:* one molded from clay which has been reduced to a soft mud by adding water. It may be either hand- or machine-molded. *Stiff-mud brick:* one molded from clay in the condition of stiff mud. It is always machine-molded. *Pressed brick:* one molded from dry or semi-dry clay. *Re-pressed brick:* usually a stiff-mud brick which has been subjected to an enormous pressure to render the form more regular and to increase its strength and density. It is doubtful whether the re-pressing increases either the strength or the density. Occasionally in the East, and more formerly than at present, a soft-mud brick, after being partially dried, is re-pressed, which process greatly improves the form and also the strength and the density. A re-pressed brick is sometimes, but inappropriately, called a pressed brick. *Slop brick:* in molding brick by hand, the molds are sometimes dipped into water just before being filled with clay, to prevent the mud from sticking to them. Brick molded by this process is known as slop brick. It is deficient in color, and has a comparatively smooth surface, with rounded edges and corners. This kind of brick is now seldom made. *Sanded brick:* ordinarily, in making soft-mud brick, sand is sprinkled into the molds to prevent the clay from sticking; the brick is then called sanded brick. The sand on the surface is of no serious advantage or disadvantage. In hand-molding, when sand is used for this purpose, it is certain to become mixed with the clay and occurs in streaks in the finished brick, which is very undesirable; and owing to details of the process, which it is here unnecessary to explain, every third brick is especially bad. *Machine-made brick:* brick is frequently described as "machine-made," but this is very indefinite, since all grades and kinds are made by machinery.

Classification of Clay Brick According to Firing. When bricks were usually burned in the old-style up-draft kiln, the classification according to position was important; but with the new styles of kilns and improved methods of burning, the quality is so nearly uniform throughout the kiln that the classification is less important. Three grades of brick are taken from the old-style kiln: arch brick, body brick, and salmon brick. *Arch or clinker bricks:* those which form the tops and sides of the arches in which the fire is built. Being overburned and partially vitrified, they are hard, brittle, and weak. *Body, cherry,* or *hard bricks:* those taken from the interior of the pile. The best bricks in the kiln. *Salmon, pale,* or *soft bricks:* those which form the exterior of the mass. Being underburned, they are too soft for ordinary work, unless it is for filling. The terms "salmon" and "pale" refer to the color of the brick, and hence are not applicable to a brick made of a clay that does not burn red. Although nearly all brick clays burn red, yet the localities where the contrary is true are sufficiently numerous to make it desirable to use a different term in designating the quality.

Classification of Clay Brick According to Form. The form of the brick gives rise to the following terms. *Compass brick:* one having one edge shorter than the other. *Featheredge brick:* one having one edge thinner than the other. Used in arches; and more properly, but less frequently, called voussoir brick. *Face brick:* those which, owing to uniformity of size and color, are suitable for the face of the wall of buildings. Sometimes face bricks are simply the best ordinary brick; but generally the term is applied only to repressed or pressed brick made specially for this purpose. *Sewer brick:* ordinary hard brick, smooth, and regular in form. *Paving brick:* very hard, ordinary brick. A vitrified clay block, very much larger than ordinary brick, is sometimes used for paving, and is called a paving brick, but more often a brick paving-block. *Vitrified brick:* the introduction of brick for street pavements about 1890 led to a new grade, one burned to the point of vitrifaction and then annealed or toughened by slowly cooling. Vitrified brick and paving blocks, though originally made for paving purposes, are now much used in building and engineering structures. Standard sizes of clay brick are given in Table III.

Classification of Clay Brick According to Strength. Table II gives the A.S.T.M. classification of clay brick according to strength. The compressive test is made on a half-brick tested flatwise and properly bedded in plaster of paris to provide an even bearing. The bending test is made with the brick flatwise, span 7 in., and the load applied at mid-span. Table IV gives the result of strength tests made on bricks from different parts of the United States. Tests of brick piers are reported in Table V.

Table II. Grades of Clay or Sand-lime Building Brick

(According to A.S.T.M. Standard Specifications C62–30, C73–30)

Name of Grade	Compressive Strength (bricks flatwise), lb per sq in., mean gross area		Modulus of Rupture (bricks flatwise), lb per sq in., gross area	
	Mean of 5 tests	Individual minimum	Mean of 5 tests	Individual minimum
Grade A	4500 or over	3500	600 or over	400
Grade B	2500–4500	2000	450 or over	300
Grade C	1250–2500	1000	300 or over	200

The above classifications are based on strength and do not necessarily measure weather resistance.

Table III. Standard Sizes for Clay and Sand-lime Building Brick

(According to A.S.T.M. Standard Specifications C62–30, C73–30)

Types	Standard Sizes, in.			Permissible Variations, in.		
	Depth	Width	Length	Depth	Width	Length
Common clay brick	2 1/4	3 3/4	8	±1/16	±1/8	±1/4
Rough-face clay brick	2 1/4	3 3/4	8	±1/16	±1/8	±1/4
Smooth-face clay brick	2 1/4	3 7/8	8	±1/16	±1/8	±1/4
Sand-lime brick	2 1/4	3 3/4	8	±1/16	±1/8	±1/4

Sand-lime Brick consist of a mass of sand cemented together with lime. There are two classes of sand-lime brick: one in which the binding material is carbonate of lime, and the other in which it is silicate of lime.

The first is virtually a brick made of ordinary lime mortar, molded as are soft-mud clay brick, and hardened in the open air or in an atmosphere rich in carbon dioxide (CO_2), either with or without pressure. This form may properly be called a lime-mortar brick. It is the older form of sand-lime brick, and was formerly made in a small way where sand and lime were cheap and clay and fuel were expensive; but the brick is so weak and friable that it has not given satisfaction, and needs no further consideration here.

The second kind is made from a mixture of sand and lime which is molded in a press and hardened by being subjected to steam under pressure. The binding material consists chiefly of hydrosilicate of lime. Probably part of the lime is converted into carbonate by absorbing carbon dioxide; but the most of the lime combines with the silica of the sand and forms hydrosilicate of lime, a stable and comparatively strong cementing material. This form is the only one to which the term sand-lime brick is now applied; but in consulting the past literature on the subject, a careful distinction should be made between the two forms of so-called sand-lime brick. This form of sand-lime brick was first manufactured in Germany about 1880, and was introduced into America about 1900. There are localities where this form of brick is an important factor in building operations.

Sand-lime brick are made which in appearance and quality are the equal of dry-clay (pressed) brick. *The average sand-lime brick will be equivalent in strength to medium clay-brick.* When sand-lime bricks are manufactured under standard specifications they may be used as a substitute for clay-brick in masonry construction. Table II gives the A.S.T.M. classification of sand-lime brick according to strength. Table III gives the standard sizes of sand-lime brick.

Table IV. Strength of Clay or Shale Building Bricks

(From "Report of Committee C-3 *Proc. A.S.T.M.*, Pt. I, 1915)

Each lot consisted of 5 samples, and the maximum and minimum values refer to lots and not to individual tests.

8. TERRA-COTTA

Terra-cotta is a burnt-clay product made in the same general way as brick. Hard terra-cotta blocks and tile are made by burning clay at a very high temperature. Porous or soft terra-cotta, sometimes called terra-cotta lumber, is made by burning a mixture of clay and straw or sawdust. The straw or sawdust burns out, leaving a light, porous material. Nails and screws can be driven into porous terra-cotta, and it can be cut with a wood saw. Terra-cotta lumber is weaker than hard terra-cotta. Terra-cotta building blocks are made hollow with walls $^3/_4$ in. to 1 in. thick.

Strength. The A.S.T.M. specifications for structural clay hollow tile list three types: floor, non-load-bearing, and load-bearing wall tile. Each of these types is divided into

Table VI. Size and Weight of Hollow Clay Wall Tile
(From A.S.T.M. Tentative Specifications C34–34T, C56–34T)

Dimensions or Horizontal Thickness. Tile as Laid in Wall, in.	Minimum Number of Cells		Average Weight per sq ft of Tile, lb	
	In unit	In wall thickness	Minimum	Maximum

two grades on the basis of absorption and compressive strength. Table VIII gives the classification. The specified absorption for non-load-bearing tile is the same as given in the table for the other two types but there are no strength requirements.

Tests of terra-cotta columns built of hollow blocks laid with portland cement mortar were made in 1908 by Talbot and Abrams and reported in *Bull.* 27, Eng. Exp. Sta., Univ.

Table VIII. Absorption and Strength Requirements for Floor and Wall Tile

(From A.S.T.M. Tentative Specifications C57–34T, C34–34T)

Class	Absorption			Compressive Strength, lb per sq in.* †			
	Average of 5 tests	Individual		End-construction Tile		Side-construction Tile	
		Max.	Min.	Average of 5 tests	Individual minimum	Average of 5 tests	Individual minimum
Floor Tile *							
5–16	5 to 16	19	4	3200 or more	2250	1600 or more	1100
16–25	25 or less	28	4	2000 or more	1400	1200 or more	850
Load-bearing Wall Tile †							
5–16	5 to 16	19	4	1400 or more	1000	700 or more	500
16–25	25 or less	28	4	1000 or more	700	700 or more	500

* For floor tile the strength is based on the net area, which is taken as the area of solid material in shells and webs carrying stresses in a direction parallel to the direction of loading.

† For load-bearing wall tile the strength is based on the gross area, which includes total area of section including area of cells perpendicular to direction of loading.

of Ill. The compressive strength of blocks loaded on end ranged from 3472 to 5170 lb per sq in. Transverse tests of the blocks gave a modulus of rupture of 562 to 1440 lb per sq in. The strength of the columns varied from 64 per cent of the compressive strength of the blocks for those poorly laid to 86 per cent for those well laid.

REFRACTORIES

By J. Spotts McDowell and E. B. Guenther

9. COMMON TYPES OF REFRACTORY BRICK

Refractories, generically classed as fire brick, are structural materials used at high temperatures in industrial furnaces. The life of refractories is affected by the high temperatures to which they are subjected, and usually by one or more of the following influences: abrasion; corrosion through chemical action by slags and fluxes; erosion by mechanical action of molten metal or slag, or by dust-laden gases moving at high velocity; spalling of various types; the effect of various gases. The principal types of refractories are fireclay, high-alumina, silica, magnesite, and chrome. Refractories of other types have less extensive application. The term " firebrick " when used alone is generally understood to mean fireclay brick. It should be here noted that the data given in the following discussion refer to current practice in the United States which differs in various respects from that abroad.

Fireclay Brick. The most widely used refractory brick are those made from flint fire clays and plastic fire clays, the essential components of which are hydrous alumina silicates of the general type formula $Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$. Kaolinite is probably the most common member of this group. Until recent years this mineral was regarded as the essential constituent or " clay base " of all clays. However, it is now believed that it may not be the predominating mineral in all refractory fire clays.

The manufacture of fireclay brick consists in blending the raw materials, flint clay, plastic clay, and calcined clay or grog, either by grinding them together in a wet pan, or by grinding together or separately in a dry pan, then mixing and tempering them with the addition of water. The brick are molded by hand or mechanically; dried, either on hot floors or in dryers; and fired in periodic downdraft kilns or in continuous tunnel kilns. Various grades of fireclay brick are available and are referred to as super-duty, high heat duty, intermediate heat duty, moderate heat duty, and low heat duty fireclay brick. See Table IX for Pyrometric Cone Equivalents.

High-alumina Brick. In many parts of furnaces where the requirements are severe, high-alumina brick may be used to decided advantage.

High-alumina raw materials include bauxite, diaspore, diasporitic clays, cyanite, andalusite, sillimanite, and crystalline alumina or corundum. In manufacturing high-alumina brick (i.e., brick containing 50 per cent or more of alumina), these materials are used singly, in combination, or blended with flint and plastic clays according to the properties and percentage of alumina desired in the finished product. High-alumina brick which are manufactured by methods similar to those used in manufacturing fireclay brick are available in the 50, 60, 70, and 80 per cent alumina classes. Other high-alumina brick may be considered as special refractories.

Silica Brick. The raw material of the silica refractories industry is quartzite or ganister. Silica brick is manufactured by the same general processes used for fireclay brick. However, grinding is usually done in a wet pan with approximately 2 per cent of lime added in the form of milk of lime or an equivalent amount of hydrated lime. The lime bonds and gives strength to the green or unfired brick. It also reacts chemically with the quartzite during firing, imparting strength and toughness to the finished product.

The true specific gravity of silica brick depends both upon the character of the quartzite used in its manufacture and upon the temperature and duration of firing, and should lie between 2.28 and 2.40.

In the firing process a permanent expansion occurs from the green brick size to the fired size. It is desirable that this permanent expansion be completed in the firing, but as the final increments of permanent expansion take place slowly under high temperature, silica brick will show a slight permanent expansion in service.

When subjected to heat, silica brick, like other refractories, exhibit a temporary or purely thermal expansion, which disappears upon cooling. The linear thermal expansion of well-burned brick amounts to 1.2 to 1.6 per cent, the greater part of which occurs below 600° C.

In laying silica brick, it is important to provide for expansion at the rate of $^1/_8$ to $^3/_{16}$ in. per ft. Expansion joints should be kept free from mortar by packing to a depth of about 1 $^1/_2$ in., with a filler which will burn out, such as sawdust, cardboard, or strips of wood.

Silica brick are sensitive to rapid temperature change, and should be heated and cooled slowly and evenly; otherwise cracking or spalling will occur.

Magnesite Brick. The chief use of magnesite is in the manufacture of refractory materials. Its chemical properties and high refractoriness make it very suitable for furnace linings for metallurgical operations. For refractory purposes, it is sold in the form of brick, of finely ground furnace magnesite for brick-laying, and of dead-burned grains for making and repairing furnace bottoms. The grains are a mixture of granules varying from $^5/_8$ in. diameter to very fine but gritty particles.

For brick-making, the crude magnesite (essentially $MgO \cdot CO_2$) must be dead-burned, i.e., calcined at a temperature that will not merely drive off nearly all carbon dioxide, but will also cause sintering of the particles. During this process, the pieces shrink considerably and become hard, dense, and inert to atmospheric moisture and carbon dioxide. The material is ground dry to the desired size, then mixed and tempered in a wet pan with a small amount of water. The brick are usually molded under heavy pressure and dried in tunnel dryers. Usually magnesite brick are fired at cone 18 to 20. Cooling must be slow to avoid cracking. Magnesite brick bonded chemically instead of by firing, are also available.

Metal encased magnesite brick consist of round or square soft steel containers filled with ground dead-burned magnesite, or with chemically bonded magnesite brick. They are used for the back walls, bulkheads, and ends of basic open-hearth furnaces and side walls of electric furnaces. Their special advantage lies in the fact that the metal containers fuse for 1 or 2 in. back from the surface exposed to the heat, impregnate the magnesite, and bind the entire face of the wall. Joints, which are usually a source of weakness, are thus eliminated and the life of the wall is extended.

Chrome Brick. Chromite, $FeO \cdot Cr_2O_3$, is the most nearly chemically neutral of all the common refractories. However, it is acted upon either by strong acids or by strong bases. Because of its chemical character and high refractoriness it is an important refractory in metallurgical furnaces. The important sources of chrome ore for refractories are Greece, Cuba, Southern Rhodesia, and the Transvaal.

In American practice, it is not customary to use bonding material in the manufacture of fired chrome brick. It is therefore essential that the ore used should bond strongly together at kiln temperatures, but without deforming or squeezing out of shape. The ground ore is mixed and tempered with a small amount of water in a wet pan to the consistency of damp sand. The brick are usually molded in a power press at high pressure and dried in tunnel dryers. They are fired in either rectangular downdraft periodic kilns or continuous tunnel kilns, at a firing temperature of cone 18 to 20. Kilns must be cooled slowly to avoid cracking of the brick. Chrome brick, bonded chemically instead of by firing, are also available.

10 PROPERTIES OF REFRACTORIES

(Arranged alphabetically)

Abrasion, Resistance to. Tests for resistance to abrasion have been rather unsatisfactory. No method so far devised has been generally regarded as sufficiently reliable to warrant adoption as standard.

Analyses, Chemical. There is considerable variation in analyses of the various types of refractories. The figures given in Table I represent approximate mean values.

Table I. Approximate Chemical Analyses of Refractories

Type of Brick	SiO_2	$Al_2O_3 + TiO_2$*	Fe_2O_3	FeO	CaO	MgO	$Cr_2O_3 + Al_2O_3$	Alkalies
Fireclay								
Super-duty	51.0	45.0	2.2	....	0.3	0.4	......	1.0
High heat duty (Aluminous)	55.0	41.0	2.2	....	0.3	0.4	......	1.2
Intermediate heat duty	61.0	34.0	3.0	....	0.3	0.4	......	1.5

High-alumina								
50% Alumina Class	43.0	53.0	1.8	....	0.2	0.5	......	1.4
70% Alumina Class	23.0	74.0	1.7	....	0.1	0.3	......	0.9
Silica	95.5	1.2	1.0	....	2.1	0.2	......	0.2
Magnesite (fired)	3	1	7	....	3	85	......	......
Chrome (fired)	5	......	....	16	....	15.5	63 †	......

* The TiO_2 content will average about 5 per cent of the combined $Al_2O_3 + TiO_2$. Thus for a brick with 53 per cent $Al_2O_3 + TiO_2$, the TiO_2 content is about 2.7 per cent and the Al_2O_3 is about 50.3 per cent.

† In brick made from different raw materials, the Al_2O_3 content will vary from 12 to 30 per cent and the Cr_2O_3 will vary from 33 to 44 per cent.

Cold Crushing Strengths of various types of refractories are given in Table II.

Table II. Cold Crushing Strength of Refractories

Cold Crushing Strength in Pounds per Square Inch; Average Values—Bricks Tested on Flat

Fireclay Brick				High-alumina Brick 70% Al_2O_3	Silica Brick	Magnesite Brick	Chrome Brick
Super-duty	High Heat Duty (Aluminous)	Moderate Heat Duty	High Heat Duty (Siliceous)				
4000	1000–4000	Up to 5000	1500	4000	2000–4000	4500	4000

Conductivity, Thermal. Table III gives the approximate thermal conductivities of various refractories over a wide range of temperatures.

Table III. Approximate Thermal Conductivity of Refractories

Modern Refractory Practice, Published by Harbison-Walker Refractories Company, Pittsburgh, Pa.

Btu per hr per sq ft per deg fahr for a thickness of 1 in.

Temp. deg fahr	Kind of Brick				Temp. deg fahr	Kind of Brick

* Standard Load Test, A.S.T.M. Designation C16–20. Under a load of 25 lb per sq in. on end, the specimen is heated according to a prescribed heating schedule to 1350 deg cent (2462 deg fahr) and held at that temperature for 90 min.

† Standard Load Test, A.S.T.M. Designation C16–20. Under a load of 25 lb per sq in. on end, the specimen is heated according to a prescribed heating schedule until failure occurs.

Modulus of Rupture. Average values of modulus of rupture of various types of refractory brick are given in Table VI.

Table VI. Modulus of Rupture at Atmospheric Temperature

(A.S.T.M. Method C67–31, 7-in. span on flat)

Type of Brick	Modulus of Rupture, lb per sq in.	Type of Brick	Modulus of Rupture, lb per sq in.
Fireclay		High-alumina	
Super-duty	400	50% Alumina	750
High heat duty (Aluminous)	600–1200	70% Alumina	1200
Intermediate heat duty	800–1400	Silica	500–1000
High heat duty (Siliceous)	400	Magnesite	1500
		Chrome	1600–2000

Porosity. The porosity of refractories depends upon various factors, among them the character and quality of the raw material, the grind, the water content at the time of molding, the pressure of molding, and the time and temperature of firing. The porosity in turn affects the resistance of the brick to temperature change, the rigidity under load at high temperatures, the thermal conductivity, and the resistance of the brick to abrasion and slag action. See A.S.T.M. Standard C20–33 for method of determining porosity of refractory materials. Porosity of various types of refractory brick is given in Table VII.

Table VII. Porosities by Volume, Average Values

Type of Brick	Process of Manufacture	Porosity, per cent	Type of Brick	Process of Manufacture	Porosity, per cent
Fireclay			High-alumina		
Super-duty	Machine	12–16	50% Alumina	Machine	20–25
High heat duty (Aluminous)	Hand	20–30	70% Alumina	Machine	28–31
High heat duty (Aluminous)	Machine	15–24	Silica	Hand or machine	24–32
Intermediate heat duty	Machine	17–21	Magnesite	Machine	20–30
High heat duty (Siliceous)	Hand or machine	30	Chrome	Machine	20–30

Pyrometric Cone Equivalent (P.C.E.) is defined, in reference to refractories, as the number of that standard cone whose tip would touch the supporting plaque simultaneously with a cone of the material being investigated, when tested in accordance with the standard method of test for softening point of fire brick. See A.S.T.M. Standard C24–33. The determination of the P.C.E. consists in testing cones made of the ceramic material by comparing them with standard pyrometric cones, all heated together in the same furnace. The softening points of standard pyrometric cones used in connection with refractories are given in Table VIII. Table IX presents the pyrometric cone equivalents of various types of refractory brick.

Table VIII. Softening Point * of Standard Pyrometric Cones Used in Connection with Refractories †

A.S.T.M. Proc., Vol. 34, Part I, 1934, p. 1264

Cone No.	Softening Point		Cone No.	Softening Point		Cone No.	Softening Point		Cone No.	Softening Point	
	Deg cent	Deg fahr		Deg cent	Deg fahr		Deg cent	Deg fahr		Deg cent	Deg fahr
15	1435	2615	20	1530	2786	29	1640	2984	34	1760	3200
16	1465	2669	23	1580	2876	30	1650	3002	35	1785	3245
17	1475	2687	26	1595	2903	31	1680	3056	36	1810	3290
18	1490	2714	27	1605	2921	32	1700	3092	37	1820	3308
19	1520	2768	28	1615	2939	33	1745	3173	38	1835	3335

* These temperatures, which were determined by Fairchild and Peters for a heating rate of 150 deg cent per hr for cones 15 to 20, and of 100 deg cent per hr for cones 23 to 38, other conditions being the same as specified, apply satisfactorily for all the conditions of this test method, but do not apply to conditions of the commercial firing and use of refractory materials.

† Fairchild and Peters, Characteristics of pyrometric cones, *Journal, Am. Ceramic Soc.*, Vol. 9, No. 11, p. 701, Nov., 1926.

Table IX. Pyrometric Cone Equivalents (P.C.E.) for Various Types of Refractory Brick

Type	P.C.E.	Temperature	
		Deg fahr	Deg cent
Fireclay			
Super-duty	33–34	3173–3200	1745–1760
High heat duty (Aluminous)	31–33	3056–3173	1680–1745
Intermediate heat duty	28–31	2939–3056	1615–1680

80% Alumina	38 (av.)	3335	1835
Silica	31–32	3092	1700
Magnesite	Above 38	3335+	1835+
Chrome	Above 38	3335+	1835+

Refractoriness. The terms fusion point, softening point, and melting point are indefinite when applied to ceramic materials, which soften over a wide temperature range. No definite temperature marks the transition from the distinctly solid to the distinctly liquid state. Instead, the pyrometric cone equivalent (P.C.E.) is generally used.

Resistance to Slagging. This property is of primary importance in selection of refractory brick for service in furnaces where they are subjected to chemical corrosion by molten slags or fluxes. The resistance of a refractory brick to slag action depends upon its chemical composition, density and porosity, the prevailing temperature, and the chemical characteristics of the slag or flux. For resistance to siliceous slags or fluxes, fireclay brick, high-alumina brick or silica brick are serviceable. Where basic slags or fluxes are present, either fireclay, high-alumina, magnesite, or chrome brick are serviceable, the selection depending upon conditions stated above. Various simulative service tests have been devised, but since slagging depends on many factors, no test as yet developed (1936) has proved sufficiently reliable to warrant its adoption as standard.

Spalling, Resistance to. Spalling is defined as the breaking or cracking or crushing of refractory brick in service to such an extent that pieces are separated or fall away, leaving new surfaces of the brick exposed.

According to the A.S.T.M. Designation C71–31 the causes of spalling may be classified under three main headings as follows:

Thermal: (*a*) *Factors Related to Service.* Rapidity in range of thermal fluctuation; contamination by slags and fluxes; tightness of joints; previous vitrification.

(*b*) *Factors Related to Refractories.* Degree and uniformity of reversible thermal expansion; heat transfer; elasticity; plastic flow.

Mechanical: (*a*) *Factors Related to Service.* Rapid heating of wet brick; abuse in removing clinker and slags; unequal and excessive stresses; pinching; no provision for expansion; thin joints.

(*b*) *Factors Related to Refractories.* Mechanical strength; toughness; accuracy of shape.

Structural: (*a*) *Factors Related to Service.* Slags and fluxes; character of the material in joints; insulation of refractories.

(*b*) *Factors Related to Refractories.* Vitrification; shrinkage; nature of bond; structure; degree of burning.

Under the heading " Structural " the slags and fluxes referred to may cause a change in the texture or mineral constitution of the hot end of the brick or the high temperature prevailing may produce a like change; either or both of these may result in the formation of differing zones between inner and outer brick surfaces with consequent spalling.

Experience has shown that " Structural " spalling may also occur as the result of improper design of brick shapes, also because of faulty design or construction of the furnace.

Of the various types of refractory brick most widely used, super-duty fireclay brick have the greatest resistance to thermal spalling. Both super-duty fireclay brick and high-alumina brick may be considerably more resistant to textural spalling than other types of fireclay brick in the presence of certain types of slag, owing to their high refractoriness and chemical composition which enable them to resist change in texture due to high temperature or slag action. Silica brick are extremely sensitive to temperature change in the range of 400–1100 deg fahr. Magnesite and chrome brick are also very sensitive to temperature change, although changes in manufacturing methods are improving this characteristic. No single method for determining resistance to spalling can be applied to all types of refractory brick. A tentative method of panel test for resistance of refractory brick to thermal and structural spalling is covered by the A.S.T.M. Tentative Standard C38–34T. It has been found to be satisfactory for testing all classes of fireclay brick including super-duty.

Specific Gravity of various types of refractories is given in Table X.

Table X. Specific Gravity of Various Types of Refractories

Type of Brick	Specific Gravity			Type of Brick	Specific Gravity		
	High	Low	Average		High	Low	Average
Fireclay				High-alumina	Somewhat higher than for super-duty fireclay		
Super-duty	2.80	2.70	2.75	Silica	2.40	2.28	2.35
High heat duty (Aluminous)	2.75	2.65	2.70	Magnesite	3.60	3.44	3.52
High heat duty (Siliceous)	Somewhat lower than for aluminous fireclay			Chrome	4.4	3.7	4.05

Specific Heat. The figures given in Table XI appear to be the most probable values of the specific heats of refractory materials. They are based upon the work of various observers, whose data do not check with exactness.

Table XI. Specific Heats of Refractory Materials

Temperature, deg cent	0	100	200	300	400	500	600	700	800	900	1000	1100	1200	1300
Fireclay brick	.193	.199	.205	.211	.218	.225	.231	.238	.244	.249	.254	.258	.261	.265
Silica brick	.169	.189	.210	.230	.236	.245	.248	.253	.258	.262	.266	.269	.272	.275
Magnesite brick	.208	.220	.232	.241	.248	.254	.260	.265	.269	.274	.278	.282	.287	.292
Chrome brick	.170	.177	.182	.188	.193	.198	.202	.206	.210	.213	.217	.220	.222	.224

Thermal Resistivity is the reciprocal of thermal conductivity.

11. MORTARS FOR LAYING REFRACTORY BRICK

Fireclay brick are generally laid with fireclay mortar. Silica fireclay usually serves for laying silica brick; finely ground dead-burned magnesite, known as furnace magnesite, for magnesite brick, and finely ground chrome ore, known as furnace chrome, for chrome brick. Depending upon service conditions these materials are replaced to advantage by other materials known as " refractory bonding mortars."

Fireclay Mortars. The fireclay mortars used in laying fireclay brick are generally composed of clays of the same quality and characteristics as those of the clays used in the manufacture of the brick with which the mortars are used. Ground fireclay, used for laying brick, should be sufficiently plastic to have good working properties when mixed with water. For high temperature service, its refractoriness should closely approximate that of the brick. It may be as much as but not more than 3 cones lower.

Refractory Bonding Mortars. Until recently the term high-temperature cement designated various refractory products now known as high-temperature bonding mortars, used in furnace masonry to bond refractory brick. Some of these will set and develop great strength merely upon air drying. Others bond only when heated; some of these require very high temperature to develop their bond fully. There is also considerable variation in the refractoriness of bonding mortars on the market. They include a wide range of base materials, with considerable variation in their properties. Care is necessary in selection in order that satisfactory results may be secured.

Certain advantages over fireclay are secured by the use of high-temperature bonding mortars, as follows: (1) increased resistance to erosion by mechanical action of molten metal, slag or dust-laden gases moving at high velocity; (2) greater resistance to chemical corrosion by slags and fluxes; (3) increased resistance to abrasion; (4) decreased permeability to gases, liquid metal, and slag; (5) more rigid construction; (6) greater resistance to spalling.

12. OTHER REFRACTORY MATERIALS

Acid-resisting Brick. Chemical process industries, and other industries where various acids are manufactured or are used in large quantities, require storage tanks, towers, and other types of equipment for which linings and packing material with acid-resisting properties are necessary. Lead, wood, asphalt, ordinary vitrified brick, chemical stoneware, and special acid-resisting refractory brick have wide application, especially acid-resisting refractory brick. Such brick are serviceable both in contact with acids and other liquid solvents, and also in conjunction with nascent gases and acid fumes at high temperatures. The best materials of this type are dense, vitreous, non-absorbent, of low porosity, and strongly resistant to the action of solvents. They are manufactured from materials of extremely low flux content. The brick are fired at temperatures sufficiently high to convert the constituents largely into crystalline minerals which are insoluble in acids and corrosive acid chemical solutions and highly resistant to concentrated alkali solutions.

Digester Brick. The largest source of raw materials for the manufacture of paper pulp is soft wood, although other materials are used. Wood is transformed into paper pulp by either mechanical or chemical methods. One of the latter, known as the sulfite process, comprises boiling wood chips in sulfite liquor, which consists mainly of calcium and magnesium bisulfates dissolved in sulfurous acid. This process is accomplished in steel tanks called digesters. Formerly, digesters were lead lined, but in most modern practice the lining consists of two courses of acid-resisting brick separated by a 1-inch space which is filled with a mixture of Portland cement and sand. Between the brick lining and the shell is a 2-inch space, also filled with the cement-sand mixture.

Various types of acid-resisting brick are used for lining the digesters. One type is exceedingly dense and impervious; another is of a slightly more open texture. The dense vitreous brick is often preferred for the back lining, with the more open-texture brick for the face. The face brick becomes readily impregnated with solids and after a short time in service is quite impervious. The open-texture type is more resistant to spalling conditions, but under certain conditions of practice, the dense impervious brick is frequently used to good advantage for both the face and back linings. For certain digester conditions, a third type of brick, of still more open texture, is made. This is exceptionally resistant to spalling but can be used to advantage only in operations where the pores readily become filled with organic constituents and the salts formed therefrom.

Forsterite Brick. Forsterite refractories are made from olivine rock to which magnesia is added in the process of manufacture. Their chief constituent is the mineral forsterite ($2MgO \cdot SiO_2$), the brick analyzing about 57 per cent MgO, 32 per cent SiO_2, 6 per cent FeO, 5 per cent other oxides. Forsterite refractories are considered to be semi-basic. They excel in stability of volume at high temperatures. Their thermal conductivity is less than that of magnesite brick and approximates that of silica brick. Steam or aqueous acids will attack them.

Forsterite brick find application in ports, bridge walls, division walls, uptakes and bulkheads of basic open-hearth steel furnaces, and in exposed sections of side walls in copper reverberatory and refining furnaces. Their ability to carry load at relatively high temperatures has made them suitable within a certain temperature range for the construction of suspended and sprung arch roofs on copper reverberatory and refining furnaces and on copper holding furnaces.

Forsterite is a new type of refractory which is undergoing development, and it is highly probable that its field of application will be extended.

Insulating Materials. Within recent years an increasing amount of attention has been paid to thermal insulation as a means of increasing the operating efficiency of industrial furnaces. The materials available for this purpose may be classified as (1) bulk insulation, (2) insulating brick, (3) insulating refractory brick.

1. Bulk insulation, in the form of diatomaceous earth powder or expanded vermiculite, is used as an insulating backing to refractory settings, especially for irregular surfaces where brick cannot be readily fitted.

2. Insulating brick have high insulating values but are not suitable for use where they may be exposed to flame or products of combustion. They are manufactured from diatomaceous earth or other materials having inherently low thermal conductivities and are used mainly as a backing for refractory brick settings to reduce heat losses.

3. Insulating refractory brick are usually made from selected fire clays, to which an open porous structure is imparted during manufacture by means of " chemical bloating," or by the addition of organic materials which burn out during the firing process. Insulating refractory brick can be used in contact with flame or combustion gases, but will not withstand slag action or mechanical abrasion.

Insulation of a refractory setting reduces the heat flow and raises the mean temperature of the wall. This may necessitate the use of a more refractory material for the setting and always increases the amount of heat stored in it. Where high heat capacity is undesirable a lining of insulating refractory brick may be used in place of a combination of refractory brick and an insulating backing. Insulating refractory brick ordinarily weigh only 30 to 40 per cent as much as refractory fireclay brick of the usual density, and their heat capacity is only 30 to 40 per cent as great. Therefore, when conditions permit their use, they promote maximum thermal efficiency in intermittently operated furnaces.

Silicon Carbide Brick. Silicon carbide is composed of carbon and silicon, the chemical formula being SiC. It is made in the electric resistance furnace and sold under various trade names. The crystalline product forms at 3340 deg fahr and dissociates into its elements at 4060 deg fahr. No softening or fusion occurs below the dissociation temperature. Its hardness is 9.6 on the Moh scale, giving a remarkable resistance to abrasion. It is inert to all acids, liquid or gaseous, excepting a mixture of hydrofluoric and nitric acids, but may be decomposed by alkali when subjected to high temperature. Silicon carbide reacts with basic slags and molten iron and steel. It is made into refractory brick and shapes of two types known as bonded and recrystallized.

Bonded SiC refractories comprise silicon carbide crystals, with small percentages of permanent binders, depending on the type of service. The standard 9 by 4 $^1/_2$ by 2 $^1/_2$ in. brick weighs approximately 9.25 lb. A wide variety of special shapes are made for use in boiler, heat-treating, malleable-iron annealing, forge and melting furnaces, soaking pits, recuperators, electric furnaces, zinc retorts, coking and calcining retorts, gas producers, water-gas generators, porcelain enameling furnaces, periodic and tunnel kilns, glass lehrs, rotary kilns, roasting furnaces, etc. SiC refractories are especially resistant to the destructive action of clinker formed from coal ash. Thermal conductivity of the higher grades of SiC refractories is high, averaging 108 Btu per sq ft for a thickness of 1 in. per deg fahr per hr in the temperature range 1200–2800 deg fahr, making them suitable for indirect heating, as in muffles, retorts, recuperators, etc. Other average physical properties are: modulus of rupture, up to 900 lb per sq in. at 2460 deg fahr; crushing strength at 2460 deg fahr up to 10,000 lb per sq in., at 68 deg fahr approximately 15,000 lb per sq in.; specific heat, 0.18; spalling resistance, exceedingly high.

Recrystallized SiC refractories consist of a dense mass of SiC crystals bonded together by a recrystallization process. Since these bricks contain no added bonds they have essentially the same refractoriness as silicon carbide itself. They have little tendency to crack and spall and are used in extremely high temperature ranges where great load-carrying capacity is essential.

13. APPLICATION OF THE COMMON TYPES OF REFRACTORY BRICK AND OF INSULATION, IN FURNACE CONSTRUCTION *

Legend

1. Fireclay Brick

Annealing furnace	Lining	1-B, 1-C, 1-D, 6-A
	Combustion chamber	1-A, 1-B, 2
	Backing	1-C, 1-D, 1-E, 6-B
Arches, sprung	Complete	1, 2, 3, 6-A
Arches, suspended	Complete	1-A, 1-B, 2, 3, 4, 6-A
Bake oven	Combustion chamber	1-A, 1-B, 2
	Lining	1-B, 1-C
	Backing	1-C, 1-D, 1-E
Blast furnace		
Copper	Crucible	1-B, 1-C, 1-D, 4, 5
	Shaft	1-B, 1-C, 1-D
	Settlers	4, 5
Iron	Hearth and bosh	1-B
	Inwall	1-B
	Top	1-B
	Piping	1-C
Lead	Crucible and shaft	1-B, 1-C, 1-D
Blast furnace stove		
Iron	Lining	1-B
	Well wall	1-A, 1-B, 2
	Checkers	1-A, 1-B, 2
Boiler setting	Combustion chamber	1-A, 1-B, 2
	Arches and side walls	1-A, 1-B, 2
	Bridge walls	1-A, 1-B, 2
	Baffles	1-B
	Second pass	1-B, 1-C, 1-D
	Backing	1-C, 1-D, 1-E
Carbon baking furnace	Lining	1-B
Carbureter		
Oil gas	Lining	1-B
	Checkers	1-A, 1-B, 1-C
Water gas	Lining	1-B
	Checkers	1-A, 1-B, 1-C, 2
Coal gas benches	Retorts	3
	Settings	1-B

---

* In some cases the applications given may appear to be conflicting. It must be borne in mind that both furnace designs and operating conditions vary considerably; consequently the refractories requirements vary correspondingly.

Table XII—*Continued*

Type of Furnace	Application	Kinds of Brick Used (alone or in combination)
Coke oven		
By-product	Above floor	3, 6–A, 6–B
	Below floor	1–B
	Regenerators	1–B
	Checkers	1–B, 3
	Flues	1–B, 1–C, 1–D
	Doors	1–B, 1–C, 1–D
	Backing	1–D, 6–B
Beehive	Floors and doors	1–B
	Walls and crown	3
Converter		
Copper	Lining	4
Steel	Lining	3
Crucible furnace	Lining	1–A, 1–B, 2
Cupola	Lining (except melting zone)	1–B, 1–C
	Melting zone	1–A, 1–B, 1–C, 3
	Backing	1–C, 1–D
Distillation furnace		
Zinc	Outer walls	1–A, 1–B
	Center walls	1–B, 3
	Roof	1–A, 1–B
Dross furnace (non-ferrous)	Bottoms	1–A, 1–B
	Side walls	1–A, 1–B, 2
	Side walls (at slag line)	2, 4
	Roof	1–A, 1–B, 2
Electric furnace		
Brass	Complete lining	1–A, 1–B, 2
Steel (acid)	Bottom	3
	Side walls	3
	Door jambs	1–A, 1–B, 3
	Roof	1–A, 1–B, 3
Steel (basic)	Bottoms	4
	Side walls	3, 4
	Door jambs	1–A, 1–B, 3
	Roof	1–A, 1–B, 3
Enameling furnace	Complete lining	1–A, 1–B
	Piers	1–A, 1–B, 2
Enamel frit furnace	Complete lining	1–A, 1–B
Forge furnace	Lining	1–A, 1–B, 2–A, 2–B
Generator		
Oil gas	Complete lining	1–A, 1–B
Producer gas	Complete lining	1–B
Water gas	Complete lining	1–B
	Wall (at clinker line)	2–A
Glass lehrs	Complete lining	1–B, 6–A
	Backing	6–B
Glass pot furnace	Lining	1–A, 1–B, 2
	Crowns	1–B, 3
Glass tank (continuous and day)	Regenerators	1–A, 1–B
	Checkers	1–A, 1–B, 2
	Ports	1–A, 1–B, 2, 3
	Breast walls	3
	Roof	3
	Bottoms and side walls	Flux blocks
Gypsum kettle	Complete lining	1–A, 1–B
	Backing	1–C, 1–D, 6–A, 6–B
Heating furnace	Bottoms and several courses in side walls	1–A, 1–B, 4, 5
	Side walls	1–A, 1–B, 2, 6–A
	Roof	1–A, 1–B, 2, 6–A

Table XII—*Continued*

Type of Furnace	Application	Kinds of Brick Used (alone or in combination)
Incinerator		
Municipal	Complete lining	1–A, 1–B
	Backing	1–C, 1–D, 1–E
Paper mill	Lining	1–B
Kilns		
Cement, rotary	Burning zone	1–B, 2, 4
	Intermediate zone	1–B
	Cold zone	1–B, 1–C, 1–D
	Coolers	1–C, 1–D
Ceramic, periodic	Lining	1–A, 1–B
	Combustion chambers	1–A, 1–B, 2
	Backing	1–C, 1–D, 1–E, 6–A, 6–B
Ceramic, continuous	Lining	1–A, 1–B
	Burning zone (walls and arch)	1–A, 1–B, 2, 3
	Backing	1–C, 1–D, 1–E, 6–A, 6–B
Dolomite, rotary	Burning zone	1–B, 2, 4
	Intermediate zone	1–B
	Cold zone	1–B, 1–C, 1–D
	Coolers	1–C, 1–D
Lime, rotary	Burning zone	1–B, 2, 4
	Intermediate zone	1–B
	Cold zone	1–B, 1–C, 1–D
	Coolers	1–C, 1–D
Lime, vertical shaft and pot type	Lining	1–B
	Top lining	1–B, 1–C, 1–D
	Hot zone and arches	1–A, 1–B, 2, 3
	Piers	1–A, 1–B, 2, 3
Ladles		
Steel, tapping	Complete lining	1–B, 1–C, 1–D, 1–E
Treadwell	Complete lining	1–B
Litharge furnace	Bottom	4
	Lower walls	4
	Upper walls	1–B
	Roof	1–B
Locomotive firebox	Complete lining	1–B
Malleable-iron furnace	Bottom	1–A, 1–B
	Side walls	1–A, 1–B
	Bungs	1–A, 1–B
	Stack base	1–B
	Stack	1–C, 1–D, 1–E
Metal mixer	Complete lining	1–B
Muffle furnace	Complete lining	1–B
	Muffle	3
Open-hearth furnace		
Steel (acid)	Furnace lining	3
	Checker chamber lining	1–A, 1–B
	Checkers	1–A, 1–B
	Top course checkers	1–A, 1–B, 2
	Backing checker chambers	1–C, 1–D, 1–E, 6–A, 6–B
	Stack	1–C, 1–D, 1–E
Steel (basic)	Bottom	4, 5
	Bottom walls to slag line	4
	Slopes	4, 5
	Upper front walls	3, 4, 5
	Upper back walls	3, 4, 5
	Upper end walls	3, 4, 5
	Corner walls	4, 5
	Ports	4, 5
	Water-cooled ports	2
	Bulkheads	3, 4, 5
	Checker chamber lining	1–A, 1–B
	Checkers	1–A, 1–B
	Top courses checkers	1–A, 1–B, 2, 3
	Backing checker chambers	1–C, 1–D, 1–E, 6–A, 6–B
	Stack	1–C, 1–D, 1–E

Table XII—*Continued*

Type of Furnace	Application	Kinds of Brick Used (alone or in combination)
Puddle furnace	Complete lining	1–A, 1–B
Recuperators	Complete lining	1–B
Refining furnace (non-ferrous)	Bottom	1–B, 4
	Side walls to slag line	4
	Side walls, upper	1–A, 1–B, 2, 3
	Roof	1–A, 1–B, 2, 3
Regenerators	Complete lining	1–A, 1–B
	Checkers	1–A, 1–B, 2, 3
	Backing	1–C, 1–D, 1–E, 6–A, 6–B
Reverberatory furnace		
Copper	Side walls	3, 4
	Roof	3, 4
	Taps	4, 5
Lead	Bottom	1–B
	Side walls	1–B, 2
	Side walls at slag line	4
	Roof	1–B, 2
Roasters	Complete lining	1–B
Silicate of soda furnace	Bottom	1–B
	Side walls	1–A, 1–B
	Roof	1–A, 1–B, 2, 3
Soaking pits (steel)	Bottom	4, 5
	Lower side walls	4, 5
	Side walls	1–A, 1–B
	Roof	1–A, 1–B
	Backing	1–C, 1–D, 1–E, 6–A, 6–B
Soda recovery furnace (Paper mill)	Bottom	5
	Walls	1–B, 5
	Backing	1–C, 1–D, 1–E, 6–A, 6–B
Softening furnace. *See* Reverberatory furnace, lead.		
Stacks, chimneys	Stack base	1–B, 1–C, 1–D
	Lining	1–C, 1–D, 1–E
Stills (oil refining)	Lining	1–A, 1–B, 6–A, 6–B
	Combustion chamber, particularly at slag line	1–A, 1–B, 2
	Bridgewall	1–A, 1–B, 2
	Backing	1–C, 1–D, 1–E
Superheater (water gas)	Complete lining	1–B
	Checkers	1–B, 1–C, 1–D
Welding furnace	Complete lining	1–A, 1–B, 2
	Bottom	1–B, 4, 5
Zinc distillation furnace. *See* Distillation furnace, zinc.		
Zinc oxide furnace	Complete lining	1–A, 1–B, 3

THERMAL INSULATING MATERIALS

14. HEAT TRANSFER

By Radiation. The energy radiated per unit area per unit time from a substance is approximately proportional to the fourth power of the absolute temperature. (For a black body the proportionality is exact.) The net loss per unit of time depends on the surroundings, being the difference between the energy radiated and the energy received by radiation from surrounding bodies.

By Convection. Transfer of heat by convection occurs in liquids and gases, the transfer being accomplished by the motion of the fluid from a locality where it receives heat to a locality where it gives up heat.

By Conduction. Transfer of heat by conduction occurs through continuous materials in which energy is transferred directly between adjacent molecular aggregates without mass motion of the materials.

When heat flows in a solid, homogeneous body in only one direction, the time rate of heat flow, after a steady state has been reached, across a given area will be proportional to the temperature drop per unit length in the direction of the flow of heat. The factor of proportionality is, by definition, the thermal conductivity.

If $\frac{dQ}{d\tau} = q =$ the time rate of heat flow;

$A =$ the area measured perpendicular to the direction of low;

$\frac{dT}{dx} =$ the temperature gradient;

and $k =$ the thermal conductivity;

$$q = \frac{dQ}{d\tau} = kA\,\frac{dT}{dx} \tag{1}$$

for a steady state where $\frac{dT}{d\tau} = 0$ at all points.

15. THERMAL CONDUCTIVITY

The Heat Conductivity of a material is a measure of the insulating value of that material: the lower the conductivity, the greater the insulating value. Obviously the best conductor of heat is the poorest heat insulator. The customary measure of the conductivity k of a material is the amount of heat in Btu (British thermal units) which will flow in 1 hr through a layer of the material 1 sq ft in area when the temperature difference between the surfaces of the layer is 1 deg fahr per in. of thickness.

The thermal conductivity k is a property of a material itself, and does not depend upon the size or shape of a particular piece of the material in question.

Thermal Conductance per Unit Area, or Unit Conductance, C_a, depends directly upon the conductivity and inversely upon the thickness of a given material, or

The Internal Resistance to heat flow or resistance of a unit area of a flat layer of any material is:

$$RA = \frac{1}{C_a} = \frac{x}{k} \tag{3}$$

where R is the thermal resistance, in degrees, per unit of heat transferred per unit of time: A is the area; and $1/k$ the resistivity.

Insulation. The same principles are involved in what is sometimes called "insulation against cold" as in "insulation against heat." The only difference is the point of view, with regard to the direction of heat flow. The insulation of a building against the outside cold is merely a question of reducing the heat flow from the inside to the outside. The insulating value of a material depends somewhat upon the temperature of the material, but this effect is small over the small temperature ranges occurring in buildings. The same layer of material would be somewhat more effective as house insulation than as oven insulation.

Coefficients of Transmission may be determined experimentally* or they may be calculated from fundamental constants. The *overall coefficient of heat transfer*, U, or heat transferred per unit time per unit area, per degree overall, for a compound wall of several materials having thicknesses x_1, x_2, x_3, etc., is

$$U = \frac{1}{\frac{1}{f_i} + \frac{x_1}{k_1} + \frac{1}{a} + \frac{x_2}{k_2} + \frac{1}{f_o} + \text{etc.}} \tag{4}$$

where a is the unit conductance of the air space; f_i and f_o the inside and outside coefficients for the two materials in contact with air,† and k_1, k_2, etc., the thermal conductivity of the separate materials.

Conductances of Air Spaces at various mean temperatures and for several widths between ordinary building materials are given in Table I. These results were obtained at the University of Minnesota under a cooperative research agreement with the American Society of Heating and Ventilating Engineers.

Conductances of Building Materials and Insulators are given in Table II. This table, published with the permission of the American Society of Heating and Ventilating Engineers, was compiled from the published values of various investigators. It should be noted that the figures in the table depend upon the mean temperatures for which they were determined.

16. THERMAL COEFFICIENTS

Table I. Conductances of Air Spaces‡ at Various Mean Temperatures

Mean Temperature, deg fahr	Conductances of Air Spaces for Various Width in Inches						
	0.128	0.250	0.364	0.493	0.713	1.00	1.500
20	2.300	1.370	1.180	1.100	1.040	1.030	1.022
30	2.385	1.425	1.234	1.148	1.080	1.070	1.065

TIMBER

By H. C. Knutson and Herbert F. Moore

17. COMMON TIMBER TREES

Classes of Timber Trees. Wood as a building material is produced by the Spermatophyta or seed-bearing trees, which may be divided botanically into two groups, the Gymnosperms, or conifers and the Angiosperms. The Angiosperms have two subclasses, the Dicotyledons and Monocotyledons. The Dicotyledons are the two seed leaved, broad-leaved trees such as ashes, elms, maples, walnuts, etc. The Monocotyledons have single seed leaves. Bamboos, palms, and yuccas belong to this subclass.

The conifers and broad-leaved trees produce the structurally valuable timbers. The conifers are generally called the softwoods while the broad-leaved trees are referred to as hardwoods. The terms softwood and hardwood as used here have no reference to the actual hardness of the wood. Many hardwoods are actually softer than the average softwood.

The conifers and the broad-leaved trees are known as the outward-growing or exogeneous trees. The structure consists of three parts, the bark. the sapwood, and the heartwood. On the outside of the tree trunk is found from 1/4 to 2 in. or more of bark or protective tissue. As a structural material this is valueless and is always removed soon after the tree is felled, as it hastens the decay of the wood. Inside of the bark there is a portion made up of thin-walled cells which constitute the living portion of the tree, called the sapwood. Arranged in a circle inside of this sapwood are many fibrous bundles making up the middle of the stem, giving it strength and stiffness and known as the heartwood. As the stem grows, new and branching bundles of these hollow fibers appear under the bark and form each season an annular ring. At the end of the season growth stops, to be resumed the following spring; and the rapid open growth of the spring against the slow and condensed growth of the summer gives rise to the peculiar marking in the bundles which indicates each year's increase. The last few rings formed constitute the sapwood, usually from 1/2 to 4 in. in thickness and light in color. The rings inside of the sapwood form the heartwood. The rings are interrupted by plates of tissue or radial cells communicating between the pith at the center of the tree and the soft tissue on the outside. These form the medullary rays. In the pine, the sapwood constitutes 40 to 60 per cent of the cross-section of the tree. The time required for sapwood to transform into heartwood varies from a few years for the fir to many years for the oak tree. The approximate composition of all woods when dry is nearly uniform and consists by weight of the following elements: 49 per cent of carbon, 6 per cent of hydrogen, 44 per cent of oxygen, and 1 per cent of ash.

Green Ash. Heavy, hard, and coarse-grained; brittle. Color, brown, with lighter sapwood. Used as a substitute for white ash.

Red Ash. Heavy, compact, and coarse-grained but brittle. Color, rich brown, with sapwood a light brown sometimes streaked with yellow. Used as a substitute for the more valuable white ash.

White Ash. Heavy, hard, very elastic, coarse-grained, and compact. Tendency to become decayed and brittle after a few years. Color, reddish-brown, with sapwood nearly white. Used for interior and cabinet work, but unfit for structural work.

Balsa. Extremely light, about half the strength of white pine. Appearance like poplar. Used for heat insulation and, when waterproofed, for life preservers.

Butternut (White Walnut). Light, soft, coarse-grained, compact, and easily worked. Polishes well. Color, light brown, turning dark on exposure. Used for interior finish.

Red Cedar. Strong pungent odor repellent to insects. Very durable and compact, but easily worked and brittle. Color, dull brown tinged with red. Used as posts, sills, ties, fencing, shingles, and lining for chests, trunks, and closets.

White Cedar. Soft, light, fine-grained, and very durable in contact with the soil; lacks strength and toughness. Color, light brown, darkening with exposure. Sapwood very thin and nearly white. Used for water tanks, shingles, posts, fencing, cooperage, and boat building.

Chestnut. Light, moderately soft, stiff, and of coarse texture. Shrinks and checks considerably in drying; works easily. Durable when exposed to weather. Color, heartwood dark and sapwood light brown. Used for cabinet work, cooperage, railway ties, telegraph poles, and exposed heavy construction.

Cypress. One of the most durable of woods, light, hard, close-grained but brittle. Easily worked, polishes highly and gives a satiny gloss. Color, bright clear yellow with nearly white sapwood. Used for interior finish and cabinet work, but used as extensively in the South as pine is in the North.

Douglas Fir. Hard, strong, varying greatly with age, conditions of growth, and amount of sap. Durable but difficult to work. Of two varieties, red and yellow, of which yellow is the more valuable. Color, light red to yellow, with white sapwood. Used in all kinds of construction.

White Elm. Heavy, hard, strong and tough, and very close-grained. Difficult to split and shape, but warps badly in drying. Capable of high polish. Color, light clear brown often tinged with red and gray, with broad whitish sapwood. Used for car, wagon, boat, and shipbuilding, bridge timbers, sills and ties, and furniture, also barrel staves.

Greenheart. Very heavy, strong, durable heartwood, dark green to dark chestnut color, free from knots. Used for shipbuilding, docks, implements, rollers.

Gum. Heavy, hard, tough, compact, and close-grained. Tendency to shrink and warp badly in seasoning. Not durable if exposed. Takes high polish. Color, bright brown tinged with red. Used in the manufacture of furniture, wagon hubs, hat blocks.

Hemlock. Brittle, splits easily and likely to be shaky. Soft, light, not durable, with coarse and uneven grain. Color, light brown tinged with red and often nearly white. Used for cheap rough framing timber, crates, and packing boxes.

Hickory. Medullary rays very numerous and distinct. Heaviest, hardest, toughest, and strongest of American woods. Very flexible. Color, brown, with very thin but valuable sapwood nearly white. Used for carriages, sleighs, handles, and bent-wood implements. Unfit for building material because of extreme hardness and liability to attack of boring insects.

Lignum Vitæ. Exceedingly heavy, hard, resinous, difficult to split and work, and has a soapy feeling. Color, rich yellow brown varying to almost black. Used for small turned articles, tool handles, and sheaves of block pulleys.

Locust. Heavy, hard, strong, and close-grained. Very durable in contact with ground. Hardness increases with age. Color, brown and rarely light green, with yellow sapwood. Used for posts and turned ornaments.

Mahogany. Strong, durable, and flexible when green, but brittle when dry. Free from shakes and less liable than most other woods to attacks of dry rot or worms. Rapid seasoning causes deep shakes. Color, red-brown of various shades and degrees of brightness, often varied and mottled. Inferior qualities contain large numbers of gray specks. Used for interior finish, handrails, patterns, etc.

Hard Maple. Heavy, hard, strong, tough, and close-grained. Medullary rays small but distinct. Curly and circular inflexion of fibers gives rise to " curly maple " and " bird's-eye maple." Susceptible of good polish. Color, very light brown to yellow. Used for flooring, interior finish, and furniture.

White Maple. Fine-grained, hard, strong, and heavy. Characteristics of grain the same as hard maple and more marked. Light colored. Used for flooring and furniture.

Chestnut Oak. Very durable in contact with soil. Color, dark brown. Used for railroad ties.

Live Oak. Very heavy, hard, tough, and strong. Difficult to work. Color, light brown or yellow, with sapwood nearly white.

Red and Black Oak. More porous than white oak and softer. Color, darker and redder than white oak. Used for interior finish and furniture, and railway ties.

White Oak. Heavy, strong, hard, tough, and close-grained. Checks if not carefully seasoned Well-known silver grain and capable of receiving high polish. Color, brown, with lighter sapwood. Used for framed structures, shipbuilding, interior finish, carriage, furniture making, and railway ties.

Palmetto. Light but difficult to work when dry. Very durable under water and less subject to attacks of the teredo. Color, light brown, with dark-colored fibers. Used for wharf piles, canes and handles.

Red Pine (Norway Pine). Light, hard, coarse-grained, compact, with few resin pockets. Color, light red, with a yellow or white sapwood. Used for all purposes of construction.

White Pine. Light, soft and straight-grained and easily worked, but not very strong. Color, light yellowish brown often slightly tinged with red. Used for interior finish and pattern making.

Yellow Pine (Long-leaf). Heavy, hard, strong, coarse-grained, and very durable when dry and well ventilated. Cells are dark colored and very resinous. Color, light yellowish red or orange. Cannot be used in contact with ground. Used for heavy framing timbers and floors. As house sills, sleepers, or posts it rapidly decays.

Yellow Pine (Short-leaf Pine). Varies greatly in amount of sap and quality. Cells broad and resinous, with numerous large resin ducts. Medullary rays well marked. Color, orange, with white sapwood. Used as a substitute for a long-leaf pine.

Yellow Poplar (Whitewood). Moderately light in weight, straight-grained, moderately soft, moderately weak, comparatively uniform in texture. Sapwood white, heartwood yellowish brown with greenish tinge. Easily worked. Finishes smoothly. Used in carpentry and joinery.

Redwood (California). Light, soft, coarse-grained, and easily worked. Durable in contact with soil, but brittle. " Shrinks lengthwise as well as crosswise." Color, dull red, resembling pine. Used for railroad ties, fence posts, telegraph poles, and general building material.

Red Spruce. Light, soft, close and straight-grained and satiny. Color, light red and often nearly white. Used for piles, lumber, and framing timber, submerged cribs and coffer dams, as it resists the destructive action of crustaceans.

Sitka Spruce. Light, soft, medium strength. Heartwood, light, reddish brown; sapwood, white; trees very large. Used for general structural purposes; also for airplane frame-work.

White Spruce. Similar to red variety, but not so common. Color, light yellow; sapwood indistinct. Used as lumber for construction.

Tamarack. Wood like pine in appearance, quality, and uses. Used for telegraph poles, railway ties, and in shipbuilding.

Black Walnut.—Heavy, hard, strong, and checks if not carefully seasoned. Coarse-grained but easily worked. Color, rich dark brown, with light sapwood. Used for interior finish and cabinet work.

18. SAWING AND SEASONING

Sawing. The manner in which the stick of lumber is sawed from the tree has a remarkable influence upon its qualities and behavior, and the selection of cutting is determined by the character of the wood and the purpose for which it is destined. *Flat sawing* consists in cutting the timber tangential to the annular rings. *Rift sawing* is cutting the boards out of the log in such a manner that the annular rings are cut through as nearly as possible in a radial direction. Rift sawing and flat sawing give rise in the lumber trade to the terms edge grain and flat grain, respectively. Rift sawing is done for the sake of the beauty of the grain thus obtained, as well as to expose the edge of the hard bands of summer wood. Edge-grain lumber shrinks and checks less, does not sliver, and wears more evenly and smoother than flat-grain lumber.

Air Seasoning. In the preparation of lumber for construction purposes, it is necessary to expel the moisture from the pores of the wood by the process of seasoning. The drier the timber, the less likely it is to shrink and decay. Natural seasoning consists in exposing the planks and boards, after sawing, to a free circulation of the air. The lumber is placed on skids in large square piles under shelter in a dry place, the layers being separated by three or four narrow strips or boards laid in the opposite direction. The lowest layer should be at least 2 ft from the ground. The time required for thorough seasoning varies from one to three years, depending upon the character of the wood, the purpose to which it is to be adapted, and the dimensions. Green wood contains from 30 to 35 per cent of water. Air seasoning reduces this to 12 to 15 per cent.

Artificial Seasoning or Kiln-drying hastens the evaporation of the moisture but at the same time tends to cause a rapid drying of the surface and ends of the material and a slow or imperfect drying of the interior. This may impair both the strength and elasticity of the wood. The timber is stacked in a drying kiln and exposed to a current of hot air, the temperature depending on the kind and the dimension of the stack. Sometimes the heat is supplemented by the employment of vacuum pumps. The best temperature to be employed depends on the kind and dimensions of the lumber, and varies from 100 deg fahr for oak to 200 deg fahr for pine. The time required depends on the thickness of the stack. About four days is necessary for 1-in. pine, spruce, or cedar boards. Hardwoods are usually dried in air from three to six months and then placed in the drying kiln from six to ten days. Kiln drying reduces the moisture content of wood to less than 10 per cent.

19. SHRINKAGE AND DEFECTS

Shrinkage. The concentric annular zones of wood are made up of pores or cells enclosed by walls of cellulose and are pierced at right angles by plates of similar fibers. As the average width of cell is 1/100 of the length, the greatest shrinkage will take place in the cross-section of the fibers or tangentially to the annular rings. This is known as the circumferential shrinkage. By rift sawing the medullary rays are cut across the length, in which direction shrinkage is least. Flat sawing produces lumber which checks and cracks to a greater extent in shrinking. The average values for shrinkage in width are:

Hardwoods: radial, 2–5%; tangential, 4–7%
Softwoods: radial, 1–4%; tangential, 2–6%

The longitudinal shrinkage is usually less than 0.1 per cent. The change in volume is therefore due to radial and tangential shrinkage, and expressed in percentage is approximately twice the figures given, as shrinkage takes place in two directions by approximately equal amounts.

The harder timbers are more compact in structure, with thicker cell walls, and therefore produce the greater shrinkage. The opposite effect to shrinkage is produced by the absorption of moisture, and protective checks must be resorted to in applying timber to construction; the expansion joints in wooden block pavement serve as checks. A roadway 40 ft wide has been observed to expand 8 in. in rainy weather.

Definitions of Standard Defects. The following definitions of standard defects are from the A.S.T.M. Standard D9–30.

Defect. Any irregularity occurring in or on the wood that may lower its strength. *Blemish.* Anything, not necessarily a defect, marring the appearance of the wood.

Bark Pocket. Bark partially or wholly enclosed in wood.

Check. A separation along the grain of wood, the greater part of which occurs across the rings of annual growth. *End check.* A check occurring at the end of a piece. *Heart check.* A check starting near the pith and extending toward but not to the surface of a piece. Several of these occurring together are called a star check. *Surface check.* A check occurring at the surface of a piece. *Through check.* A check extending through the piece from one surface to an opposite or to an adjoining surface.

Collapse. A caving at a surface of a piece of wood. It sometimes occurs in streaks, giving the surface a corrugated appearance and often is due to the flattening of the cells when wet wood is dried quickly. *Honeycombing.* Checks that occur in the interior of a piece of wood, often not visible at the surface. On a cross-section they usually appear as slits or pockets the width of which may be very large relative to the radial length. *Cross break.* A separation of the wood cells across the grain. Such breaks may be due to internal strains resulting from unequal shrinkage or to external forces.

Cross-grained Wood. Wood in which the fibers are not parallel with the axis of the piece. *Curly grained wood.* Wood in which the fibers are distorted so that they afford a curled appearance, as in " bird's-eye " wood. Areas showing curly grain may vary up to several inches in diameter. *Diagonal-grained wood.* Wood in which fibers are at an angle with (that is, diagonal to) the axis of a piece as a result of sawing at an angle with the axis of the tree. It may appear on either the radial or flat-grain surface. *Dip-grained wood.* Wood which has single waves or undulations of the fibers, such as occur around knots and pitch pockets. *Interlocked-grained wood.* Wood in which fibers are inclined in one direction in a number of rings of annual growth, then gradually reverse and are inclined in an opposite direction in succeeding growth rings, then later again reverse, etc. *Spiral-grained wood.* Wood in which the fibers take a more or less winding or spiral course, as in a twisted tree. It may be detected on the flat grain surface. *Wavy-grained wood.* Wood in which the fibers collectively take the form of waves or undulations. It may appear on either the radial or flat-grained surface and is indicated by the wavy surface of a split piece.

Decay. Destruction of the wood substance due to the action of wood-destroying fungi. " Dote " and " rot " are synonymous with " decay "; they are any form of decay, which may be evident either as dark red discolorations not found in the sound wood, or as white or red rotten spots. *Advanced (or typical) decay.* The older stage of decay in which the destruction is readily recognized because the wood has become punky, soft and spongy, stringy, ring-shaked, pitted, or crumbly. Decided discoloration or bleaching of the rotted wood is often apparent as, for example, brown and white rots, pocket rots. *Incipient decay.* The early stages of decay which has not proceeded far enough to soften or otherwise perceptibly impair the hardness of the wood. It is accompanied by a slight discoloration or bleaching of the wood as instanced by the " firm red heart " in softwoods and the " water-soaked " stage in certain types of decay. *Firm red heart.* A stage of incipient

decay in wood characterized by a reddish color produced in the heartwood, which does not, however, make the wood unfit for the majority of yard purposes. It is caused by the fungus *Trametes pini* and occurs chiefly in the pines. *Water-soak* (*or stain*). A term applied to a generally water-soaked area in heartwood, which is usually interpreted as the incipient stage of certain wood decays. It occurs in hemlock and possibly in other woods.

Knot.* That portion of a branch which has become incorporated in the body of a tree. *Pin knot.* A knot not more than 1/2 in. in diameter. *Small knot.* A knot more than 1/2 in. but no more than 3/4 in. in diameter. *Medium knot.* A knot more than 3/4 in. but not more than 1 1/2 in. in diameter. *Large knot.* A knot more than 1 1/2 in. in diameter. *Encased knot.* A knot whose rings of annual growth are not intergrown and homogeneous with those of the surrounding wood. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a tight knot; if completely intergrown on one face, it is a watertight knot. *Intergrown knot.* A knot whose rings of annual growth are completely intergrown with those of the surrounding wood. *Loose knot.* A knot not firmly held in place by growth or position. *Tight knot.* A knot so fixed by growth or position that it will firmly retain its place in the piece. *Pith knot.* A sound knot with a pith hole not more than 1/4 in. in diameter in the center. *Round knot.* A knot whose sawn section is oval or circular. *Spike knot.* A knot sawn in a lengthwise direction. *Decayed knot.* A knot which owing to advanced decay is not as hard as the surrounding wood. *Sound knot.* A knot which is solid across the face and which is as hard as the surrounding wood. Red or black knots may be sound.

Pitch Pocket. An opening between the grain of the wood, containing more or less pitch. Pitch pockets are classified as small, medium, and large. *Small pitch pocket.* A pocket not more than 1/8 in. in width or 4 in. in length, or not more than 1/4 in. in width or 2 in. in length. *Medium pitch pocket.* A pocket not more than 3/8 in. in width or 4 in. in length, or not more than 1/8 in. in width or 8 in. in length. *Large pitch pocket.* A pocket more than 3/8 in. in width and more than 4 in. in length, or more than 1/8 in. in width and more than 8 in. in length. *Pitch streak.* A well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains, that is, the coarse-grained fiber, usually termed "springwood," is not saturated with pitch, it is not considered a defect.

Shake. A separation along the grain of wood, the greater part of which occurs between the rings of annual growth. *Through shake.* A shake which extends between any two faces of a timber.

Wane. Bark or lack of wood, from any cause, on edges of timbers.

Molds, Stains and Decays in wood are caused by fungi, which are microscopic plants that must have organic material on which to live, and for some of them wood offers the required food supply. Their growth, however, is dependent upon suitable surroundings of mild temperature and dampness, the latter being aggravated by sluggish circulation of air. Most decay occurs in wood having moisture above the fiber-saturation point. Wood that is continuously water-soaked or continuously dry (below 20 per cent moisture) will not decay. Under proper conditions, wood has proved itself good for centuries of service.

Molds and Stains, which are confined largely to the sapwood, are characterized by cottony or powdery surface growths of various colors. Little direct staining of the wood is caused by molds. Such blemishes are easily brushed or surfaced off. Stains penetrate into the sapwood (not heartwood) and cannot be removed by surfacing. The discoloration of the wood occurs as specks, spots, streaks, or patches of varying intensities of color. Stains should not be considered a stage of decay, since staining fungi do not attack the wood substance appreciably. Ordinarily, they affect the strength of the wood only slightly.

Decay (see also Decay, p. 12–41). Decay-producing or wood-destroying fungi may, under conditions that favor their growth, attack either heartwood or sapwood, causing a condition of the wood that is variously designated as decay, rot, or dote. The fresh surface growths of decay fungi are usually fluffy or cottony, and only seldom powdery as the molds are. Some wood-destroying fungi live largely on the cellulose whereas others use the lignin more than the cellulose.

Every brown, crumbly rot is commonly called "dry rot," but since no wood will rot while it is dry, the term "dry rot" is a misnomer. There are a few fungi that have water-conducting strands and are therefore capable of carrying water from some source, usually in the soil, up into buildings or lumber piles, where they moisten and rot wood that would otherwise be dry. After these fungi cease to work, the decayed wood commonly becomes dry again; the term "dry rot," if used at all, is probably best limited to the work of these fungi.

In living trees the sapwood is less subject to fungus attack than the heartwood. The sapwood of logs or products, on the other hand, decays more readily than the heartwood; this may be due to the more available food supply in the sapwood, or to the presence in the heartwood of certain extractives that are toxic to the fungus.

Incipient decay induced by fungi is not always reflected immediately in pronounced weakening of the wood. In the later stages of decay serious reduction in strength will always occur.

20. PRESERVATION OF TIMBER

Preservative Processes. The average life of timber used in the United States, which is subject to decay, is about 8 years; its life can be extended to 12 years either by a chemical impregnation of the wood cells or by an exterior application of a preservative coating which will penetrate the fibers. Creosote oil is the preservative in most common use.

Preservation. The general method followed in the commercial treatment of timber with creosote involves the following steps: (1) seasoning the timber, (2) steaming the timber in a large cylinder to soften the wood fiber, (3) removal of air and moisture from the wood fibers by means of a vacuum pump, (4) admission of creosote oil to the evacuated chamber—the oil penetrates some distance into the timber, (5) the application of pressure forcing the preservative into the innermost fibers of the timber, and (6) the removal of pressure, after which the excess of creosote is allowed to drip off the timber and run into a tank.

In the best non-pressure process, the timber is heated and cooled in an open tank of creosote. The contraction of gases upon cooling draws the creosote into the timber. The penetration of creosote is less in this process than in the pressure-vacuum process.

Since creosote is rather expensive, other preservatives have been tried. Zinc chloride, which is violently poisonous to timber-destroying bacteria, can be forced into the inner fibers of wood; it is cheaper than creosote. However, zinc chloride is soluble in water, whereas creosote is not, and zinc chloride is an effective preservative only in extremely dry regions.

The following table gives approximate weights of creosote required per cubic foot of timber for various services.

Railroad ties:	
Hardwood	6–14 lb per cu ft
Softwood	13–20 lb per cu ft
Dimension timbers	15–20 lb per cu ft
Piles	20–30 lb per cu ft
Poles and posts, treated by open tank method for a length of 7 ft:	
Chestnut poles	21 lb per pole
Western pine poles	65 lb per pole

21. CLASSIFICATION AND GRADING OF LUMBER

Classification of Lumber (Simplified Practice Recommendation 16, U. S. Department of Commerce). Lumber is defined as the product of the saw and planing mill not further manufactured than by sawing, resawing, and passing lengthwise through a standard planing machine, cross-cut to length and matched.

Use Classification

Yard Lumber. Lumber that is less than 6 in. in thickness, and is intended for general building purposes.

Structural Timbers. Lumber that is 6 in. or over in thickness and width.

Factory or Shop Lumber. Lumber intended to be cut up for further manufacture.

Size Classification

Strips. Yard lumber less than 2 in. thick and less than 8 in. wide.

Boards. Yard lumber less than 2 in. thick, 8 in. or over in width.

Dimension Lumber. All yard lumber except boards, strips, and timbers; that is, yard lumber not less than 2 and under 6 in. thick, and of any width; this includes (1) planks, yard lumber not less than 2 and under 4 in. thick and 8 in. or more wide; (2) scantlings, yard lumber not less than 2 and under 6 in. thick and under 8 in. wide; (3) heavy joists, yard lumber not less than 4 and under 6 in. thick and 8 in. or over wide.

Timbers. Lumber 6 in. or larger in least dimension.

Manufacturing Classification

Rough Lumber. Undressed as it comes from the saw.

Surfaced Lumber. Lumber that is dressed by running through a planer. It may be surfaced on one side (S1S), two sides (S2S), one edge (S1E), two edges (S2E), or a combination of sides and edges, (S1S1E), (S2S1E), (S1S2E), or (S4S).

Worked Lumber. Lumber which has been run through a matching machine, sticker, or molder. Worked lumber includes: (1) matched lumber, which is edge dressed and shaped to make a close tongued and grooved joint at the edges or end when laid edge to edge or end to end; (2) shiplapped lumber, which is edge dressed to make a close rabbeted or lapped joint; (3) patterned lumber, which is shaped to a patterned or molded form.

Table I. Strength Properties of Some Commercially Important Woods Grown in the United States

(From Wood Handbook, U. S. Department of Agriculture, prepared by Forest Products Laboratory, Madison, Wis.)

(Results of tests on small,[1] clear specimens in the green and air-dry condition [2])

---

[1] Test specimens 2 by 2 in. in section. Bending specimens 30 in. long; others shorter depending on kind of test.

[2] The values in the first line for each species are from tests of green material; those in the second line are from tests of seasoned material adjusted to an average air dry condition of 12 per cent moisture.

[3] Based on weight when oven dry and volume when green or at 12 per cent moisture content.

[4] Average of Biltmore white ash (*Fraxinus biltmoreana*), blue ash (*F. quadrangulata*), green ash (*F. pennsylvanica lanceolata*), and white ash (*F. americana*).

[5] Average of sweet birch (*Betula lenta*) and yellow birch (*B. lutea*).

[6] Average of lowland white fir (*Abies grandis*) and white fir (*A. concolor*).

Table I. Strength Properties of Some Commercially Important Woods Grown in the United States—*Continued*

(From Wood Handbook, U. S. Department of Agriculture, prepared by Forest Products Laboratory, Madison, Wis.)

(Results of tests on small, clear specimens in the green and air-dry condition)

Commercial and Botanical Name of Species	Moisture Content	Specific Gravity	Static Bending					Impact Bending		Compression Parallel to Grain		Compression Perpendicular to Grain—Fiber Stress at Proportional Limit	Shear Parallel to Grain—Maximum Shearing Strength	Hardness	
			Fiber Stress at Proportional Limit	Modulus of—		Work to—		Fiber Stress at Proportional Limit	Height of Drop Causing Complete Failure (50-lb Hammer)	Fiber Stress at Proportional Limit	Maximum Crushing Strength			Load Required to Embed a 0.444-in. Ball to ½ Its Diameter	
				Rupture	Elasticity	Proportional Limit	Maximum Load							End	Side
1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16

[7] Average of bitternut hickory (*Hicoria cordiformis*), nutmeg hickory (*H. myristicaeformis*), water hickory (*H. aquatica*), and pecan (*H. pecan*).

[8] Average of bigleaf shagbark hickory (*Hicoria laciniosa*), mockernut hickory (*H. alba*), pignut hickory (*H. glabra*), and shagbark hickory (*H. ovata*).

[9] Average of black oak (*Quercus velutina*), laurel oak (*Q. laurifolia*), pin oak (*Q. palustris*), red oak (*Q. borealis*), scarlet oak (*Q. coccinea*), southern red oak (*Q. rubra*), swamp red oak (*Q. rubra pagodaefolia*), water oak (*Q. nigra*), and willow oak (*Q. phellos*).

[10] Average of bur oak (*Quercus macrocarpa*), chestnut oak (*Q. montana*), post oak (*Q. stellata*), swamp chestnut oak (*Q. prinus*), swamp white oak (*Q. bicolor*), and white oak (*Q. alba*).

[11] Average of black spruce (*Picea mariana*), red spruce (*P. rubra*), and white spruce (*P. glauca*).

Grades of Softwood Yard Lumber. The term " yard lumber " as here used means lumber that is manufactured and classified into those sizes, shapes, and qualities required for ordinary construction and general-purpose uses. Heavy timbers for structural purposes, softwood factory lumber, and other special-use materials are not considered yard stock. In the rules of the American Lumber Association, finish, siding, flooring, ceiling, partition, common boards and strips, shiplap, D. & M. (dressed and matched), grooved roofing, dimension and lath are considered yard lumber.

On the basis of quality, yard lumber is divided into two main divisions: (*a*) select lumber and (*b*) common lumber. Each of these is again divided into two classes: select lumber into (1) that suitable for natural finishes, and (2) that suitable for paint finishes; common lumber into (1) that which can be used without waste, and (2) that which permits some waste. Each of these four classes is further divided into quality classes or grades as hereinafter described.

The following diagram shows the general characteristics of, and the relationship existing between, the various grades of lumber:

Diagrammatic Summary of the Basic Grades for Yard Lumber

Select (Lumber of good appearance and finishing qualities)	Suitable for natural finishes	Grade B and better—Allows a few small defects or blemishes
	Suitable for paint finishes	Grade C—Allows a limited number of small defects or blemishes that can be covered with paint
		Grade D—Allows any number of defects or blemishes which do not detract from a finish appearance, especially when painted
Common (Lumber containing defects or blemishes which detract from a finish appearance but which is suitable for general utility and construction purposes)	Lumber suitable for use without waste	No. 1 Common—Sound and tight knotted stock; size of defects and blemishes limited; may be considered watertight lumber
		No. 2 Common—Allows large and coarse defects; may be considered graintight lumber
	Lumber permitting waste	No. 3 Common—Allows larger and coarser defects than No. 2 and occasional knot holes
		No. 4 Common—Low-quality lumber admitting the coarsest defects such as rot and holes
		No. 5 Common—Must hold together under ordinary handling

Grades of Hardwood Lumber. (From Rules of the National Hardwood Lumber Association, 1934.) The standard grades of hardwood lumber shall consist of firsts, seconds, selects, No. 1 common, No. 2 common, sound wormy, No. 3A common, and No. 3B common. Firsts and seconds are combined as one grade, and the percentage of firsts in the combined grade shall not be less than as follows: poplar and Philippine mahogany, 40 per cent; African and Mexican mahogany, 35 per cent; tupelo, sycamore, plain oak, chestnut, red gum, sap gum, black gum, cottonwood, magnolia, locust, hackberry, willow and aspen, 33 $^1/_3$ per cent; cherry, soft elm, buckeye, box elder, quartered oak and quartered gum, 25 per cent; hard maple, soft maple, red alder, white ash, beech, birch, black ash and basswood, 20 per cent.

Selects and No. 1 common may be combined as one grade, except in mahogany, walnut, and cherry, and when so combined and specified shall be understood to include all selects that the logs produce.

No. 3A common and No. 3B common may be combined as one grade, No. 3 common, and when so combined and specified shall be understood to include all the No. 3A common that the logs produce.

For details concerning each grade, see the rules published by the National Hardwood Lumber Association.

22. PROPERTIES OF TIMBER

Mechanical Properties of Timber. Table I gives the mechanical properties of some important woods grown in the United States. For allowable safe loads on timbers see pp. 12–44 and 12–47.

Time Element in the Strength of Wood. Under long-continued steady load wood will fail under stresses much lower than those found at the ultimate strength in laboratory tests, which cover only a few moments. Under longtime loading test pieces of wood have broken under stresses only a little above 50 per cent of the ultimate as given by short-time laboratory tests. This very pronounced time effect is one of the reasons why working stresses for timber are low as compared with ultimate strength.

Effect of Moisture on Strength of Wood. Up to a moisture content of about 25 per cent for softwoods, the fibers absorb water and are weakened and softened by it. For moisture content above this " fiber saturation point " water no longer affects the strength and stiffness of wood.

Increase in Strength Due to Seasoning. The increase in strength of woods due to drying is more uniform in small test specimens than in the large sizes used in construction. However, if the seasoning is done carefully so as to avoid the formation of checks, there should be a marked increase in the strength of structural timber after drying.

23. PLYWOOD

Manufacture. Plywood is made by gluing together thin layers of wood. The grain in one layer is at right angles to the grain in the next layer. An odd number of layers is used. It is important that the layers of wood are all split or sawed the same way from a stick of timber, and that the moisture content is approximately the same for all layers. If these precautions are not taken the plywood will tend to warp owing to uneven stresses in the different layers.

Strength of Plywood. A limitation of the use of large boards is the difference in strength of wood in various directions. The tensile strength of wood parallel to the grain may be as much as twenty times the strength perpendicular to the grain, and the shearing strength parallel to the grain is much lower than the shearing strength across the grain, In plywood the strength is approximately equal in all directions and is equal, approximately, to the mean of the strength with and the strength across the grain. As plywood is built up of thin layers it becomes feasible to use a high grade of wood in its manufacture. The tensile strength of plywood is given in Table II.

Woods Available for Plywood. Basswood, redwood, poplar, maple, birch, and red gum are domestic woods which can be cut into the thin sheets necessary for making plywood. Basswood, redwood, and poplar are not often used for the face layers.

Plywood is used mainly in the shape of thin sheets, and is of importance in manufacture of automobiles, street and railway cars, airplanes, and boats.

Table II. Tensile Strength of Plywood

Based on test data from the U. S. Forest Products Laboratory, Madison, Wis.

Species	Weight of Plywood, Kiln-dry, lb per cu ft	Moisture at Test, per cent	Tensile Strength of 3-ply Plywood Parallel to Grain of Faces, lb per sq in.	Tensile Strength of Single-ply Veneer, Parallel to Grain, lb per sq in.
Basswood	28	9.2	6,900	10,300
Yellow birch	45	8.5	13,200	19,800
Maple, soft	38	8.9	8,200	12,300
hard	46	8.0	10,200	15,300
Yellow poplar	34	3.4	7,400	11,100
Red gum	36	8.7	7,800	11,800
Redwood	28	9.7	4,800	7,200

PAINTS, ENAMELS, VARNISHES, AND LACQUERS

By Joseph Mattiello

24. PAINTS AND ENAMELS

Paints and Enamels. Paint, technically a plastic solid, covers a wide variety of pigmented coatings designed for the purpose of protecting and decorating the surface to which they are applied.

There are various types of paints, such as: exterior house paints, interior flat wall paints, enamels, semi-gloss finishes, primers and undercoaters, floor enamels, anti-corrosive and metal-preservative paints, heat-resisting paints, and hundreds of others. Each type is formulated to give the best results for its specific use. For instance, house paint is formulated with three major properties in mind—protection, durability, and beautification; flat wall paint is formulated primarily for decorative value; floor paints, for wear and resistance to abrasion, etc.

In general, paints are mechanical mixtures of pigments and vehicles (oils, varnishes, thinners, and driers). The paint technologist selects the proper vehicle combination to give specific results according to the type of paint being formulated. The proper pigment or pigment combination is then selected, again according to the purpose for which the paint is to be used. Extensive tests have proved that the volume of pigment present is of great importance. From 28 to 30 per cent pigment volume concentration, based on the non-volatile vehicle, gives greater durability and protection than lesser amounts of pigment.

Exposure tests have shown that primers for new wood should contain a pigment volume of about 35 per cent rather than 28 to 30 per cent as in finishing coats.

Flat wall paints are very high in pigment volume (about 60 per cent based on the non-volatile vehicle) and the vehicles which produce a flat finish are low in non-volatile content (30 to 37 per cent non-volatile content, 70 to 63 per cent volatile thinner). Enamels are low in pigment content and higher in non-volatile vehicle, producing a gloss finish. Enamels are usually made of pigments and varnishes.

Manufacture. The pigments are first mixed to a paste consistency with a portion of the total vehicle. This paste is ground through either a roller mill, consisting of steel rolls, one of which goes faster than another, or a stone mill, one stone of which is stationary and the other revolving. This grinding action breaks down the agglomerates of the pigment and disperses them throughout the vehicle. After grinding, the paste is thinned to the proper consistency with the balance of the vehicle, stored, and filled.

In a variation of this process, the pigment and vehicles are "loaded" without premixing, in a pebble mill, which is a revolving barrel half filled with flint pebbles. The drum is revolved for many hours. The pebbles falling through the paint disperse the pigment agglomerates. This mill grinds paint in the "ready-mixed" or liquid form so that it does not require a separate thinning operation after grinding, but may be canned directly from the mill.

Vehicles. The vehicles used in the formulation of paints may be any of the drying oils (linseed, tung, perilla, etc.), or semi-drying oils (soya, fish, etc.) with or without the addition of resin varnishes, or straight resin varnish, the manufacture of which is treated under varnishes, thinners, and driers.

Pigments. The pigments may be divided into the following three general classes:

1. The white opaque pigments shown in Table I.
2. The extender pigments: asbestine, whiting, silica, barites, clay, etc.
3. The colored opaque pigments:
    - *a.* The earth colors: ochers, siennas, umbers, red oxides, etc.
    - *b.* The chemical color pigments: chrome yellows, chrome and nitrate greens, blues, etc.
    - *c.* The lake colors: precipitated dyes.
    - *d.* The blacks, gasblack, lampblack, boneblack, etc.
    - *e.* Numerous others.

The principal difference between the white opaque pigments and the extender pigments is in opacity. The extender pigments are white in the dry form, but they become transparent when mixed or wetted with paint oils or vehicles. This phenomenon is due to the fact that there is very little difference between the refractive indices of the extender pigments (1.53–1.60) and those of the oils (media) with which they are wetted (1.47–1.53).

Any pigment used to increase opacity must have a high refractive index; and the difference between its refractive index and that of the vehicle media should be as great as possible. The refractive indices of the opaque pigments vary from 1.84 for lithopone to 2.55 for titanium dioxide. The relative tinting strength and hiding power of the white opaque pigments are given in Table I.

Table I. Properties of White Opaque Pigments

(From Handbook published by the Titanium Pigment Co., Inc., and other sources)

	Tinting Strength	Hiding Power, sq ft per lb	Hiding Units	Refractive Indices
Basic lead sulfate	85	13	0.87	
Basic lead carbonate	100	15	1.00	2.02
Zinc oxide	200	20	1.33	2.01
Lithopone	260	27	1.80	1.84
Titanox B (titanium barium pigment)	380	40	2.67	1.90
High-strength lithopone	400	44	2.93	
Titanated lithopone	400	44	2.93	
Titanox C (titanium calcium pigment)	450	48	3.20	1.91
Zinc sulfide	540	58	3.87	2.34
Titanox A (titanium dioxide pigment)	1150	115	7.67	2.55

Properties and Uses of the Important White Opaque Pigments. The choice of pigments, and oils, and varnishes for vehicles depends upon the serviceability expected of the particular paint or enamel. Protective coatings made from a good combination of mixed pigments are more durable than those containing one single pigment. Some of the characteristics of important white pigments are:

Basic Carbonate White Lead in a paint exhibits excellent durability and freedom from cracking and scaling, but fails by chalking. (Chalking is an advantage for repainting.)

Zinc Oxide imparts hardness to the paint film and improves gloss, but it fails by cracking and scaling. Being opaque to ultraviolet rays, it retards chalking to a greater extent than white lead. Zinc oxide has good color retention. Its greatest use is in interior enamels.

Zinc Sulfide has excellent hiding power and color.

Titanox B (titanium barium pigment: 25 per cent titanium oxide, 75 per cent barium sulfate) is used for both exterior and interior paints and enamels. In exterior house paints, it adds greatly to the hiding power of the paint, reduces the tendency to crack and scale, but fails by chalking.

Titanox C (30 per cent titanium oxide, 70 per cent calcium sulfate) is used principally in interior paints and enamels. It has excellent hiding power and brightness. Its low specific gravity produces high bulking.

Titanium Oxide is the most opaque pigment known to science. It is particularly valuable in low pigment content and fume-resistant paint. It is also used in high-grade interior and exterior enamels. It chalks badly on exterior exposure when used alone.

Lithopone (28 per cent zinc sulfide, 72 per cent barium sulfate) is generally used for interior paints. It has good hiding power and color.

Preparation of Surface. The preparation of the surface to be painted is important. The surface should be dry and free from grease and dirt. A metal surface should also be free from rust and scale. If it is to be used for exterior exposure, metal should first be primed with a pure red lead or specially prepared primer which may contain zinc chromate as part of the pigment. Galvanized iron should be treated with copper sulfate or copper acetate before the first coat of paint is applied. Wooden surfaces, as on frame houses, should be thoroughly dry and all knot holes shellacked before the priming coat is applied. Three thin, well-brushed-out coats give greater durability than two heavy coats. Common practice calls for three coats on new work and two coats on old work.

Plaster walls should be well pointed, dry, and primed or sealed before the finish coats are applied.

Application. Paints for either exterior or interior use are applied either by brush or by air spraying; enamels for industrial use are applied by brushing, spraying, roller-coating, dipping, tumbling, etc. The formulation of the paint or enamel is varied according to the method used. If the paint is to be brushed, careful attention must be given its brushing qualities, flow, etc. If it is to be sprayed it must be formulated to work well in the air gun without clogging, and to atomize easily and properly.

Some industrial finishes are baked. In such finishes the pigment and vehicle must be carefully selected to dry hard in a given time and to resist wrinkling, gas effects, discoloration at baking temperature, etc.

Properties of Paint Films. Air-dry paint films dry, initially, by evaporation of the thinners, and finally by oxidation of the drying oils. The initial setting period is complete within several hours, but from six hours to several days are required for the final drying.

Baking paint films or enamels dry, initially, by evaporation of the thinner, then slightly by oxidation of the drying oils, but finally and mainly by the polymerization of the oil and resin content.

Exterior paints are effected by various rays of the sun. The ultraviolet rays probably disintegrate the oils, thus producing chalking. The disintegrating effects of sunlight, atmospheric gases, and moisture are such that repainting is usually necessary after two or three years of outdoor exposure.

Aluminum Paint. Aluminum paint is made by mixing aluminum powder with a suitable vehicle. Aluminum powder is composed of minute flake-like particles of metallic aluminum produced by a stamping process. It is supplied either as a dry powder or in paste form mixed with mineral spirits. Aluminum paint, mixed in the proportion of 2 lb of powder to 1 gallon of vehicle, gives a coating of high moisture-proofing resistance and superior protective qualities. By proper choice of vehicle it can be used on metal, wood, plaster, or concrete, and is particularly recommended for the painting of aluminum and its alloys.

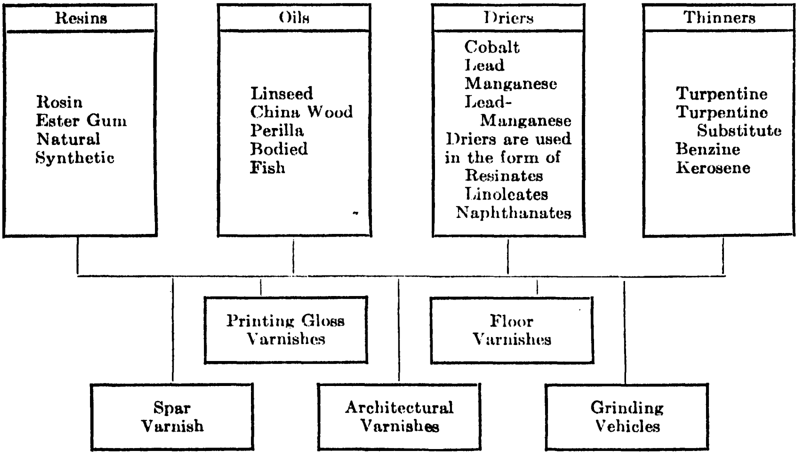
25. OLEORESINOUS VARNISHES

Varnishes. A varnish is partly a solution, but mainly a colloid. It is a combination of resins and thinners; or resins, oils, driers, and thinners; and of such fluidity that it can readily be applied to a surface. After the thinners evaporate, the remaining material dries to a solid film either by oxidation, or oxidation and polymerization, or by simple evaporation. This solid film protects, preserves, and beautifies the surface.

There are two types of varnish, oleoresinous and spirit. The oleoresinous varnishes dry to a solid film by oxidation (air drying), or by oxidation and polymerization (baking). The spirit varnishes dry purely by evaporation.

General Composition. The four general constituents of oleoresinous varnishes are resins, drying and semi-drying vegetable and animal oils, driers, and thinners or solvents. These are illustrated diagrammatically in Table II.

Table II. Composition of Oleoresinous Varnishes



Courtesy Joseph Mattiello, Technical Director: Hilo Varnish Corp., Brooklyn, N. Y.

Function of Each Constituent. *The resins* provide the elements of hardness, resistance to wear, and waterproofness; they also impart gloss and slightly accelerate drying. The synthetic phenol-formaldehyde resins definitely improve durability.

The oils supply the elements of toughness, adhesion, durability, and waterproofness. China wood (tung), has better waterproofness than linseed oil, both give good durability.

Driers. The only important function of the drier is to accelerate drying. For example, linseed oil requires eight days to air-dry by itself when flowed out to a thin film, but with the proper combination and amount of drier it will dry within as brief a time as eight hours. The most effective driers are cobalt, manganese, and lead. They are used in the form of resinates, linoleates, tungates, or naphthanates. Cobalt, the most efficient

of the three, is a "surface" drier, lead is a "bottom" drier, and manganese is a "through" drier. Zinc, as a naphthanate, is used to retard wrinkling.

In the formulation of a paint, varnish, or other protective coating, great care must be exercised in the choice of driers. A combination of lead with small amounts of manganese is an ideal drier for colored enamels. Manganese has a tendency to discolor white paints or enamels, causing a very bad after-yellow. The best drier to use for white paints or enamels is a lead or cobalt combination in the form of linoleates, naphthanates, etc.

There is an optimum amount of drier which can be added to paint above which the drier not only becomes ineffective, but actually retards drying. Too much drier also causes the loss of gloss in enamels. It reduces the durability of protective coatings.

Representative figures for the amount of cobalt and lead to be used as a drier for white paint are:

	1	2	3
Lead metal	None	0.20%	0.25%
Cobalt metal	0.025%	0.015%	0.005%

and for a drier composed of lead, manganese, and cobalt:

Lead metal	0.20%
Manganese metal	0.03%
Cobalt	0.01%

All percentages are based on the non-volatile content of the vehicle.

Thinners or Solvents. The most important function of the solvent is to reduce viscosity or increase fluidity so as to permit easy application of the coating to the surface. When vegetable oils are cooked with resins, a very heavy viscous substance is obtained, which may be considered a new resin. As in this state it cannot be applied to a surface, the reduction of viscosity with solvents is necessary. Driers in any form have but slight influence on viscosity.

Formulation of Varnish. Which particular resin or resins, oil or oils, are used in a varnish depends upon the application for which it is being formulated. A varnish may be composed of one resin, one oil, several driers, and one thinner, but most are composed of several resins, oils, driers, and thinners. Varnishes are usually called long or short oil, but more specifically, by the number of gallons of oils used for each 100 lb of resins. Table III illustrates a 35-gallon varnish which is of the usual spar varnish type, and an 18-gallon varnish of the usual floor varnish type.

Table III

35-gallon varnish

Basis:	100 lb resin 35 gallons oil x gallons drier	varies from 45 to 60% non-volatile
	y gallons thinner	varies from 55 to 40% volatile
Yield:	100% by weight	

18-gallon varnish

Basis:	100 lb resin 18 gallons oil x' gallons drier	varies from 45 to 50% non-volatile
	y' gallons thinner	varies from 55 to 50% volatile
Yield:	100% by weight	

Manufacture of Oleoresinous Varnishes. Natural hard resins, such as Congo, are insoluble in linseed oil. It is necessary to heat the resin to a temperature above the softening point, whereupon decomposition and depolymerization take place. This causes a loss in weight of 15 to 30 per cent, depending upon the hardness of the natural resin. The resulting fused mass has a lower acid value and a higher iodine number,* and is readily soluble in drying oils. The oil is now added in either the raw or bodied state. With many of the synthetic resins, the oil and resin are added together. In many cases, a definite amount of oil (usually linseed oil) is held out to be used as a chill-back. The varnish is cooked or boiled until the oil and resin are thoroughly miscible in each other. A definite chemical reaction takes place, probably forming a new resin with a higher softening point than the original resin. This mass becomes very viscous if permitted to cool. Driers are usually added on the down heat, after which the varnish is thinned, clarified by filtering or centrifuging, stored, and, wherever necessary, natured.

---

* The iodine number is a measure of the unsaturation of the oil. Generally, the higher the iodine number is, the better are the drying properties of the oil.

Application. Varnishes are applied either by brushing (mainly for painting homes and buildings), or by spraying or dipping (mainly for commercial use).

Uses. Varnish is used on interior and exterior woodwork, on furniture, on enamels to give added gloss, and on many hundreds of industrial articles.

Resins

Natural Resins. The natural resins are found in nearly all the tropical and semi-tropical countries. They are the hardened sap of trees, ancient or living. The most important natural varnish resins used are Kauri, Congo, Pontianok, East India, Dammar and Manila. There are many other resins, but their use is limited.

Synthetic Resins constitute an extremely numerous and heterogeneous class of products. They have been studied since the middle of the nineteenth century, when Beyer investigated the reaction products of phenols and aldehydes. Since Baekeland's commercial success with Bakelite, an increasing amount of research has been devoted to the utilization of these products in oleoresinous varnishes.

Phenol-formaldehyde Resins. When phenol and formaldehyde are caused to give a series of condensation products, and these in turn polymerize, the resulting product is a synthetic resin. If an acid catalyst is used during the condensation reactions, the so-called Novelack resin is obtained, which remains fusible and soluble under all conditions. With an alkali catalyst, the so-called Bakelite or reactive type is obtained. In the early stages of condensation, this resin is fusible, and soluble in alcohol and in certain other petroleum solvents, but on further heating or under heat and pressure as in a molding press the substance changes to resins of a very great hardness and complete insolubility. These are not the resins that have found extensive use in the varnish industry, since *they are not oil-reactive resins.*

Oil-reactive Synthetic Resins. When phenol and formaldehyde are condensed and polymerized in the presence of a natural resin, ester gum, or rosin, oil-reactive synthetic resins are obtained. These are the resins that have become increasingly important to the varnish industry since 1925. Compounded with China wood and a small amount of linseed oil used as a chill-back, they are used to make the so-called *four-hour varnishes.*

The term phenol-formaldehyde is now used somewhat loosely, because many resins are made in which phenol is replaced by one of its homologues, such as creosol and other more complex phenols. Formaldehyde can also be replaced by its homologues.

Alkyd (Glyptal) was first made by the General Electric Co. It is produced by condensation reactions between phthalic anhydride and glycerin or modifications of these substances. The simple phthalic anhydride and glycerin resins, during the early part of the condensation, are soft and soluble in certain solvents, such as the esters. Then, as condensation proceeds, the resins increase in hardness and decrease in solubility, until an extremely hard, insoluble product is obtained. These simple forms have not found wide use because the soluble ones have lacked hardness and waterproofness, while the harder ones have lacked solubility.

The modified forms of these resins which are being adopted by the protective coating industry are those in which part of the phthalic anhydride or acid is replaced by the fatty acids of either linseed, China wood, or castor oil, etc., or by mixtures of several of the fatty acids. The simpler resins in which the phthalic anhydride or acid is replaced by acids of castor oil or oleic acid are insoluble, as a rule, in drying oils and hydrocarbons. Those resins in which the phthalic acid is replaced by the fatty acid of the drying oils are soluble in thinners used in oleoresinous varnishes, thereby allowing many of these resins to be incorporated in oil varnishes, particularly the baking type. Many of the alkyd resins have found considerable use in lacquers.

From a chemical point of view, practically any dibasic acid will react with any polyhydroxy alcohol to give resinous materials. The phthalic acid can be replaced by dibasic acids of the aliphatic series, such as succinic, tartaric, citric, etc., or by aromatic polybasic acids. On the other hand, glycerin can be wholly or partly replaced by other polyhydroxy alcohols, for example, glycol.

Cumarone and Indene Resins. These resins are derived from the unsaturated hydrocarbons such as cumarone and indene, which occur in certain fractions of coal-tar naphtha. Their use has been limited, however, because they show a marked tendency to yellow under the action of sunlight. It has been stated that this yellowing tendency is caused by the presence of traces of iron resulting from the use of acid catalysts in iron equipment, and the use of alkalies in washing out the traces of the acid catalyst. Lately, improved forms of these resins have been offered. In the improved forms, polymerization agents are used which considerably reduce the yellowing tendency. Varnishes made from these resins are practically unaffected by alkalies.

Vinyl Resins are obtained by the polymerization of esters, particularly the acetates of the unsaturated vinyl alcohol. These resins are flexible, and compatible with nitrocellulose. The vinyl resins are harder, less soluble, and less compatible with oils than other synthetic resins. The vinyl ester resins may be used by themselves, without oil or nitrocellulose. They are soluble in special solvents, particularly of the type of ketones.

Urea-formaldehyde Resins are not used to any great extent in the varnish industry.

The Petroleum Industry is now producing synthetic resins from the residue of the distillation process.

Ester Gum. Ester was the first synthetic resin to be widely used in varnish production. Curiously enough, ester gum was not considered a synthetic resin until the phenol-formaldehyde and alkyd resins were introduced. Ester gum is a glycerin ester of rosin. Rosin, chemically speaking, consists for the most part of a complex acid known as abietic acid. Up to the present (1936), only the glycerin esters of rosin have received any practical attention. They are used extensively in oleoresinous varnishes, and nitrocellulose (pyroxylin) lacquers.

Many other rosin esters of the monohydroxy alcohols, both aliphatic and aromatic, have been prepared but have not found any practical use. Polyhydroxy alcohols containing four hydroxy groups and of higher molecular weight than glycerin have been described as giving esters of higher melting point. These would unquestionably find wide commercial application, but unfortunately, the commercially available quantities are very limited. Research will undoubtedly find new sources of these materials.

Recently (about 1931), modified ester gums, such as mixed esters, have appeared in the lacquer industry. Mixed esters are those in which the glycerin, or even a dihydroxy alcohol such as glycol, is esterified partly with rosin and partly with another acid. An example of such an ester is the one resulting from esterification of glycerin with rosin and phthalic acid.

An ester gum varnish is more durable than a limed rosin varnish, in which the acidity of rosin is partly neutralized by means of calcium oxide. Before synthetic resins appeared, ester gum was used extensively in the making of spar varnishes.

Oils

Linseed Oil is obtained from the seeds of the flax plant (*Linum usitatissimum*). The principal flaxseed-producing countries are Argentina, Russia, India, the United States, and Canada.

Linseed oil is essentially a mixture of mixed triglycerides of unsaturated acids, oleic, linolenic, linolic, and small amounts of saturated stearic and palmitic acids. A series of analyses made by many investigators varied as

Saturated acids	Stearic and palmitic	4.8 to 9.0%
Unsaturated acids	Oleic	13.3 to 14.5%
	Linolenic	38.9 to 40.3%
	Linolic	37.9 to 41.6%
Unsaponifiable matter		1.05 to 1.4%
Combined with glycerin radical		4.6%

Raw linseed oil has a golden yellow color with a pleasant odor. Its iodine number usually varies from 175 to 181. It is (1) acid refined by means of concentrated sulfuric acid, (2) alkali refined by means of sodium hydroxide. The acid-refined oil is used as a grinding medium, particularly for basic carbonate white lead; the alkali-refined oil is used for oeloresinous and lithographic varnishes.

Perilla Oil is obtained from the seeds of *Perilla ocymoides*, a plant found in China, Japan, and southeastern Asia. Perilla oil is closely similar to linseed oil, but its degree of unsaturation as indicated by the iodine number, which is above 200, is greater. According to J. S. Long, this oil has a higher percentage of linolenic and linolic acid. The available quantity of this oil is much smaller than that of linseed.

Tung, or China Wood Oil, is a nut oil. It is mainly a glyceride of the fatty acid known as oleostearic acid, which is supposed to be isomeric with linolic acid. It contains about 10 per cent of glyceride of oleic acid, and from 2 and 3 per cent of the glyceride of saturated fatty acids, mainly palmitic and stearic. This oil has decidedly better waterproofness than linseed. The iodine number of Tung oil varies from 163 to 170.

Menhaden Oil (Fish Oil). Many different oils are produced from fish. A kind much used is menhaden oil which has an iodine number varying from 139 to 180. It may be used in varnishes and other protective coatings.

Semi-drying Oils

Soya bean oil	iodine number 124 to 143
Hempseed	iodine number 140 to 166
Lumbang	iodine number 140 to 164
Walnut	iodine number 140 to 158

Other semi-drying oils are on the market.

Special Varnishes

Crystallizing and Wrinkle Varnishes are representative of certain special varnishes on the market for producing unusual decorative surface effects. In the crystallizing varnish, the crystals are formed when the freshly painted article is placed in an atmosphere deprived of oxygen at a temperature of about 110 deg fahr. The usual method is to have a yellow flame burning in the oven with the draft closed until the crystals appear. The film is then made hard and durable by baking at higher temperatures in the oven with the draft opened. These crystal effects can also be obtained in colors.

A wrinkle or shrivel finish may be obtained on an article by baking it at temperatures ranging from 150 to 300 deg fahr after application of the special " wrinkle varnish."

The formation of these effects appears to be due to the rapid oxidation at the surface, forming a skin over the less oxidized material beneath. The surface increases in volume during the continued drying, and the less viscous material in the interior flows to the hilly or high surfaces.

Rubbing Varnishes are so compounded that they generally dry in 48 hr, some in 24 hr, to a hard film which may be rubbed to a dull, smooth finish with pumice and oil or water. After being rubbed, they may be polished to a high gloss with rotten stone and crude oil, or other polishing compounds which are on the market.

26. SPIRIT VARNISHES

Spirit Varnishes are simple solutions of resins in volatile solvents. They dry entirely by evaporation of the solvent which leaves the original resin in a thin film.

These varnishes dry rapidly, generally within 10 or 20 min. They form hard films of limited elasticity which are somewhat impervious to moisture. These hard films are readily removed by abrasion and by solvents.

Manila Copal Spirit Varnish. The greatest quantity of spirit varnish is made by dissolving Manila copal (spirit-soluble resin) in industrial ethyl alcohol. Sometimes rosin and a limited quantity of petroleum solvent are added for cheapening. A small proportion (usually 1 per cent) of castor oil (plasticizer) is added to give elasticity to the film.

Spirit varnishes are prepared by placing the resin in a churn provided with a stirrer. The solvent is added and the resin dissolved by stirring action. The solution is run into another container, allowed to settle to deposit dirt, and clarified by filtering and centrifuging.

These varnishes are used mainly for coating paper, including wallpaper, and for sealing packages.

Shellac Spirit Varnish. Shellac is a resinous material of animal origin. This resinous substance is a natural exudation from the tree on which it is found, actually produced by the larvae of insects feeding on the sap. Shellac comes mainly from India, although large quantities are produced in Siam. It is found on a large variety of trees, the most important of which is the dhak tree (*Butea frondosa*).

Shellac is soluble in ethyl alcohol and methylated spirits, forming a turbid solution. The turbidity is due to the presence of insoluble wax. In ether, chloroform, and turpentine, shellac is partially soluble. It is insoluble in petroleum solvents and oils. Sometimes a limited quantity of butyl or amyl alcohol is used to give greater flow to the shellac varnish.

Because of the partial insolubility in turpentine, and complete insolubility in oils and petroleum solvents, shellac is largely used as a sealing coat on the knots of uncoated wood before painting, to prevent resin in the knots from bleeding into the oil of the applied paint, thereby avoiding glossy and unsightly patches.

Shellac is mainly employed for the preparation of spirit varnishes. Its alcohol solution dries by the evaporation of the solvent to a hard film which takes a high polish. The film is fairly durable but it is not resistant to moisture. Shellac varnishes are used for general decorative purposes, such as *brown hard varnishes* for polishing furniture, and also to make colored spirit and colored matt stains. The largest quantity of the shellac is used for floors and as a sealer coat for stain in furniture and other articles. In nitrocellulose lacquers it imparts adhesion.

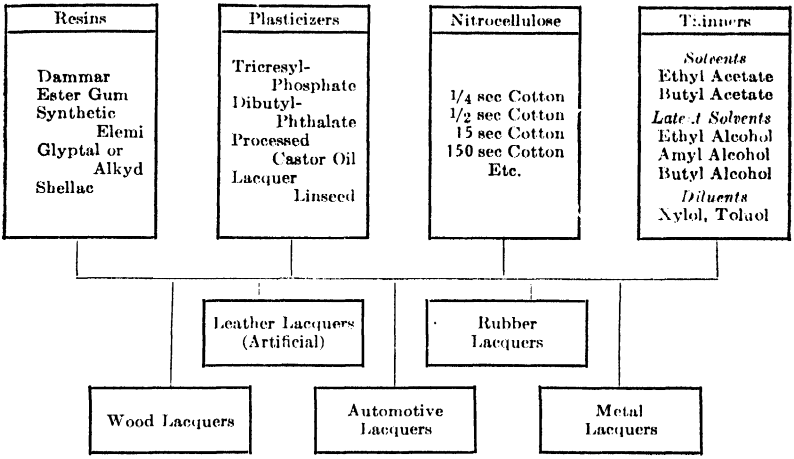
Shellac Water Varnishes are made of shellac, borax, and water. These varnishes are used as a vehicle for water colors, and as a wallpaper varnish.

Turpentine Varnishes are made by dissolving dammar, mastic, or sandarac in turpentine. Rosin is sometimes added as a cheapening agent. The Dammar varnish is largely used for varnishing wallpapers; mastic varnish, mainly for varnishing oil paintings and maps.

27. LACQUERS

Lacquers, at the present time (1936), are composed mainly of nitrocellulose (pyroxylin), plasticizers, resins, and thinners. The thinner consists of a mixture of solvents, latent solvents, and diluents. Table IV illustrates diagrammatically types of lacquers and their compositions.

Table IV. Composition of Nitrocellulose Lacquers



Courtesy of Joseph Matticllo, Technical Director Hilo Varnish Corp., Brooklyn, N. Y.

Nitrocellulose (Pyroxylin) provides the element of toughness, and assists in making a continuous film. The nitrocellulose solutions offered on the market vary in viscosity from 1/2-sec to 150-sec. For example, the term 1/2-sec nitrocellulose is used commercially to indicate a 12 1/2 per cent solution of dry cotton dispersed in a definite solvent mixture, whose final viscosity, measured at 20 deg fahr by the falling-ball method, is 1/2 sec. Viscosity, the most important physical property, is of great value in controlling the finished product.

Resins. The resins mainly used in lacquers are ester gum, dammar, elemi, alkyd, some modified phenol-formaldehydes, and shellac. In a particular lacquer, one or more resins may be used. The resin imparts adhesion, gloss, and hardness; it improves the rubbing and polishing qualities, increases the solid content (non-volatile), accelerates drying, and with some of the glyptal or alkyd resin, imparts some plasticizing action and gives greater durability.

Plasticizers (Softeners). The plasticizers impart the elements of elasticity, durability, and adhesion. They are either solid or difficultly volatile, high-boiling liquids. They improve the flowing properties of lacquers, inhibit blushing, and enhance the luster of the dry film. Camphor was the earliest plasticizer used. The other important plasticizers are given in Table IV.

Solvents, Latent Solvents, and Diluents. The important function of these is solvency, and reduction of the viscosity of the viscous mass, which is composed of nitrocellulose, resin, and plasticizer, to that fluidity which will permit the spreading of lacquers.

The esters, such as ethyl, butyl acetate, etc., are good solvents for nitrocellulose. Other organic liquids, such as acetone, other ketones, and glacial acetic acid, are also good solvents for nitrocellulose.

The alcohols, ethyl, butyl, and amyl, are latent solvents. That is, alone they are not good solvents for nitrocellulose, but in the presence of esters act as good solvents.

Diluents are non-solvents, and the proportion of these which a lacquer will tolerate without destroying quality, or without causing the precipitation of nitrocellulose, is of importance in reducing the cost of a lacquer. Diluents extensively used are: coal-tar thinners such as toluol, xylol, high-flash naphthas; petroleum hydrocarbons such as benzine, gasoline, and, more recently, hydrogenated petroleum hydrocarbons, whose solvency is the same as that of coal tar but whose evaporation rate is slower.

Evaporation of Non-volatile Content and Character of Film Obtained. In order to get perfectly smooth lacquer film, without an orange peel (wrinkled surface), or precipitation of nitrocellulose, or bloom, an evaporation equilibrium must exist between the solvents and non-solvents. The rate of evaporation of various organic solvents depends primarily upon the vapor pressure of the solvents and non-solvents, and only secondarily upon the boiling point. If the evaporation rates of the solvent and non-solvent used in the lacquer are roughly the same, a satisfactorily dried film will be obtained. If in a solvent mixture the solvents evaporate first, leaving behind only the diluent, precipitation of the nitrocellulose will take place. It is extremely important that the last volatile portion evaporating from the lacquer film be a satisfactory solvent for all the constituents present in the film-forming phase of the particular lacquer.

Manufacture. The nitrocellulose and compatible solvents are mixed together, slightly warmed if necessary, and continuously stirred until complete solution takes place. The resins are dissolved separately in solvents. Both solutions are then mixed together, plasticizers are added, and in many instances special solvents are added.

Lacquer Enamels. When pigments are dispersed into clear lacquer vehicles, lacquer enamels are obtained. These are produced by means of roller mills, stone mills, and ball mills.

Application and Uses. Both clear and pigmented (enamel) lacquers are applied, by roller coating machine, spraying, automatic and hand dipping, to fabrics, automobiles, furniture, caskets, toys, and many other articles. Brushing lacquers are also available, but only small quantities are used. Both lacquer enamels and clear lacquers can be made to give films of high gloss, semi-gloss, and dull lusters.

ELECTRIC INSULATING MATERIALS

By D. F. Miner

28. CLASSIFICATION OF INSULATING MATERIALS

Thermal Classification as defined in the A.I.E.E. standards.

CLASS	DESCRIPTION OF MATERIAL
O	Class O insulation consists of cotton, silk, paper, and similar organic materials when neither impregnated* nor immersed in oil.
A	Class A insulation consists of cotton, silk, paper, and similar organic materials when impregnated* or immersed in oil; also enamel as applied to conductors.
B	Class B insulation consists of inorganic materials such as mica and asbestos in built-up form combined with binding substances. If Class A material is used in small quantities in conjunction for structural purposes only, the combined material may be considered as Class B, provided the electrical and mechanical properties of the insulated winding are not impaired by the application of the temperature permitted for Class B material. (The word " impair " is here used in the sense of causing any change which could disqualify the insulating material for continuous service.)
C	Class C insulation consists of inorganic materials such as pure mica, porcelain, quartz, etc.

Physical Classification. Insulation material may be divided according to physical state into four general major classes each of which may be further subdivided as shown on the top of the next page.

---

* Impregnated cotton, paper, or silk. An insulation is considered to be impregnated when a suitable substance replaces the air between its fibers, even if this substance does not completely fill the spaces between the insulated conductors. The impregnating substance, in order to be considered suitable, must have good insulating properties; must entirely cover the fibers and render them adherent to each other and to the conductor; must not produce interstices within itself as a consequence of evaporation of the solvent or through any other cause; must not flow during the operation of the machine at full working load or at the temperature limit specified; must not unduly deteriorate under prolonged action of heat.

1. **Solid.** **Natural; vitreous; fibrous; organic; rubber and substitutes.**
2. **Plastics.** Synthetic resins; waxes; gums.
3. **Liquids.** Natural oils; mineral oils; varnishes; solvents.
4. **Gases.**

Electrical Classification according to dielectric properties. Table I gives the electrical properties of various insulating materials.

29. SOLID INSULATING MATERIALS

Insulating materials are often described in general terms without specific data. A material is said to be " heat proof " which may mean that it will not deteriorate when used continuously at some temperature within the range of 30 to 250 deg cent. Dielectric strength is sometimes quoted without reference to the thickness of the test specimen. If the test has been made on a very thin specimen, the dielectric strength obtained will be misleading to those who are not aware of the law of the increase of dielectric strength with the decrease of the thickness of the test specimen. Claims may be made that an insulating material is insoluble in certain solvents and is weatherproof. Such claims are not absolute. They are only general and refer to ordinary conditions found in the use of insulations. If the working conditions are unusual and severe, specific information should be obtained on the appropriateness of the insulation under consideration.

Natural Solid Insulating Materials

Asbestos is a mineral consisting chiefly of silica, magnesia, lime, alumina, water, and oxide of iron. The structure is of fibers, the ultimate fiber of which is thought to be a single row of the molecular structure of the crystal. The fibers are exceedingly smooth and glossy and have very little friction to hold them together when they are spun into yarn, thus resulting in a low tensile strength. This difficulty, however, has been partly overcome so that now threads are made which have fair tensile strength. The more important varieties, amianthus and amphibole, are used in the form of asbestos paper, cardboard, yarn, cloth, tape, and as a filler in molding mixtures.

Asbestos contains small particles of iron oxide or grit which cannot be entirely removed and which affect to a slight degree its insulating qualities. It is hygroscopic and should therefore not be used on high voltage, in general not over 3300 volts. It is unaffected by oils, acids, and alkalies, and it withstands very high temperatures. Above 500 deg cent it loses its mechanical strength; it melts at about 1300 deg cent. It has extensive applications as a heat insulator.

Lava is a mineral talc, machined in its natural condition and then baked at a temperature of 1100 deg cent to a condition of extreme hardness. It is then unaffected by any subsequent temperature short of its baking temperature. It is slowly attacked by hydrochloric acid but is not affected by other acids or alkalies.

Marble is the name given to any limestone which is sufficiently compact to admit of a polish. Pure marble is white, but the presence of iron oxide or other impurities gives it different colors. It is used principally for switchboard work and should not contain metallic veins, which reduce its insulating qualities. If used on circuits of 1000 volts or more, it should be saturated with an insulating varnish and baked. It shows oil spots and for that reason it is sometimes stained black and given a so-called marine finish. Very little marble is now used except to match old installations.

Slate is a microgranular crystalline stone, derived from argillaceous sediments by regional metamorphism and characterized by a perfect cleavage entirely independent of original bedding, which cleavage has been induced by pressure within the earth. The essential mineral constituents are white mica (chiefly sericite) and quartz. Prominent accessory constituents are black mica (biotite), chlorite, and hematite. Minor accessory constituents are carbonates, magnetite, apatite, clay, andalusite, barite, rutile, pyrite, graphite, feldspar, zircon, tourmaline, and carbonaceous matter. Slate is hygroscopic. It is often permeated by metallic veins, making it unfit for use unless the electrical connections are insulated by bushings. It is useful for switchboard and switch-base work owing to its desirable mechanical and fireproof qualities. Its dielectric strength decreases rapidly as the temperature increases, and at a high temperature slate becomes a conductor. When a high voltage is impressed upon a piece of slate for some time, the slate usually is not punctured but, owing to the consequent rise in temperature, the slate acts as a short circuit to the impressed voltage. The breakdown is thus only apparent as the specimens regain their dielectric properties after cooling.

Purple slate from Vermont and vicinity is considered superior to black slate from Pennsylvania. The use of slate for electrical purposes is rapidly declining.

Table I. Electrical Properties of Insulating Materials

Material	Dielectric Strength			Resistivity				Specific Inductive Capacity	
	Specimen thickness, mm	Kv per per mm *	Authority	Volume, ohm-cm	Authority	Surface † Ohms, 30%	Surface † Ohms, 90%	Air unity	Authority

Quartz, a form of silica, naturally formed into hexagonal crystals, has a density of about 2.7. It may be fused and cast into usable shapes and is sometimes used as a ceramic type of insulation for high temperatures.

Soapstone, a form of talc or steatite, is gray in color and feels smooth and soapy. It is very easily machined and is sometimes used as an insulator and structural part where resistance to heat and chemicals is desired. It is weak mechanically, and hygroscopic.

Mica is an anhydrous silicate of aluminum and potassium or sodium. It crystallises in a laminated mass, some grades of which may be subdivided down to a thickness of 0.0008 mm. The ultimate thickness of cleavage layers is unknown and may be finally but one layer of the molecular structure. It is useful as an insulator because of its high insulating qualities and its ability to withstand high temperatures. Owing to its impurity, lack of flexibility and excessive surface leakage in the natural state, the laminae are separated and sorted into various grades of purity and are then cemented together to form plate or flexible reconstructed mica of any thickness or purity.

Two kinds of mica are in common use, muscovite (white mica) and phlogopite (amber mica). The former is usually obtained from India and the latter from Madagascar.

Mica can be built into various useful forms, including plate, flexible mica, tape, coil wrappers, and tubing. Mica is combined with thin paper or cloth as a backing when made into tape or wrappers. The bond is frequently shellac, although asphalts, synthetic resins, and other materials are preferred for special purposes.

White mica is hard and is used in building segment mica for undercut commutators. The maximum safe temperature for white mica is 500 deg cent.

Amber mica is softer and is used in mica plate for flush commutators. It is also used in making plate for heating appliance insulation. It will withstand temperatures up to 800 deg cent.

Flexible mica or molding mica may be made for hot or cold molding. White mica is generally used with a bond which is plastic at the molding temperature. Shellac bond may be made flexible with castor oil.

Sheet insulation is made with mica and some other insulation, such as fish paper, rope paper, Kraft paper, etc., for special purposes.

30. VITREOUS SOLID INSULATING MATERIALS

Glass is essentially a mixture of silicates of sodium, potassium, calcium, or barium. A given specimen may contain one or more of these silicates, the composition being chosen so as to produce the desired properties. Metallic oxides are often added, and if a low-expansion, heat-resisting glass is desired, boron trioxide is used, to make the borosilicate glass.

At normal temperatures glass is a good insulator, but at red heat it is a fair conductor. It resists most chemicals except hydrofluoric acid. Most glass is brittle and weak on heat shock. Newer glasses of the borosilicate type (Pyrex) have lower coefficients of expansion and do not shatter with wide temperature variations. Successful line insulators have been placed on the market, competing with porcelain.

Porcelain is distinguished from other forms of earthenware by a vitrified and non-porous structure. It is composed of china clay, ball clay, flint, and feldspar. China clay, sometimes called kaolin, is slightly plastic whereas ball clay is very tough and plastic. By a proper combination of the two the desired plasticity is obtained. Flint is in the form of pure sand or quartz ground so finely as to be entirely free from any gritty feeling. Feldspar is a natural rock and is ground as fine as the flint. These four ingredients are mixed in proper proportions and passed through the manufacturing processes which require very skillful care and experience.

Such articles as knobs, cleats, and lamp sockets are made by a dry process. Dry-process porcelain is porous and not usually suitable for high-voltage outdoor applications. It is of value because of the accuracy with which intricate pieces can be molded, and is applicable for indoor or low-voltage purposes.

High-voltage insulators are made by a wet process and are non-porous, which is necessary for high-voltage use. The glaze is provided to protect the porcelain from dust and deterioration in the weather, and it should have the same temperature coefficient of expansion as the porcelain itself. In the wet process, the ingredients are thoroughly ground in a ball mill and then mixed with water to a consistency about the same as that of paint. After several hours of stirring (blunging), this liquid (slip) is pumped through a filter press, where the water is extracted and press cakes left. These are stacked in bins for use, being kept moist. The press cake material is thoroughly mixed by a screw type of mixer called a pug mill. The wet clay is extruded in cylindrical form, and sections are cut off for forming into insulators or other parts. Forming is usually done either by hot pressing the plastic clay soon after it leaves the pug mill, or by turning operations performed after the clay has partially dried. Wet-process material may also be cast in plaster of paris molds, a special liquid body being prepared for this purpose. Porcelain is fired for several days at temperatures ranging from 1250 to 1300 deg cent.

The mechanical strength of porcelain depends upon the flint content, the heat resistance upon the clay, and the dielectric strength upon the feldspar which unfortunately also adds brittleness. In a special type of porcelain for spark plugs, magnesia is added to promote mechanical strength at high temperatures. Porcelain, because of its low tensile strength, should be used under a compressive strain. It is comparatively inexpensive, chemically inert, and not sensitive to changes of temperature. The fracture of good porcelain is conchoidal, fine grained, white, and bright.

31. FIBROUS ORGANIC SOLID INSULATING MATERIALS

Cotton occurs as an insulator in many forms, such as cloth, tape, and yarn. These products serve as mechanical supports or separators of conductors and are usually impregnated with an insulating liquid or compound. The insulating value of cotton is considered equivalent only to the same thickness of air, reliance being placed usually on the impregnation for dielectric strength and moisture proofing. Cloth is used in making varnished " cambric " of various types. Tape is employed largely in insulating coils of all types, and yarn, in covering wires or insulating layers of enameled wire in "universal" wound magnet coils.

Silk infrequently serves as an insulator, except where space is an important factor. It is sometimes used as a varnished fabric or as wire covering for appearance and because it can easily be obtained thinner than cotton materials. The cost is higher, however. Its insulating properties are approximately the same as those of cotton.

Linen thread or twine is valuable for fastening the coils of rotating machines because of its high unit strength.

Insulating Papers. The principal papers used in electrical apparatus are described below.

Absorbent Papers made of 100 per cent purified sulfite wood pulp are used in making laminated phenolic products. The paper has a soft fiber, thoroughly cleaned of natural resin, and takes the impregnating phenolic varnishes readily. A " high ratio " plate can be made with absorbent papers. A common thickness is 0.10 in.

Another type of absorbent paper is made from 100 per cent cotton rag stock and it is used in filter presses employed in purifying insulator oils. It is very porous, in order to absorb water readily, and yet let oil through. The sheets are approximately 0.025 in. thick.

Asbestos Paper is not all asbestos fiber, the usual grades containing not more than 80 per cent asbestos, the remainder being sulfite wood pulp fibers. Papers from 0.005 to 0.010 in. thick are used in insulating heavy copper in field coils, and in tape form as a covering for wire. Certain grades of heat-resisting laminated phenolic plate are made of asbestos paper impregnated with materials like Bakelite. Asbestos papers are not high-grade insulators owing to conducting particles and moisture absorption.

Rag Base Papers. (*a*) Tough insulating papers, used where resistance to mechanical damage, as in motor and generator slots, is important, are manufactured from 100 per cent cotton rags. Most of them are identified by trade names, such as Duro, Capacio, and Armco papers.

(*b*) Fish paper is a special type of rag paper made wholly from old cotton rags. The paper during manufacture is treated with zinc chloride which partially dissolves the cellulose. A paper is obtained without a definite fiber structure. It is hard, tough in both directions, and does not dislaminate. Fish paper may be obtained in thicknesses from 0.007 to 0.056 in., it is used for slot insulation, layer insulation of coils, and as switch barriers. Paraffin impregnation or varnish treatments are frequently applied to overcome the inherent hygroscopic property of fish paper.

Fullerboard (or Pressboard). (*a*) Rag fullerboard is composed of 75 per cent rag stock and 25 per cent sulfite wood pulp. It is made on a cylinder machine, cut off, dried, and pressed in sheets. It may be obtained in thickness from 0.007 to $^1/_2$ in. and in sheets as large as 84 in. by 120 in. Fullerboard is particularly adapted for oil impregnation and is extensively used in transformer construction for barriers, coil sides, and washers. It may be formed into angles and channels. Shrinkage and distortion are low.

(*b*) Kraft fullerboard, made of 100 per cent sulfite wood pulp in the same general manner as rag fullerboard, is a cheaper type of material and is valuable for many applications for which rag fullerboard was once used. It is used for barriers, coil spacers, washers, etc., for electrical machinery. It has much greater shrinkage and warping tendencies than rag material. Forming is not so readily done. These limitations result in the continued use of both rag and Kraft types. Varnish treatment is frequently applied when fullerboard is to be exposed to air.

(c) A similar material in thin papers with a highly calendered surface is called express paper. It is used in making varnish treated papers where only a surface coating and not impregnation is desired.

Kraft Papers contain 100 per cent sulfite wood pulp and may be obtained in a range of thickness from 0.0005 in. to fullerboard thicknesses. It is brown in color, is readily impregnated, and is one of the most useful electrical papers. Many grades of laminated resin (phenolic or other) plate and tubing are made with Kraft paper. It is also used, shellac coated, in making rolled paper bushings and terminals. Very thin Kraft tissue (0.0005 in.) now largely replaces the linen and cotton tissue formerly used in capacitors.

Linen Paper. So-called linen papers are part, sometimes as much as 60 per cent cotton. They are strong and tough, and the very thin grades have been employed for condenser (capacitor) insulation. The use of linen in all forms (cloth, paper, and twine) is not nearly so extensive as it once was. Cheaper satisfactory substitutes have been found.

Japanese Paper is imported from Japan and is made of mulberry pulp fiber. The particular feature of this fiber is the great length, giving good strength, although the paper looks frail and not dense. Tissue (0.001 in.) finds use as a backing for mica tape, and as wire insulation. It is not suitable for capacitors because of small holes and lack of uniform structure.

Rope Paper may be manufactured either from manila hemp fiber or from old manila hemp rope. It is very strong, resisting tear better than cotton paper. It is frequently impregnated with varnish and used in combination insulations such as mica and rope paper. Paper made from old rope frequently contains metal particles. For this reason, other papers are usually preferred for high insulation duty. Rope paper can be folded and crimped. It is thus used in holding wires in some types of coils where flanges are omitted.

Cellophane is a pure cellulose product made from wood pulp by chemical treatment. It is transparent. It is obtainable in sheet, tubing, and tape forms. The dielectric strength and specific inductive capacity are high, and its inflammability is no greater than that of paper. Because of its purity it has much promise as an insulator and has been used as wire insulation and coil taping. Some varieties termed " flame proof " and " moisture proof " are now available. Moisture proofing is accomplished by a lacquer coating. Some grades of cellophane are flexibilized with the addition of glycerin.

Cellulose Acetate is obtained by acetic anhydride treatment of cotton fiber or purified wood pulp. It has high dielectric properties and uniformity of characteristics. It can be obtained in the same forms as cellophane and has similar applications. It is comparable in inflammability to paper. It is not so hygroscopic as regular cellophane.

Varnish-treated Cloth, usually muslin, is widely used as an insulating material. It is sometimes known as varnished cambric or empire cloth. It enters the manufacture of cloth insulated cables, is used as coil wrappings, especially on end turns of rotating machines, and in combination with paper as lining for coil slots. Coil terminals on large transformers are taped with varnished cloth.

The fabric is most commonly an unbleached cotton cloth of 60 by 64 threads per inch and in various thickness from 0.005 to 0.015 in. Treatment consists of impregnating and coating with varnish. This is done in a tower through which the cloth passes continuously. It passes through successive varnish baths and is dried by heat between dips. When it emerges it has had from two to four dips and bakes. The varnishes used are generally natural oil varnishes of two types, tan cloth varnish or black. The tan is somewhat more oil proof and less moisture proof than the black. The black is usually asphaltic but can be made satisfactorily oil proof. The dielectric properties of black cloth are generally superior to those of tan. Black cloth finds extensive application in cable manufacture. For this purpose it must possess low power factor and small losses. The surface coat of varnish may be made: relatively hard and smooth; tacky so that, in taping, successive layers will stick together; or greasy so that layers of tape on irregular forms will slip into place easily. Table II gives the dielectric strengths of some treated insulating fabrics and papers.

Wood. Dry wood is a good dielectric and possesses the advantages of low cost, light weight, and strength with toughness. Probably the most frequently used woods are maple and hickory. White pine is a good insulator, especially when oil treated, but is not strong. Wood is generally treated with oil (linseed, tung, or transformer) or some wax or gum to fill the pores and keep out moisture. For use in air it is frequently given a finish of baking varnish.

Table II. Dielectric Strength of Some Insulating Fabrics and Papers

	Thickness, inches	Breakdown Volts	
		1 Layer	Per mil
Treated Cloths			
Asbestos cloth, varnished	0.047	3,780	80
Asbestos tape, varnished	.037	3,145	85
Cambric tape, varnished, black, bias	.010	13,640	1364

Cambric, rolls, varnished, black, straight	.010	13,320	1332
Cambric, rolls, varnished, tan, straight	.007	7,850	1121
Drilling, rolls, varnished, black, flexible	.020	9,250	462
Duck, rolls, varnished, black, flexible	.030	8,947	298
Friction, cloth tape, commercial	.015	3,290	219
Friction, cloth tape, bias	.015	1,480	99
Friction cloth	.024	1,815	76
Silk, oiled	.004	4,450	1112
Surgical tape, varnished	.023	1,240	54
Treated Papers			
Asbestos paper, shellac 1 side	.010	2,120	212
Asbestos paper, shellac 1 side	.029	2,610	90
Express paper, paraffin 2 sides	.008	5,370	671
Fishpaper, shellac 1 side	.003	1,710	570
Fishpaper, paraffin 1 side	.010	8,840	884
Fullerboard, shellac 2 sides	.013	3,390	260
Fullerboard, varnish 2 sides	.035	13,130	375
Japanned paper, shellac 2 sides	.003	1,136	379
Kraft paper, tan, shellac 1 side	.0045	1,270	282
Rope cement paper, varnish 2 sides	.008	9,746	1218
Rope cement paper, shellac 2 sides	.016	8,850	553

Cloths and papers tested flat between 2-in. circular electrodes. Average of 10 breaks. (60 cycles.)

Tapes tested by wrapping on 1-in. diameter rod in half lapped layers. Average of 10 breaks. (60 cycles.)

Fiber is pure cotton cellulose chemically treated to form a hard bone-like material. It is known by various trade names such as Fiber, Vulcanized Fiber, Hard Fiber, Horn Fiber. Fiber of best quality has its origin in old rags because the natural oil of the virgin cotton fiber is deleterious and cannot be easily removed by chemical processes. This oil is removed in the wearing and washing of the garment. All dirt and grit must be removed from the rags. The quality also depends on the softness of the rags.

" Vulcanized Fiber sheets are made by passing cotton rag paper through a strong acid or zinc chloride bath and rolling it up on a large drum where each layer of paper sticks to the layer beneath it. When the proper thickness is obtained the acid-soaked material is cut from the drum and cut in half, forming two sheets of raw fiber. These sheets are put through a soaking process in large wooden tubs, each subsequent tub containing a weaker solution, the last tub containing pure water." (Catalogue of the Continental Fiber Co.)

The soaking process requires from one week to one year depending on the thickness of the sheet. A very small amount of acid or chloride will remain in spite of all the soaking. The sheets are air dried and seasoned at a constant temperature. During the drying, they warp and shrink to one-half the original thickness. They are flattened in a steam-heated hydraulic press and then calendered to exact thickness.

According to Almy, the mechanical and physical properties of fiber vary between wide limits according to the manipulation of the chemical treatment and the varying quality of the original paper or rags. A fiber for a particular use should therefore be selected with great care.

Fiber is not waterproof. Dilute acids and alkalies cause no other effects than water, but concentrated acids cause disintegration. Organic solvents and oils have no effect whatever. At a sustained temperature of 80 to 100 deg cent it loses its water of condition and becomes brittle and it chars in a short period of time at 200 deg cent.

Fiber is widely used because of its strength, toughness, and comparatively high insulating values when dry. It is easily formed and machined. It resists the action of arcs on the surface to a great degree.

Table III gives the N.E.M.A. specifications for hard fiber.

Table III. N.E.M.A. Specifications for Hard Fiber

Minimum Tensile Strength at 20° C
(Lb per sq in.)

Grades Thickness, in.	Bone		Commercial	
	Cross-wise	Length-wise	Cross-wise	Length-wise
Up to 1/8 incl.	6500	8500	6000	8000

Adopted Standard 12-9-1930.

32. RUBBER AND RUBBER SUBSTITUTES

Rubber is derived from the milky secretion or latex of certain tropical trees, creepers, and shrubs found chiefly in America, Africa, Ceylon, and Malacca. When these plants are tapped, a thick milky-looking fluid or latex exudes from them. This latex is composed of very minute oil-like refractive globules, varying in size, which are in a state of rapid Brownian movement in a clear transparent liquid, called the serum. Besides these *caoutchouc* globules, or rubber-gum proper, the serum contains resins, protein, enzymes, and various organic and inorganic compounds. Rubber or India rubber is the dried-up or coagulated latex. The best rubber is from a tree known as the *Hevea brasiliensis*, and is known as hevea rubber. It grows wild in Brazil and is cultivated in Ceylon and the Malay Peninsula. In Brazil coagulation is effected principally by dry heat or smoking. A wooden paddle is dipped in the latex and held over a smoky fire until the latex has coagulated. This process is repeated until the caoutchouc layers have become sufficiently thick, when the lump of raw rubber is cut off, dried for several days, and dispatched usually as " fine Para biscuits " to a trading center. The plantation rubber is coagulated in sheets by means of acetic acid. If subsequently smoked it is known as *smoked sheets*. Para enterfine, Negro Heads and Sernamby are usually prepared from fine Para rubber which adheres to the tree during tapping or to the vessels containing the latex. A relatively recent development is the shipping of the preserved latex in the liquid form. This may then be treated to precipitate the rubber particles, or used directly for impregnation of cords or fabrics.

Manufacture of Rubber Insulation. The washed, dried rubber is passed between heavy rollers and flattened into thin sheets. It is then cut into small pieces and again passed through the rollers with a large proportion of fine powder consisting usually of inert mineral substances, waxy hydrocarbons, and sulfur. The mixture is thus masticated until all its constituents are thoroughly mixed and a smooth homogeneous paste obtained. This process is known as compounding.

Fillers Used in Compounding Rubber. Experience has shown that 60 or 70 per cent of mineral filler, or even a greater proportion of rubber substitute, may be added to rubber gum, before the essential qualities of the rubber cease to predominate. The majority of commercial 30 per cent insulating compounds have compositions which fall within the following limits.

Ingredient	Percent
Rubber	30–32
Whiting	0–30
Zinc oxide	28–67
Litharge	1–12
Ozokerite or paraffin	2– 4

In addition to the above fillers, from 2 to 4 per cent of sulfur is added to the compound, the greater part of which combines with the rubber in the vulcanizing process (see below).

Barium sulfate, sublimed white lead, lead carbonate, lampblack, talc, magnesium carbonate, red lead, barium carbonate, and other substances are also used in small quantities. Talc is often objected to, as making the compound porous, and lampblack, as rendering analysis difficult.

Applying the Rubber Compound to Wires. The rubber compound is applied to the wire by " tubing " machines, or is applied in strips, and the wire thus covered with the compound is coiled up ready for vulcanizing.

Vulcanizing Rubber. If exposed for a long time to air and sunlight, rubber loses its elasticity and finally oxidizes completely into resinous matter soluble in acetone. By vulcanization, however, rubber is rendered more or less immune from deterioration by weathering. Vulcanization is the chemical union of rubber gum with sulfur. It takes place at a temperature of 248 to 302 deg fahr.

The coils of wire, covered with the compound as above described, are placed in a suitable chamber to which steam at the proper temperature is admitted. The time required for vulcanization depends upon the thickness of the insulation, the nature of the compound, the temperature and pressure of the steam, etc., ranging from 2 to 8 hours.

Sulfur Required for Vulcanization of Rubber. The amount of sulfur required to produce vulcanization varies with the brand of rubber and the nature of the compounding materials with which it is mixed. The ratio of the weight of combined sulfur to the weight of caoutchouc, which is insoluble in acetone, is called the vulcanization coefficient. The highest grades of 30 per cent hevea insulation usually have a coefficient between 5 and 10 per cent.

The vulcanization of some brands of rubber cannot be accomplished without either an excess of sulfur or the presence of excessive quantities of some mineral accelerator, such as red lead. Such rubber is to be avoided where permanency is an important consideration. It does not follow from this that red lead in reasonable amounts is a detrimental ingredient.

Certain classes of organic compounds are used in small amounts to accelerate the cure greatly, thus largely decreasing the investment in molds and ovens for a given production. Anti-oxidants such as aniline and related compounds, are often added to the mix to resist the action of corona, thus increasing the useful life of the article made from the mix.

Specific Resistance of Rubber. The specific resistance of 30 per cent hevea rubber compounds is exceedingly variable, depending largely upon the success with which steam is prevented from condensing in the insulation during vulcanization. The megohm-miles are usually computed from the following formula:

$$M = K \log_{10} \frac{D}{d}$$

where M = insulation resistance of a cable, megohm-miles.
d = diameter of cylindrical conductor.
D = diameter of cable over its insulation.
K = 5.8 × (millions of megohms per inch cube at 60 deg fahr).

The value of K varies from 3000 to 7000, the usual specification value being 4000 for 30% hevea compounds.

The specific resistance is not an indication of the quality of rubber insulation as it depends more upon the dryness, the proportion of mineral wax, and the degree of vulcanization, than upon the quality of the ingredients. When the megohms are low they can almost invariably be raised by drying the insulation in a desiccator. The specific resistance of very poor-quality rubber compound, however, sometimes is so low that, when a cable lies in damp earth, sufficient leakage current may flow to permit the passage of water by endosmose, when the conductor is negative to the ground.

Dielectric Strength of Rubber. The disruptive strength of rubber insulation is generally given as between 350 and 450 kv per in. or about 140 to 180 kv per cm effective a-c values. The pressures which should be used in commercial testing do not depend entirely upon the dielectric strength of the rubber, as air in the rubber or between the rubber and conductor or between the rubber and ground becomes ionized at a pressure of about 30 kv per cm with consequent generation of ozone, which rapidly oxidizes and destroys the rubber. This does not occur with paper insulation because the impregnating oil precludes the possibility of air spaces; and no harm results in the case of varnished cambric because it is not seriously attacked by ozone. Hence test pressures for rubber insulation must be based upon experience rather than upon theory and. if sufficiently high to permit ionization of the air, should not last long enough to permit the formation of an appreciable amount of ozone.

Specific Inductive Capacity of Rubber. The specific inductive capacity of pure rubber is about 2.3 (Floy), but the vulcanized compounds used for insulation have specific capacities ranging between 3 and 5, the latter value being nearer the average. The specific capacities of several compounds of stated composition are given by E. Jona (St. Louis, 1904), but they cannot be considered as representative of American practice.

Gutta-percha is derived from the milky secretion or latex of the bark of certain trees of the order of Sapotaceæ, especially the Dichopsis Gutta, found chiefly in the Straits Settlements and Malaccan Archipelago. The trees are felled immediately after the rainy season, and the gutta or gum collected as it exudes from incisions in the bark Latex is also extracted from the leaves by digesting them in toluol. However it may be extracted, the latex is boiled in water and it is then ready for export. Gutta-percha is becoming quite scarce, and practically the whole available supply is used by British cable makers.

The chemical composition of gutta-percha is represented by the formula $C_{10}H_{16}$. It resembles dark brown leather at temperatures between 0 and 27 deg cent. At higher temperatures it softens, and at 65 deg cent it is plastic and capable of being molded or rolled. On cooling it returns to the non-plastic condition.

Gutta-percha oxidizes when exposed to the air, changing from dark brown or black to yellowish gray and becoming brittle.

Preparation of Gutta-percha Insulation. For insulating purposes gutta-percha is shredded and squeezed in warm water. It is then kneaded and strained through fine wire gauze and rolled into sheets. Its further refinement is carried on differently by various manufacturers, the processes being more or less trade secrets. Like rubber it is applied to the wire either by a tubing machine or by strips. Unlike rubber it is used in the pure state without mixture with minerals Gutta-percha is less porous than rubber and therefore more waterproof, a quality which makes it the best material for submarine cables. Its specific gravity is just above unity.

Specific Resistance of Gutta-percha. The constant K in the formula

$$M = K \log \frac{D}{d}$$

has the value 900 approximately, at 75 deg fahr after 1 min electrification.

Temperature Coefficient of Resistance of Gutta-percha is of the same nature as that of rubber, i.e.,

$$R_T = R_{75}\,\epsilon^{(75-T)C},$$

where R_{75} is the resistance at 75 deg fahr, R_T the resistance at T degrees fahrenheit, and C a constant which varies from 0.065 to 0.085.

Effect of Pressure upon Resistance of Gutta-percha. Gutta-percha being used principally for submarine cables, the effect of pressure is important. Resistance and permittance decrease somewhat with increase in pressure, substantially in proportion to the change in density with pressure.

Duprene is a synthetic rubber developed by the Dupont Co. It is a chlorinated derivative of acetylene, and is similar in molecular structure to rubber. The advantages of Duprene are its resistance to age brittleness and to the action of oil. The material is permanently flexible and in accelerated aging at high temperature shows superiority to rubber. Light mineral oils soften Duprene somewhat but not as seriously as they do rubber. It may be obtained in sheets and is used chiefly for gaskets.

Thiokol, chemically olein polysulfide, derived from natural gas, is an oil proof rubber substitute made by the Thiokol Corp. It is unaffected by oil, gasoline, or similar materials. In accelerated aging tests, its life compares with that of high-grade long-life rubber. The "cold flow" under pressure (as in a gasket) is greater than that of either rubber or Duprene. Because of the composition, Thiokol produces corrosion in contact with copper; and with transformer oil, sludging and acid formation result. It cannot be used as transformer gaskets with ordinary designs. The chief application is for oil and gasoline hose. It may be used as a surface layer over rubber for gaskets on lubricating oil and gasoline containers. Also, an outside coating of thiokol on rubber-insulated cables is valuable where cables are subjected to oily conditions.

33. PLASTIC INSULATING MATERIALS

Synthetic Resin Products

Synthetic Resin Products. (See also Resins under Paints, Enamels, Varnishes, Lacquers, pp. 12–54, et seq.) In recent years great advances have been made in the manufacture of countless varieties of insulating products using some organic filler (cloth, paper, or other fiber) bonded with some type of synthetic resin. The first important material of this type was Bakelite, developed by Dr. Bakeland. This is a condensation product resulting from the combination of phenol and formaldehyde under certain conditions. The resin in its initial state is thermoplastic and soluble in alcohol-benzol solvent or acetone. Further heat will polymerize the resin and render it insoluble and infusible. In treating materials with Bakelite, the first stage is used in varnish form and the impregnated filler is then pressed with accompanying heat to cause polymerization.

Many other resins have been introduced since Bakelite was developed. Some are modifications of the phenolic class, but many are of other distinct types. A useful series of resins is known as Glyptal. These are made of glycerin and phthalic anhydride. Other types are resorcinal-formaldehyde, furfural-formaldehyde, vinyl resins, and urea resins. Some are permanently thermoplastic; others are infusible. The urea resins have the advantage of being more nearly colorless, so that light shades of color for decorative purposes are possible.

Synthetic resin products are usually water and oil proof and resist mild acids and alkalies well. Their electrical properties are in general good, being dependent to an extent on the type of filler used.

The physical forms of resin products are many:

(*a*) Resin alone can be molded for ornamental objects such as umbrella handles. It is clear or translucent and can be colored, if desired, by dyes or pigments.

(*b*) Paper or cloth, impregnated with resin and molded in layers, is used for making plate, tubing, angles, channels, etc.

(*c*) Essentially homogeneous fillers such as wood flour, asbestos fiber, chopped cloth may be mixed with dry resin and molded into intricate shapes. The mixture (filler and dry resin) is usually called a molding powder.

Synthetic resin varnishes are also used for impregnating coils and other parts in a manner similar to regular varnishes. Baking completes the polymerization.

Low-grade molding compositions are used for parts not highly stressed either mechanically or electrically. They made be made of a large variety of finely divided materials mixed with shellac, gums, pitch, sodium silicate, etc.

Properties of laminated phenolic sheet and laminated tubing are given in Tables IV and V, respectively.

Table IV. Properties of Laminated Phenolic Sheet Materials (N.E.M.A. Standards, 1931)

Grade	Description	Average Tensile Strength, lbs per sq in.	Average Flexural Strength, lbs per sq in.	Average Dielectric Strength, volts per mil		1,000,000 Cycles			Moisture Absorption, % in 24 hr
				Short Time	Step by Step	Power Factor %	s.i.c.	Dielectric Loss Factor	
X	Paper base	12,000	21,000	700	500	...	...	...	4.0
P	Paper base	8,000	15,000	600	400	...	...	...	4.0
XX	Paper base	8,000	16,000	700	500	4.5	5.5	0.25	1.3
XXX	Paper base	7,000	15,000	650	450	3.5	5.0	0.18	1.0
C	Heavy fibre base for mechanical purposes	10,000	20,000	150	100	10.0	7.0	0.70	1.7
CE	Heavy fabric base electrical and mechanical	9,500	19,000	425	275	5.5	5.5	0.30	1.5
L	Fine weave fabric mechanical	10,000	20,000	150	100	10.0	7.0	0.70	2.0
LE	Fine weave fabric electrical and mechanical	9,000	19,000	500	300	4.5	5.0	0.22	1.2

Table V. Properties of Typical Laminated Tubing

Description	Color	Specific Gravity	Water Absorption, % Increase in Weight After 24 hr	Ultimate Strength, lb per sq in. Axial Stresses		Dielectric Strength $^1/_{16}$ Wall, volts per mil	
				Tensile	Compression	In Oil	In Oil After 24 hr in Water
Kraft paper and synthetic resin. Applications where machining qualities are desirable. Superior mechanical and electrical properties. Special tools for shapes other than round.	Dark tan	1.29	3	11,000	20,000	1000	800
Kraft paper and shellac. For general use (except brush holder tubes) under 75 deg. cent. Will collapse at 100 deg. cent., unless mechanically supported. Resists arcing slightly more than phenolic materials. Made in round and other shapes. Not baked.	Brown	1.12	55	8,000	7,000	800	...
Fine weave fabric and synthetic resin. Where extra strength and high impact are desired. Has lowest moisture absorption of any grade, and is preferred for most chemical applications.	Tan	1.25	2	5,800	22,000	350	300
Kraft paper and synthetic resin.	Black	1.29	3	11,000	20,000	650	500

Waxes

Several waxes, mostly of mineral origin, are used as impregnating materials. They have the advantage when melted of penetrating fibrous insulation and making it moisture proof. Since they are made liquid by heating, no difficulty is presented in the evaporation of solvent, as with varnishes. Most waxes are not oil proof. Natural waxes are composed of carbon, hydrogen, and oxygen. The mineral waxes differ in having no oxygen. Some of the most useful waxes are described below.

Montan Wax is a mineral wax derived from lignite. It has a sharp melting point (75–80 deg cent) and is very fluid when melted. Density at 25 deg cent is 0.90 to 1.00. Frequently, when used for coil impregnation, it is mixed with asphalt gums to give increased fluidity without lowering the melting point.

Mineral Wax (petroleum) has a melting point of 37.5 deg cent and resembles a very viscous petrolatum. It is used as a substitute for beeswax in the impregnation of radio coils and capacitors. It gives good moisture proofing and low dielectric losses.

Beeswax, sometimes mixed with rosin, is used for the impregnation of radio coils and various wire coverings. It has the advantage of avoiding solvents, is very fluid when melted, and has excellent dielectric properties. Density is 0.96 to 0.97 at 15 deg cent. Melting point is 62 to 64 deg cent.

Halowax, a halogenated naphthalene, is an excellent wax dielectric used widely for capacitor insulation. It is also flame resisting and enters the composition of preparations applied to insulation such as cable braid.

Paraffin. The grade of paraffin most common for impregnation has a melting point 50–52 deg cent. It is used to exclude moisture from fish paper, wood, cotton insulation on coils, and other applications where the operating temperature is low. Paraffin, being usually a petroleum product is not oil proof. Specific gravity 0.85 to 0.95, and s.i.c. 1.9 to 2.3.

Ozokerite is a natural mineral wax, related to petroleum products. It may vary from white to brown in color, depending on degree of purification. One purified form is called ceresine wax. The specific gravity at 25 deg cent is 0.85–1.00, and the melting point is 60–95 deg cent. Some impregnating compounds contain this type of material.

Gums, Asphalts, Etc.

Fossil Gums. A numerous group of so-called "fossil gums" have found considerable application both in insulating compounds and as major constituents of varnishes. Among these may be mentioned acroides, dammar, and copal as typical. Gum acroides is soluble in alcohol and sometimes serves as a substitute for shellac, but is more brittle. Copal is used in a variety of compounds. It is also a shellac substitute, being cheaper but having less adhesion. It does possess the advantage, however, of resisting change in flow with continued heating. It does not polymerize as readily as shellac, and is frequently used with powdered shellac to provide good flow properties for coating mica. For other forms of mica products, copal is employed in the compounding of "sticking" varnishes.

A common type of oil-proof impregnating compound consists largely of copal gum, castor oil, and sometimes rosin. It is amber in color and is used for transformer coils, magnet coils, and other apparatus where varnish is not suitable.

Asphaltic gums, both natural (gilsonite) and that made from distillation of petroleum, are very valuable as insulating materials. They range in consistency from viscous tar-like substances to hard, glossy black brittle grades. They may be combined with oils, other gums, or resins in many impregnating compounds. Asphaltic materials are quite moisture resistant, are unaffected by ordinary acids or alkalies, but are generally oil soluble. They cannot be used, therefore, with transformer oil but are excellent for coils operated in air. Natural asphalt is a mixture of hydrocarbons, brown to black in color, with a density 1.04 to 1.40 and s.i.c of 2.7. It starts to soften at about 70 deg cent and is liquid at 90–100 deg cent. Asphalt impregnating compounds give more complete filling of deep coils than varnish, and being melted for use, require no removal of solvents.

Stearin Pitch. This material has a high melting point, 110 deg cent, and is very low in volatile matter. It also possesses flame-resisting characteristics. It is an ingredient in mica bonding compounds.

Pine Tar, derived from yellow pine distillation, is permanently plastic and is therefore very valuable as a flexibilizer. It is a component in spirit and sticking varnishes and in filling and sealing compounds.

Solventless Varnishes. A recent addition to impregnating compounds of a semi-solid type is made in the same manner as insulating varnish (see Insulating Varnishes) except that the final dilution with solvents is omitted. The material is about the consistency of medium asphalt, will just flow at room temperature, and is considered 100 per cent solid. Impregnation is done by heating, to increase fluidity. The difficulty of evaporating solvents, which is a problem with usual varnishes, is thus eliminated.

Shellac (see shellac under Liquid Insulating Materials) obtained from a natural resin, secreted by insects, is used both as a spirit varnish and as a gum. Powdered shellac is used in a number of hot-molding compounds when mixed with a filler. Liquid or powdered shellac is also coated on paper for making insulating bushings and tubing. When rolled, heat is applied to melt the shellac and drive off any residual solvent. Melted shellac is sometimes used for impregnation. It changes to an infusible state if heated for long periods, however, and cannot be readily used in large vats kept hot for impregnating work unless replenished frequently.

34. LIQUID INSULATING MATERIALS

Natural Oils

Linseed Oil, an impregnating material and a major constituent of paints and varnishes, comes from flaxseed. The specific gravity at 15 deg cent is 0.934. Linseed oil dries principally by atmospheric oxidation, finally to a hard gum. With " raw " linseed this process in air is quite slow. " Boiled " oil will oxidize fairly rapidly in air. The action is accelerated by heat or chemical driers. Linseed oil is frequently employed to impregnate wood, making it moisture proof and capable of withstanding exposure to the weather. Impregnation is usually done hot (60 deg cent) to aid in penetration. Baking oxidizes the oil to give a satisfactory surface coat.

Tung Oil (China wood oil) comes from the nuts of an oriental tree, and its main application is in the manufacture of varnishes. It hardens chiefly by polymerization rather than oxidation, thus differing from linseed oil. It may be used for impregnating coils or wood.

Non-drying Oils, such as castor, rosin, or olive oil, are good insulators, but are almost always combined with other materials.

Mineral Oils are used mainly in transformers, induction regulators, and circuit breakers. In transformers and induction regulators, the oil provides an electrical insulating medium which also will carry the heat away from the windings. In circuit breakers, the oil serves primarily as an electrical insulating medium which interrupts the arc when the circuit breaker operates. The requirements for insulating oil for transformers and induction regulators are not inconsistent with those for oil for service in circuit breakers, and hence a single oil will often meet all requirements satisfactorily. Some special switches require a different grade of oil with respect to viscosity, but the properties in general are not materially different.

The Primary Requirements for Transformer and Induction Regulator Oils are as follows:

High dielectric strength; freedom from inorganic acid, alkali, and corrosive sulfur to prevent injury to insulation or conductors; low viscosity to provide good heat transfer; good resistance to emulsion, so that the oil will throw down any moisture entering the apparatus instead of holding it in suspension. (Water in suspension is a menace to safe operation.)

The Primary Requirements for Circuit Breaker Oils are as follows:

High dielectric strength; freedom from inorganic acid, alkali, and corrosive sulfur, to prevent injury to insulation or conductors; low viscosity to aid in dissipating the arc when the circuit is interrupted; low freezing point to insure proper fluidity at all operating temperatures; good resistance to emulsion so that any moisture entering the apparatus or carbon formed by arcing will settle to the bottom of the tank.

Properties of Mineral Oils. It has not been found feasible to cover the performance of an insulating oil completely by specification. Changes in oil with temperature and time cannot always be foretold from physical or chemical tests on the oil. Certain characteristics, however, are indicative of satisfactory oil as far as laboratory tests can determine. The following values may be taken as representative of acceptable unused transformer oil which is also suitable for most circuit breakers.

Specific gravity	0.898 at 15.5 deg cent
Flash point	132 deg cent
Fire point	149 deg cent
Viscosity (Saybolt)	57 sec at 40 deg cent 280 sec at 0 deg cent
Pour test	−45.6 deg cent
Demulsibility (resistance to emulsion value)	25 sec
Neutralization value	0.03 mg. of KOH per g

Insulating Varnishes. See also Paints, Varnishes, Enamels, and Lacquers, p. 12–50.

A Varnish is generally considered as a solution of gums (fossil or synthetic) in (1) volatile solvents, e.g., spirit varnishes, or (2) drying oils, e.g., oleoresinous varnishes.

Spirit Varnishes are generally those composed of shellac (various grades) or synthetic resins dissolved in alcohol or other volatile solvents. They are valuable for rapid air-drying applications and are better for finishes or surface coatings than for impregnating purposes. They commonly possess low flexibility and good cementing properties.

Oil and Asphaltic Varnishes consist of varnish gums or resins, such as copal, succin, dammar, or mastic, combined with a vehicle compounded from linseed oil and tung oil. In black varnishes, clear gums are replaced by asphaltic materials or pitches. The drying time is governed by the proportion of gums and oils and by the quantity of oxidizing agents or driers in the varnish. The greater the proportion of oils, the longer the drying time.

Some of the quick air-drying black varnishes may contain no drying oil. Such varnishes are of neither the oil nor the spirit type and may be termed "asphaltic varnishes." They may consist of an asphaltic base and solvent derived from petroleum or coal tar.

For most electrical work the following varnishes cover the requirements satisfactorily; a clear and a black varnish for both air drying and baking, and a plastic coil impregnation varnish, making five varieties. These varnishes are useful as well for finishing apparatus (metal and insulation) or to provide good appearance and a surface easily kept clean.

Air-drying varnishes do not produce so hard a moisture-resistant coating as baking varnishes under usual conditions but are necessary for apparatus that cannot be baked or for repairs away from the factory. The black varnishes are generally more moisture resistant than the clear but are less oil resistant. The dielectric properties of the black varnishes are somewhat superior to those of clear varnishes. Table VI gives the properties of the common insulating varnishes.

Table VI. Insulating Varnishes

Varnish	Drying Time, hours	Moisture Resistance Rating	Oil Resistance Rating	Acid Resistance, Seconds till Failure		Dielectric		Life at 110° C, hours	Chemical Analysis, Percent										Applications
				H_2SO_4	HNO_3	Dry	Wet		Rosin	Asphaltum	Lime	Linseed Oil	China Wood Oil	Lead and Manganese	Iron Oxide Drier	Benzine 50° to 60°	Heavy Benzine	Turpentine	
Black plastic baking.	4	90	65	72	150	1923	947	770											Plastic insulator for coils and stators
Black coil baking....	5	90	80	128	65	1890	610	528	6.1	14.9	.....	23	11.5	0.77	.....	44			For coils, armatures and wound apparatus. Also finish

Black air dry.......	4	65	0	107	141	1642	527	24	.....	29	.....	13	......	.....	.43	59	54		General use where baking cannot be done
Clear air dry........	4	75	100	27	22	1128	246	675	8.2	......	.....	3	27	1.4	.....	55	.....	6.1	General use where baking cannot be done

Specific gravity of all varnishes, 0.835 or 0.850. Thinner for all varnishes, benzine.

Requirements for Insulating Varnishes. Varnishes to be satisfactory must possess desirable properties in all three states—as a liquid, during drying, and when solid. The most important characteristics to consider are:

Liquid
- Color
- Viscosity
- Specific gravity
- Per cent solids
- Nature of solvent
- Penetration
- Flow
- Tendency to skin in tanks

While Drying
- Spreading
- Draining
- Drying time
- Relation of surface to subsurface drying
- Chemical action on metals or insulating materials

Solid
- Hardness
- Toughness
- Cementing ability
- Dielectric strength
- Softening temperature
- Resistance to water, oil, chemicals

It is not possible to combine in one varnish the maximum degree of all desirable attributes. There are, therefore, a number of useful types of insulating varnish, adapted for particular needs. For example, it is not yet (1936) possible to make a quick-drying varnish that has the ultimate degree of flexibility and heat life. Further, a plastic varnish is not considered the best for a hard surface finishing material.

Application of Varnishes. Varnishes may be applied by brushing, dipping, or spraying. Coils are usually dipped for sufficient time to drive out air, then drained, and then baked. The temperature of baking depends on many factors such as time allowable, type of material, etc. Short time baking (15 min) may be done up to 205 deg cent. A more usual temperature for baking time of 1 to 3 hr is 150 deg cent. Good oven circulation to remove solvent and thus hasten drying is important. Vacuum drying of coils is frequently employed to remove moisture and air. The impregnating material may be admitted to the tank while under vacuum to prevent entrapping air.

Wire Enamels. Certain special insulating varnishes, called wire enamels, are used in coating wires with an insulating film. Most of them are composed of fossil gums combined with drying oils. They differ from usual insulating varnishes in containing less oil (linseed and tung) and are thinned with coal-tar solvents quite similar to kerosene.

In the coating operation, the wire is passed successively through the tank of liquid enamel (" dope pan ") and vertically through a baking chamber, over sheaves, and then the cycle is repeated. From three to six layers are applied, depending on size of wire and service required. Baking is best done by controlled electric heat in the range 400-500 deg cent. The speed of wire travel depends on height of baking oven, temperature, and size of wire. Heavy wires (No. 10 B. & S.) may travel 12 ft per min, whereas fine wire (Nos. 40-44 B. & S.) may pass through at 80 ft per min.

Common American enamels are mahogany red in color when properly baked. Color is a fair indicator of degree of bake or cure, but it is not infallible since it changes with time. Underbaked wire (copper red) is tougher and will elongate without rupture of enamel, but may be less resistant to abrasion and not oil proof. On the other hand, a black wire (overbaked) will probably be brittle but harder and more oil resistant. A good wire enamel properly baked should:

(*a*) Produce a uniform coating, no beading, and no thin spots; (*b*) be flexible to withstand elongation in coil winding and show no breaks when wire is stretched to breaking point; (*c*) be resistant to abrasion; (*d*) have reasonably high dielectric strength (1500 volts per mil); (*e*) withstand hot oil and varnish, e.g., withstand varnish at 80 deg cent for 16 hr without softening; (*f*) have long life. Elongation should not decrease appreciably when wire is stored for 6 months.

Solvents

Solvents. It is important to know the insulating characteristics of ordinary solvents, since some quantity of solvent is usually still present after coils are baked or insulating structures finished.

Because of its high affinity for water, alcohol must be thoroughly removed from spirit varnish impregnation. In deep coils this is difficult, and drying must be done carefully.

Turpentine, benzine, toluol, benzol, and related solvents do not mix with water and are good insulators. It is not, therefore, required for insulating reasons that all solvent be completely removed in impregnation processes. Evaporation will continue for some time. For mechanical reasons (to prevent throwing of " wet " varnish or distortion of coils) it is important to carry evaporation far enough to produce a hardening of the varnish or compound. Under some conditions, organic acids develop in " wet " varnish.

Gases

Gases, when stressed below rupturing gradients, are excellent insulators. Their s.i.c. under normal atmospheric conditions is nearly the same as that in a vacuum, being less than 1 per cent greater. Dielectric strength is rather low, being 31 kv (crest) per cm for air in a uniform electrostatic field. Where the field is non-uniform, local breakdown (corona) induces complete rupture at much lower values. The dielectric strength increases directly with pressure.

Air occurs as an insulator on every piece of electrical apparatus. The distance externally between live parts or between terminals and a grounded part must be great enough to prevent breakdown or excessive leakage in an air path. It is true that frequently the effect of a solid insulation creepage surface is important, but in many cases air is the effective external dielectric. In solid insulation, air is a detriment. Its low s.i.c. causes concentration of voltage gradient on the air layers or pockets (inversely proportional to s.i.c.) and may lead to corona and progressive breakdown.

The dielectric strength of air gaps depends largely on the type of electrodes with their local electrostatic fields. Needle-point gaps have a fairly uniform strength of approximately 4 kv per cm. Sphere gaps or gaps between large curved surfaces have much higher unit breakdown strength, especially at spacings less than the diameter of the spheres. With most types of air gaps, humidity, air density, and frequency greatly influence the dielectric strength.

Carbon Dioxide. Compressed carbon dioxide has been employed as an insulator in high-voltage condensers for apparatus used in measurement of power factor and capacitance. It is an inert gas, obtainable in a relatively pure state.

Nitrogen. There is little difference in the dielectric properties of the common gases. The choice for any application is usually determined by cost or chemical properties. Nitrogen is inert and finds application as an atmosphere in sealed transformers. It prevents absorption of oxygen by the oil and thus eliminates formation of organic acids and sludge. (" Inertaire " type of transformer.)

Hydrogen. Because of its high specific heat (3.41 compared to 0.237 for air) hydrogen is useful as a dielectric to absorb heat from electrical machinery. It is used in a closed system for cooling large generators. Care must be taken to keep a positive gas pressure in the system to prevent influx of sufficient air to produce an explosive mixture.

Relative Dielectric Strength of Gases. Although the dielectric strength of gases varies roughly as the pressure, there are small differences in behavior of the different common gases. Considering the strength of air as 1.00 at the various pressures, Table VII shows the relative dielectric strengths as a factor of the air values.

Table VII. Relative Dielectric Strengths of Gases (Air = 1.00)

(Wolf)

Atmospheres Pressure	Carbon Dioxide	Nitrogen	Hydrogen
1	1.20	1.16	0.87
2	1.10	1.15	0.76
3	1.05	1.15	0.72
4	1.03	1.14	0.69
5	1.02	1.14	0.68

LUBRICANTS

By D. F. Miner

35. CLASSES OF LUBRICANTS

Classification of Lubricants. There are three general classes of lubricants: (1) mineral oils, (2) animal and vegetable oils, and (3) greases.

1. Mineral oils may be of either naphthenic (asphaltic) or paraffin base origin, the former being fluid at low temperatures, and the latter being more highly resistant to oxidation. They cover the range from light spindle oils to heavy cylinder oils.

2. Animal or vegetable oils, though occasionally employed for lubricating purposes, either straight or blended with mineral oils, are not considered primarily as lubricants. Their use is sometimes justified to increase lubricity or oiliness. They are subject to the general characteristics of their class, i.e., tendency to oxidize and to gum in the vegetable oils, and to rancidify in animal oils.

3. The term grease is applied to a mixture of mineral oil and fats which have been saponified with an alkali. Grease is available, either with or without fillers, in three general classes: (*a*) hard grease, (*b*) soft grease, and (*c*) non-fluid oil. More definite classification is being sponsored by the A.S.T.M. by standardizing penetration values.

Source of Lubricants. (*a*) Animal oils are made by rendering the fatty parts of animals, usually with steam. The resulting material is chilled and the oil pressed out. Some of the varieties are: tallow from cattle or sheep, lard oil from cattle, neatsfoot oil from bones of cattle feet, whale oil, and porpoise oil.

(*b*) Most vegetable oils come from the seeds of various plants, by crushing or by chemical extraction. Examples are: castor oil, cottonseed oil, rapeseed oil, corn oil, olive oil.

(*c*) Mineral oils result from the distillation of crude petroleum. One method of refining is to treat by agitation with sulfuric acid, followed by washing with water and caustic soda. In the last few years, laboratory methods of purification have been applied to installations of commercial size. Oils are now being refined by means of aluminum chloride and by use of special selective solvents, which remove the naphthene and aromatic portions from mid-continent and western crudes, the products having essentially the properties of Pennsylvania oils (high heat resistance and flat viscosity curve). Catalytic hydrogenation of oils is being practiced, with the production of very desirable oils having a flat viscosity curve. Accurate temperature control of distillation by means of heat-transfer media such as mercury and diphenyl is being employed to give uniform high-quality products.

36. PROPERTIES OF LUBRICANTS

Definitions and Tests Pertaining to Lubricants. (*a*) *Viscosity* is the term used to signify the body or degree of fluidity of an oil at a given temperature. Measurement is made by means of a viscosimeter, such as the Standard Saybolt Universal in this country, or the Engler, Barbier, and Redwood in Europe. The values obtained by these instruments, that is, the time required for a given amount of oil to flow through an orifice at a given temperature, are purely relative. However, actual measurement may be made in cgs units and is known as absolute viscosity.

(*b*) *Flash Point* is the lowest temperature at which the lubricant will give off sufficient vapor to ignite momentarily when a flame is applied to the vapor.

(*c*) *Fire Point* is the lowest temperature at which the vapors given off will burn continuously.

(*d*) *The Evaporation Test* indicates the quantity of oily vapor an oil will give off on heating under definite conditions of test. It gives an indication of the volatility of oils used in such applications as in the lubrication of vacuum pumps, and serves as an additional check on fire hazard.

(*e*) *Test for Acidity* indicates the amount of uncombined acid in the oil. Since modern refining methods of mineral oils have practically eliminated the danger of contamination from inorganic acids such as sulfuric, the acidity, due to organic acids, is usually referred to as the acid number or neutralization number. It is expressed as the number of milligrams of potassium hydroxide required to neutralize 1 g of oil. However, the vegetable or mineral oils, which are sometimes used for lubricating purposes, are tested for what is termed " free fatty acids," and the acidity is expressed in terms of oleic acid. The acid number divided by 1.99 will give the acidity in terms of oleic acid. The permissible amount of oleic acid varies according to the application.

(*f*) *Saponification Value* is used to determine if an animal or vegetable oil has been mixed with a mineral oil, as well as the degree of oxidation of the mineral oil.

(*g*) *Specific Gravity* of oils is sometimes expressed as a decimal relation to the specific gravity of water. Another method of expression is the number on the Baumé hydrometer scale.

(*h*) *Pour Test* is the lowest temperature at which the oil will just flow, an indication of its usefulness in cold weather.

Properties of Oils. A satisfactory oil should have:

1. Low cohesion to facilitate spreading an adequate oil film between a shaft and its bearing.

2. High adhesion to prevent the oil film from being squeezed out of the bearing contacts and from running freely away from parts to be lubricated.

3. Resistance to oxidation on continued exposure to high temperatures, thus maintaining its original properties over long periods.

4. Freedom from foreign matter. Water may emulsify the oil and ruin its lubricating value. Dirt, metal particles, etc., injure bearings or restrict flow of lubricant in small passages.

Properties of Greases. Grease should have the proper consistency and the ability to resist heat in certain applications,' should not turn rancid nor permit the separation of the oil from the soap,and should have the ability to cling to bearings and not break down under violent churning. The amount and kind of soap used in preparing the grease, as well as the type of oil with which it is compounded, have a bearing on these requirements. Relatively higher melting points can be obtained through the use of a given amount of sodium soap, but, in contact with water, such a grease has a greater tendency to disintegrate than grease with a calcium or lime soap base. Therefore, the choice of a grease necessitates a definite knowledge of the requirements for a given application.

37. USES OF LUBRICANTS

Suggestions for Selection of Lubricants. 1. The flash point should be as high as possible, and still be consistent with other characteristics, particularly viscosity. A safe minimum may be taken as 300 deg fahr.

2. For light pressures and high speeds, mineral oils having viscosities of about 150 sec at 100 deg fahr may be used.

3. For general-purpose machinery, mineral oils having a viscosity of 175 to 225 sec at 100 deg fahr will give satisfactory results. Such oils have a flash point of around 370 deg fahr. In some instances animal and vegetable oils are employed, but usually straight-run mineral oils are preferable.

4. For heavy duty, industrial heavy mineral oils having a viscosity range of about 300 to 1200 sec at 100 deg fahr are recommended.

5. For internal-combustion engines, mineral oils having viscosities of 200 to 600 sec are used in winter and of 400 to 1500 sec in summer. Pour tests of +20 deg fahr maximum are imperative in cold climates.

6. For steam cylinder or extra heavy duty, cylinder oils, either straight-run oils or oils compounded with several per cent of acidless tallow, are in general use. Their flash point is about 600 deg fahr, and their viscosity is 2500 to 3000 sec at 100 deg fahr and 150 to 175 sec at 210 deg fahr.

7. For watches and fine machinery several oils are in use, including, highly refined water-white mineral oils having low pour tests, specially refined low pour test black fish " melon " oil, and other less efficient fish oils.

8. For very high pressure and slow speed, or where ordinary oils will not stay in position, greases give satisfactory results. Roller and ball bearings are frequently lubricated with greases.

Automotive Oils. The viscosity of oils used for automotive purposes has been standardized, and a list of S.A.E. numbers used for identification is as follows:

S.A.E. No.	Saybolt Viscosity
10	90–120 at 130 deg fahr
20	120–185 at 130 deg fahr
30	185–255 at 130 deg fahr
40	255 at 130 deg fahr, not less than 75 at 210 deg fahr
50	75–105 at 210 deg fahr
60	105–125 at 210 deg fahr
70	125–150 at 210 deg fahr

FUELS AND EXPLOSIVES *

38. FUELS

Carbon and Hydrogen are the principal constituents of solid, liquid, and gaseous fuels. In burning, the carbon and hydrogen combine with oxygen from the air, yielding, when combustion is complete, carbon dioxide and water, respectively. When insufficient air is admitted over the bed of fuel, or into the firebox when liquid or gaseous fuels are used, much of the fuel may be lost, either as solids (smoke, soot) and tars, or in the form of unburned gases, especially carbon monoxide. It is almost impossible to attain complete combustion of solid fuels by forcing air under the grate and through the bed of coals, because part of the carbon dioxide formed near the grate is reduced to carbon monoxide on passing through the overlying layers of hot fuel. This monoxide, which has a high heating value, can be burned completely only when a plentiful supply of air is available over the bed of fuel. The blue flames seen when anthracite, coke, or charcoal is burned are due to carbon monoxide.

Wood consists mainly of lignin and cellulose, compounds of carbon with hydrogen and oxygen, together with varying amounts of water and mineral matter. The last largely remains behind in the ash.

Charcoal is made by piling wood into heaps which are covered with earth, leaving a few small openings to admit a limited amount of air and allow the products of combustion to escape when the wood is ignited. When sufficient wood has burned to insure thorough charring (" destructive distillation ") of the remainder, the openings are closed and the pile allowed to cool completely. By this method of making charcoal only a little tar is obtained and all the volatile constituents are allowed to escape. When wood is heated in closed retorts, large amounts of tar, creosote, wood or methyl alcohol, acetone, and pyroligneous (acetic) acid, etc., are obtained. The yield of charcoal is also nearly doubled. Charcoal consists mainly of carbon and the mineral matter of the wood. Its value in metallurgy is due to its low content of phosphorus and sulfur. The calorific value of charcoal is about 95 per cent that of anthracite.

Peat is the result of the partial decay of mosses and other bog plants under water. Even when compressed and dried it contains much water and its mineral content may be high. Its calorific value is 3000 to 4000 cal per kg in air-dried condition.

Lignite, or brown coal, is a stage beyond peat in the formation of coal. It contains much moisture and is often high in ash. Its calorific value as mined is 3500 to 4500 cal per kg. Owing to its large amount of volatile matter, lignite burns with a long, smoky flame.

Bituminous Coal was formed by the further transformation of lignite by heat and pressure. It comprises many varieties, including gas, coking, steam, and cannel coals. They differ principally in their content of volatile matter, the " fat " coals having at times as high as 50 per cent of the compounds of carbon and hydrogen, which are readily driven off by heating. The length of flame of burning bituminous coal depends on the percentage of volatile matter.

Anthracite Coal was produced by the further action of heat and pressure upon bituminous coal, whereby nearly all the volatile constituents were driven off, leaving mainly carbon and mineral matter. These coals burn with little flame and no visible smoke, and do not cake. Their calorific value may be 6500 to 7500 cal per kg.

Coke. As charcoal is the residue left by heating wood in retorts or partially burning it with a limited air supply, so coke is made by heating bituminous coals. In the older types of coke ovens the gaseous and liquid products formed by the destructive distillation are allowed to escape into the air; with modern types of ovens this loss is not permitted and valuable by-products are obtained, such as ammonia, fuel and illuminating gas, and coal tar. Coke is mainly carbon but contains also the mineral constituents of the coal. It is low in volatile matter and sulfur. Upon this and its infusibility and resistance to crushing depends its value as a fuel in blast furnaces. Its calorific value is about 90 per cent that of anthracite.

Chemical Examination of Coal and Coke. The heating value of any fuel can be determined conveniently by means of one of the numerous forms of bomb calorimeters. But this leaves unanswered many questions which have a very practical bearing, for example, the percentages of volatile matter, sulfur, and ash, and the amount of coke the coal will yield. In general, the lower the percentage of ash the better the quality of the fuel. The only mineral constituent that has any heating value is the sulfur of pyrites. But as sulfur is injurious in practically all metallurgical operations and the oxides of sulfur have a corroding effect upon boiler tubes, etc., a coal high in either pyritic or organic sulfur is undesirable. Coals for use in stoker-fired boiler plants operating at high ratings should have high ash fusion temperatures. Coals which are to be burned in pulverized form under boilers should be easily pulverized and have either high or low ash fusion temperatures for plants designed for dry bottom or slag tap operation, respectively. Gas coals and coal for use in certain metallurgical operations requiring long reducing flames should be high in volatile matter. Coals that are to be worked economically for coke may be low in volatile matter but must possess the property of partially fusing or caking together when heated in the ovens.

---

* Written by C. E. Waters, Chemist, National Bureau of Standards, in 1930, for the American Civil Engineers' Handbook by Merriman and Wiggin and reviewed in 1935 by engineers of the U. S. Bureau of Mines.

Samples for calorimetric determinations or for chemical analysis should be collected by the American Standard method promulgated by the American Society for Testing Materials. In sampling at the mine, the coal should be cut from a freshly exposed face, and the sample, after quartering to suitable size, should fairly represent not only the actual coal but also the interpenetrating veins of shale, etc., if these are regularly mined with the coal. It is very important to prepare the sample, not only with great care but also as rapidly as possible, to minimize the inevitable loss of moisture in breaking up the lumps. This explains the necessity of placing the fuel sample in air-tight receptacles, such as fruit jars with rubber rings.

39. LIQUID AND GASEOUS FUELS

Crude Petroleum is the most important of the liquid fuels. It owes its importance not only to its comparative cheapness but also to the ease with which it is handled and its high efficiency, which is two or more times that of anthracite. It is usually burned in the form of a spray obtained by means of a blast of air or superheated steam. Petroleum residues and coal-tar residues are also burned to some extent. Their calorific value is not as great as that of crude petroleum, but may run as high as 10,000 cal per kg.

Gasoline is the lowest-boiling distillate from crude petroleum, or from the " cracking " of the higher-boiling fractions by high temperature, usually under excess pressure, and sometimes in the presence of catalysts which facilitate the breaking down of the more complex hydrocarbon molecules into simpler ones. *Casinghead gasoline* is condensed from natural gas by compression and cooling, before the gas enters the mains through which it is distributed. It is too volatile to be used alone for ordinary purposes, but large quantities of it are mixed with the other forms of gasoline. Each of the kinds of gasoline is a mixture of hydrocarbons containing different percentages of carbon and hydrogen. When mixed with the proper amount of air the vapors form a mixture which is readily ignited and burns with explosive violence. If the vapor is largely in excess of the proportion needed for complete combustion the force of the explosion is weakened, so that, apart from the actual loss of unburned gases, the full power of the engine is not developed. There is a similar loss in power when too much air is present. For the complete combustion of 1 cu ft of the vapor of the hydrocarbon hexane, C_6H_{14}, 45.2 cu ft of air are required, whereas the same volume of heptane, C_7H_{16}, vapor requires 52.4 cu ft of air, or 16 per cent more.

The chief use for gasoline is as the fuel for internal-combustion engines. Most of it is used without the addition of anything else, but various mixtures of gasoline with benzol from coal tar, and with alcohol, are on the market. The value of a motor fuel depends not only upon its volatility and calorific value, but also upon its " anti-knocking " characteristics, upon the degree to which the mixture of its vapor with air can be compressed without pre-ignition, upon its relative freedom from sulfur compounds, which yield sulfuric acid when burned, and upon other factors.

Natural Gas consists mainly of methane, CH_4, with 10 per cent or less of ethane and other gases. Methane is also known as marsh gas, from its abundant formation when vegetable matter decays under water. The name fire damp refers to its occurrence in coal mines, where it is one of the causes of explosions.

Coal Gas, which is made by distilling bituminous coal in retorts, contains 80 to 85 per cent of a mixture of nearly equal parts of hydrogen and methane, and ethane, with much smaller amounts of oxygen, nitrogen, carbon monoxide and dioxide, etc. It is used to some extent in gas engines and as a fuel.

Water Gas is formed by the action of superheated steam upon white-hot coal or coke. The steam gives up its oxygen to the carbon of the fuel, forming carbon monoxide, CO, and leaving hydrogen, thus: $C + H_2O = CO + H_2$. The reaction is endothermic, that is, it requires the addition of heat, so that it is necessary to cut off the steam every few minutes and reheat the fuel by an air blast. Water gas consists of about 45 per cent each of hydrogen and carbon monoxide, with small percentages of oxygen, nitrogen, carbon dioxide, etc. The first two gases burn with very hot, non-luminous flames. For use as an illuminant it must be " enriched " with oil gas.

Producer Gas is made in much the same way as water gas, except that only air and no steam is passed through the incandescent coal or coke. The carbon is burned to carbon monoxide, which makes about 25 per cent of the gas. Smaller amounts of hydrogen, methane, and carbon dioxide are present. There is also nearly 65 per cent of nitrogen from the air which is used. This is unavoidable, though the presence of such a large amount of inert gas reduces the thermal efficiency.

The reaction whereby carbon is burned to carbon monoxide is accompanied by the evolution of about one-third the total heating value of the fuel. It is evident that, if the gas can be burned without allowing it to cool, a great saving of heat can be effected. This is not always feasible, and it is the practice, with some forms of producers, to pass some steam with the air, thus making a mixed water-producer gas. The heat which would otherwise be lost is used up in forming water gas, and the resultant fuel gas has an increased fuel value. It is much more economical to convert the fuel into producer gas and use it in explosion engines than to burn it under steam boilers.

40. EXPLOSIVES

The Fundamental Property of an explosive is that when ignited or subjected to a sudden shock it shall decompose, or its components react, suddenly yielding a relatively large volume of highly heated gas. This definition includes not only gunpowder, nitroglycerin, and similar substances, but also mixtures of inflammable gases and vapors with air; or even coal dust, fine sawdust, or flour suspended in the air. The last three have all been the cause of disasters, the reason being that when some of the particles are ignited the flame is rapidly communicated to adjacent ones, yielding large volumes of highly heated gaseous products of combustion, in addition to which the surrounding air is also heated. Thus, 1 g of anthracite, of specific gravity 1.5, occupies a volume equal to only $^2/_3$ cc. If it contains 95 per cent of carbon, it will yield when burnt about 1761 cc, or 2642 times its own volume, of carbon dioxide measured at 0 deg cent and 760 mm pressure. If suspended as dust in a large volume of air and burned in a fraction of a second, it is evident that the large amount of hot gases must expand with explosive violence.

Gunpowder is a mixture of 75 parts by weight of saltpeter, or potassium nitrate, 15 parts of charcoal, and 10 parts of sulfur, made by grinding the ingredients together with enough water to moisten the mass. It is then compressed into a cake and broken into grains, which are glazed by revolving with graphite and sorted into sizes by sieves. The larger grains are used for blasting, and the smaller ones for small arms. *Blasting powder* is frequently made with the cheaper Chile saltpeter, or sodium nitrate, which produces a cheaper and less powerful powder than that made from ordinary saltpeter. Chile saltpeter, however, has the disadvantage of absorbing moisture from the air, and powder made from it cannot be kept too long nor stored in a damp place. The proportions used are 73 parts of Chile saltpeter, 16 parts of charcoal, and 11 parts of sulfur.

Guncotton, Nitrocellulose, typical of another class of explosives, is made by the action of a mixture of nitric and sulfuric acids upon cotton. When only moderately strong acids are allowed to act on the cotton for a short time, the product is pyroxylin, or soluble nitrocellulose, used for making collodion and celluloid. By longer action with more concentrated acids, guncotton is formed. It is then washed in a machine of the kind used for making paper pulp to remove all traces of acids that might cause spontaneous explosions. While still moist, it is compressed into blocks or sticks. Guncotton is usually stored and transported in a moist condition, and can be exploded without drying. It is comparatively safe to handle, as ordinary shocks do not explode it readily. In the open, it burns with extreme rapidity.

Nitroglycerin is made by the cautious addition of glycerin to a well-stirred and cooled mixture of the strongest nitric and sulfuric acids. The oily product is washed to remove all traces of acids that might cause spontaneous explosion. Under the most favorable conditions, nitroglycerin is not safe to handle. The fact that it is a liquid with consequent liability to leakage from containers greatly increases the danger of transportation and storage. For this reason, it is commonly mixed with some absorbent or transformed into a gelatinous mass.

Dynamite is a mixture of nitroglycerin with infusorial earth, powdered " rottenstone," or similar porous material, known as " dope." Instead of these inactive dopes that take no part in the explosion, explosive mixtures are generally used to absorb the nitroglycerin. Gunpowder is one of these. Dynamite, consisting of 40 per cent nitroglycerin, 44 per cent sodium nitrate, 15 per cent wood pulp, and 1 per cent calcium carbonate, is an example of dynamite with an active dope.

Explosive gelatin is a jelly-like mass made from a solution of soluble nitrocellulose in nitroglycerin. Too powerful for common work, it is used with success for very hard rock in tunnels. Gelatin dynamite is a mixture of explosive gelatin with a dope such as sodium nitrate and wood pulp; it is not so powerful as the straight gelatin. Smokeless powder is a general term covering many modifications of explosive gelatin and mixtures of nitrocellulose with nitrobenzene, etc.; they are usually given fanciful names, as ballistite, cordite, indurite, and so forth. Nitroglycerin and mixtures containing it are all likely to freeze at moderately low temperatures. They cannot be used satisfactorily in that condition, and should not be thawed by placing them near a fire or on steam pipes but by leaving them in a warm chamber kept at a temperature not above 90 deg fahr.

Picric Acid, or trinitrophenol, is made by the action of nitric and sulfuric acids upon phenol (carbolic acid). It is a yellow, crystalline substance, formerly used only as a dye for silks, and so forth. For years it was not known as an explosive, but it is now known that it will explode with great violence when detonated. If ignited, it usually burns without exploding and is not very susceptible to shock. Lyddite, melinite, and shimose are composed of picric acid. Some of the salts, or picrates, are exploded by slight blows.

Nitrocellulose, Nitroglycerin, and Nitrostarch are true nitrates, as they all contain the atomic group NO_3. They are chemically quite different from the true nitro-compounds, such as picric acid, which contain the atomic group NO_2. Benzene, toluene, naphthalene, and other substances obtained from coal tar yield nitro-compounds when treated with nitric acid. The best known of these is trinitrotoluene, or " TNT," which was used in such enormous quantities in the Great War. They are used as components of explosives, mixed with either ammonium nitrate or other nitrates, or with chlorates, which are good oxidizing agents, or they may be used in dynamite because they lower the freezing point of the nitroglycerin. Rack-a-rock, roburite, bellite, and securite are typical of the explosives made from these nitro-compounds and oxidizing agents.

A Detonator contains a high explosive, too powerful and sensitive to be employed alone, which by its sudden disruptive force brings about the instantaneous explosion of a large amount of a less sensitive explosive. The ones commonly in use consist of copper capsules containing a definite amount of a mixture of chlorate of potash and mercury fulminate, which is exploded either by a fuse or a wire heated electrically. The fulminate is made by mixing a solution of mercury in strong nitric acid with alcohol. The gray crystalline powder which is precipitated must be well washed to remove all acid. It is sensitive to shock and may explode even when wet.

Explosives must be selected with reference to the character of the work. For quarrying building stone, those that act slowly, with little shattering effect, must be chosen. When the stone is to be crushed after quarrying, or for breaking up rock so that it can be handled by a steam shovel, a quick shattering effect is desired. Generally in open work, the character of the gases arising from the explosion may be disregarded, but in tunnels or mines, especially if not well ventilated, this factor is of great importance. No explosive is absolutely safe in this respect. In coal mines, where the presence of fire damp (methane) is a menace, no explosive giving a long flame or a high heat of detonation should be used. Even in the absence of gas, there is danger of igniting the coal dust.

Explosives should be stored in a dry place so that the sodium or ammonium nitrates will not take up enough moisture to lessen their power. But if in too dry a place, they may lose the moisture they naturally contain, which will change their speed of explosion and thus modify the character of the results obtained. Explosives should not be stored for a longer time than absolutely necessary, on account of the possibility of chemical changes taking place in such mixtures.

ADHESIVE MATERIALS

By D. F. Miner

41. TYPES OF ADHESIVES

Spirit Solutions consist of alcoholic solutions of shellac, resins, gums, or combination of similar organic materials. A filler is sometimes added to give body. Shellac, copal, gum, rosin, pine tar, and castor oil are commonly constituents of these cements. Pine tar and castor oil are used as plasticizers to reduce brittleness. Spirit cements are employed on gaskets and on coil spacers. They are thermoplastic and fairly moisture proof.

Benzine or Benzol Solutions. These adhesives are generally solutions of resins, quite similar to varnishes. The resins include Bakelite, other synthetic resins, fossil gums, pitch, copal, and rubber compounds. Varnish types of cements are oil and moisture proof, but are more brittle than spirit cements. They are used on gaskets and for sticking insulating materials to metal.

Cellulose Cements. A series of lacquer cements, with cellulose nitrate or acetate base and lacquer thinner solvent, has proved to be of considerable value when a quick-drying, strong adhesive is required. They are used for cementing celluloid and leather and for fastening instrument parts.

Solids, melted for use. Several kinds of pitches, asphalts, and gums are used hot as adhesives. They are suitable where there is little chance for evaporation of solvent, and for high operating temperatures. Most of these adhesives are not oil proof but are water proof.

Water Solutions. The ordinary glues are water soluble and cover a variety of materials, such as casein, fish glue, hide glue, sodium silicate, and dextrin. Table I gives the properties of various glues.

Table I. Properties of Various Glues

Technical Note 207, U. S. Forest Products Laboratory, Madison, Wis.

Point of Comparison	Animal Glue	Casein Glue	Vegetable Glue	Blood Glue	Liquid Glue
Source of principal ingredient	Animal hides, bones, etc.	Casein from milk	Starch, generally cassava	Soluble dried blood	Animal glue, or skins, bones, etc., of fish
Spread* Extremes reported Common range	 20 to 50 25 to 35	 30 to 80 35 to 55	 35 to 70 35 to 55	 30 to 100	 No data
Mixing	Soaked in water, then melted	Mixed cold	Mixed with alkali and water, with or without heat; can be made without alkali	Mixed cold	Requires no preparation
Application	Applied warm with brush or mechanical spreader	Applied cold with brush or mechanical spreader	Applied cold with mechanical spreader	Applied cold by hand or with mechanical spreader	Applied cold or warm, usually by hand
Temperature of press	Cold; hot cauls frequently used	Cold	Cold	Hot or cold, depending on formula used	Cold
Strength (block shear test)	High grade; has greater shear strength than strongest American woods; medium grades, slightly lower	Similar to medium grade animal glue	Similar to medium grade animal glue	Similar to or slightly less than medium grade animal glue	Good grades similar to medium grade animal glue; some brands very weak
Water resistance	Naturally low, but can be increased by chemical treatment	High or low, as required	Low	High	Low
Staining	Does not stain	Stains wood of some species	If mixed with caustic soda, stains wood of some species	Does not stain, but the glue is very dark and may show through thin veneer	Does not stain
Uses in woodworking	High grade, where a strong joint is desired: low grade sometimes used for veneering, especially where it is desired to prevent staining	Mainly where water resistance is desired in veneered or joint work	To some extent for joint work, but mainly in veneered work where good strength at low cost is desired	Almost entirely for water-resistant plywood for aircraft or automobiles and for articles to be molded after boiling in water	Mainly for repair work and gluing small articles by hand

* For veneer work, expressed in square feet of single glue line per pound of dry glue.

MISCELLANEOUS MATERIALS

42. CORK

Cork is the spongy outer bark of the cork oak tree, which grows principally in Spain, Portugal, and northern Africa. It is of cellular structure, each cell comprising a strong impenetrable skin, enclosing air. As many as 80 distinct grades of corkwood are recognized.

Natural Cork. The uses of natural cork are limited by the variability of the raw material, by structural flaws, which are uncontrollable in a natural material, and by the irregularity in size, thickness and shape. These limitations can be overcome by laminating the corkwood to produce a material of greater uniformity and structural strength.

Cork Compositions.—Finely ground cork combined with various binders forms materials having all the desirable basic qualities of natural cork. Compositions can be made to provide for expansion or contraction, or to be fabricated into sheets, disks, tubes, blocks, rings, strips, balls, wheels, rods, and irregularly shaped articles. It also can be molded directly to a desired pattern. Composition cork is laminated with cloth, vulcanized fiber, or other material to increase the tensile strength. Cork has also been combined with rubber and synthetic resins.

Properties of Cork. 1. *Resistance to Liquid Penetration.* Cork is highly resistant to penetration by liquids. Since it is not fibrous, liquids are not drawn through it by capillarity.

2. *Compressibility.* Prolonged compression, under heavy loads, will cause little permanent deformation. Eight small pieces of cork composition 7/8 in. thick, used as cushions between journal box and the car body of railway cars, supporting approximately 120,000 lb, after one year showed a reduction of total thickness of only 1/8 in. and were still resilient.

3. *Resilience.* Long subjection to pressure does not destroy the structure or resilience of cork. It will not harden or deteriorate under normal conditions.

4. *Frictional Properties.* The coefficient of friction of natural cork and compositions is higher than that of most materials used for friction. This coefficient is not materially decreased by the presence of moisture, oil, or grease. Compositions are more extensively used, as it is possible to control, within reasonable limits, their coefficient of friction. The softer compositions have the higher coefficients of friction, but dense materials for severe conditions have a sufficiently high coefficient for ordinary work.

5. *Buoyancy.* Natural cork, with a specific gravity of 0.15 to 0.20, is generally used for floats and other devices requiring buoyancy.

6. *Low Thermal Conductivity.* The air-cell structure of cork makes it an excellent insulator. It is highly resistant to charring and ignition. At about 250 deg fahr slow distillation begins and the cork discolors slightly. It does not ignite except in contact with flame, and it burns only as long as flame is applied from an external source. Combustion produces a carbonized coating which retards further burning.

7. *Chemical Inertness.* Cork resists chemical action better than most natural materials, and can be safely used in contact with most chemicals. In industrial processes it does not corrode, discolor, or deteriorate and is not affected by oil, grease, gasoline, or other petroleum products. Alkalies and certain acids and organic solvents have a destructive action, and in general, cork should not be used in contact with them. Iron solutions sometimes react with the natural tannin in the cork to cause surface discoloration which, however, does not affect the properties of the cork.

8. *Stability.* Cork retains its initial properties practically unimpaired under all temperature, humidity, or other atmospheric conditions. Its compressibility and resilience enable it to withstand abrasive wear.

Uses. *Seals.* Gaskets for sealing and cushioning, and for sealing anti-friction bearings. Cork closures are sometimes made as split rings, but the continuous ring is generally used. Cork seals should not be distorted either in assembling or in use. They are not recommended for assembly in internal grooves and must be lubricated before assembly, with graphite grease thinned with lubricating oil to the consistency of vaseline. Cork gaskets should not be used on steam or other high-temperature connections or in contact with strong alkaline solutions such as ammonia. *Cushioning* between adjoining surfaces of metal and glass; metal and porcelain or similar combinations; automobile bodies; to deaden vibration in machinery. *Friction.* In the textile industry for drawing yarn and cloth through machines; friction drives; clutches; feed rolls for machines handling paper, cloth, foil, etc. *Floats.* Gage mechanisms for carburetors; dispensing pumps for oil and gasoline. *Insulation.* Under roofs to reduce heat losses, to lessen condensation, and to eliminate ceiling drip; pipe covering for drinking water, brine, and ammonia lines and cold lines in the oil-refining and chemical industries. *Natural Cork Products.* Bottle corks; wheels for polishing glass; floats for carburetors and gages; handles for tools and instruments; disks, washers, and gaskets for various applications; life preservers; yacht fenders; cork balls and paper.

43. LEATHER

Leather as an engineering material is mostly applied in the manufacturing of belting for transmission trains. The best quality of well-tanned ox hide is cut into strips of 4 to 6 ft long and usually about $^3/_{16}$ in. in thickness, which are scarfed, spliced, or cemented end to end to make the desired length of belt. According to the strength required, these are in turn cemented or riveted together in thickness to form "single" or "double" belts. Under light loads, the "single belt" gives the greater adhesion, but under heavy loads the "double belt" proves the more satisfactory. The "flesh side" or inside of the belt is customarily placed next to the pulley, as it gives the best wear, although when placed grain side to the pulley the belt is less likely to slip.

The weight of a hard well-tanned belt leather is about $62\,^1/_2$ lb per cu ft and the tensile strength of a good quality is about 650 lb per in. of width of single belt. When spliced or riveted, the tenacity is about one-half of the above figure, and when laced about one-third of the strength is developed. A safe working tension may be taken at about 50 lb per in. of width.

Rawhide, or untanned leather, finds many applications in textile machinery connections, looms, ships' tiller ropes, etc., and also in the manufacture of high-speed gear wheels. When sound, it is much stronger than tanned leather and gives greater resistance to violent impact. Its tensile strength may be taken as one-half greater than that of tanned leather

44. GASKETS AND PACKINGS

Packing Materials, used to prevent entrance or exit of liquids or gases between metal parts, may be classified according to materials or application. They embrace metals, inorganic, and organic materials. The following list, arranged by type of application, may be found convenient:

Purpose	Materials	Apparatus
a. Splash proof	1. Square flax	Liquid tanks
	2. Folded asbestos tape	Circuit breakers Transformers
b. Dust proof	1. Felt cemented with shellac	Control boxes Bearing housings
c. Gas and moisture proof	1. Fiber (vellumoid) sheet laminated with cork sheet	Mine apparatus Manhole circuit breakers
	2. Rubber sheet	
d. Oil proof	1. Cork cemented with synthetic resin cements	Static condenser tanks Transformer tanks Circuit breaker tanks
	2. Oil proof rubber	
	3. Rubber substitute (Duprene)	
e. Heat proof For machined surfaces (high pressure)	1. Lead (where flow is required)	Compressors Engine heads
	2. Copper (takes less "set" than lead)	
	3. Aluminum (for high pressures where copper flows too much)	
For rough surfaces	1. Asbestos with rubber binder	Solder pots Furnaces Steam lines
f. Moving parts	1. Asbestos with graphite	Pumps, motor shafts
	2. Rubber and duck	Pump and ram plungers

45. ICE

Ice at 32 deg fahr weighs 57.5 lb per cu ft, its specific gravity being 0.922 (water at 62 deg fahr = 1). Its volume relative to water is 1.0855. Its melting point decreases from 32 deg fahr at the rate of 0.0133 deg fahr for each additional atmospheric pressure. Its specific heat is 0.504 (water = 1). Some German experiments made in 1885 gave a tensile strength of 142 to 223 lb per sq in. Tests made by the U. S. Engineer Corps on 6- and 12-in. cubes, gave crushing strengths varying from 100 to 1000 lb per sq in. depending on the structure of the ice and the purity of water from which it was formed. Before crushing, ice in cubes will compress from 6 to 30 per cent. The sustaining capacity of ice is not definitely determined; 2-in. ice is considered safe for infantry, 4-in. ice for cavalry or light guns, 6-in. ice for heavy field guns, and 8-in. ice for loads not over 1000 lb per sq ft on sledges. Railway trains have been run across ice which was 15 in. thick.

The expansive force of ice is given by Trautwine as probably not less than 30,000 lb per sq ft. The coefficient of expansion, as given by Ganot, is 0.000052. By its expansion a sheet of ice 150 ft in width has been known to tip a masonry bridge pier weighing 1000 tons 2 in. out of plumb, and in another instance to move masonry piers on pile foundations from 2 to 12 in. out of line. The expansive effect in river or lake ice, however, does not make itself felt until the ice is at least 5 in. thick.

Freshly fallen snow weighs from 5 to 12 lb per cu ft; compacted or wet snow weighs from 15 to 50 lb per cu ft.

CONTRACTS

1. CONDITIONS OF CONTRACTUAL RELATIONSHIP

A Contract is an agreement to do or to refrain from doing a specified lawful act.

In order that a contract may be enforceable at law, it must fulfil certain conditions, as follows:

1. There must be at least two parties to a contract.
2. The parties signing a contract must be competent in the eyes of the law.
3. They must agree, or there must be " a meeting of the minds."
4. The subject matter of the contract must be legal.
5. There must be a consideration, except that in certain documents a seal is adequate.

Certain contracts are required by statute to be in writing, but with those exceptions an oral contract is as legal as a written instrument. However, oral contracts are more susceptible of misunderstandings and may be the cause of litigation. In case of doubt reduce the agreement to writing.

1. Two or More Parties

A principal cannot contract with himself since he cannot sue himself to secure enforcement or to obtain damages. A person cannot be both plaintiff and defendant.

Neither can a party acting as principal have a major interest, or an official position of importance, in a company or corporation which is the second party.

Being a stockholder or holding a position of minor importance in a corporation does not prevent a person from contracting as a principal with such a corporation. A city official may contract for the municipality with a corporation provided that his position with the latter does not create a strong suspicion that he influenced the contract for his personal profit. A municipal, state, or federal officer should resign an official position with a corporation which would create a suspicion of dual interest.

A party cannot act for himself and at the same time act as agent for another.

2. Competence

Minors. Legally, a contract cannot be enforced against a minor, although a moral obligation may exist, except that a minor may compel a principal to perform especially where the necessities of life are involved and can himself be held therefor. Contracts with minors are said to be voidable rather than void; i.e., the minor may enforce fulfilment but the other party cannot. When a contract is void, neither party can enforce it. If a contract with a minor continues until he is of age, he may then ratify the contract and enforce it if he elects, where otherwise it would be voidable at the instance of the other party.

The parents of a minor are entitled to his services or to the income from his work. The parent may contract for the employment of his child; such a contract is enforceable during the minority of the child, but becomes void when the infant comes of age. See Agent.

Persons of Unsound Mind are incompetent to sign a contract. The infirmities of age or illness may render one incompetent. A confirmed drunkard is also incapable of contracting, but degrees of drunkenness are such as to make the boundary between competency and incompetency a matter to be decided by the evidence.

Women are coming by statute to have the same status before the law as men in contracting. In cases involving a woman as party to a contract, an attorney should be consulted to be certain of the right of women to contract in that state.

Partnerships. The duly authorized representative of a partnership may contract for the partnership, and in so doing he binds the partners individually to the limit of their resources.

A Corporation may enter into a contract when duly authorized by action of the board of directors designating an official or officials to sign contracts. By-laws and minutes of the board of directors should establish the legality of the proceedings by which a corporation binds itself.

In the case of contracts with a municipal corporation, certain legal procedures should be examined by a competent attorney, such as the law, actions of the municipal council, minutes of their proceedings, advertisement, hearing, etc., as technicalities may make the contract void. John C. Waite states: " If the contract is ultra vires, the contractor will not only be unable to recover on the contract but he will even be precluded from getting back the value of his labor and materials on a quantum meruit and will lose everything he has put into the structure."*

3. Agreement

The parties to a contract must have a common understanding of the terms of the agreement; in other words, "There must be a meeting of their minds."

Even though an oral contract is legal, memory may fail, misunderstandings may creep in, and evidence may be conflicting concerning intent. The more complicated the terms of the agreement, the more important it is to have them written and witnessed.

Statute of Frauds. In order to prevent fraud, English law provided that certain contracts, to be enforceable at law, must be in writing; the states of the United States have adopted similar statutes. Two sections of the English law are as follows:

> Section 4. No action shall be brought to charge any executor or administrator on any special promise to answer damages out of his own estate; (2) or to charge the defendant upon any special promise to answer for the debt, default, or miscarriage of another person; (3) or to charge any person upon any agreement made upon consideration of marriage; (4) or upon any contract or sale of lands or any interest therein; (5) or upon any agreement that is not to be performed within one year of the making thereof; unless the agreement or some memorandum or note thereof shall be in writing and signed by the party to be charged, or by some person thereunto by him lawfully authorized.
>
> Section 17. No contract for the sale of any goods, wares, and merchandises for the price of ten pounds sterling, or upwards, shall be allowed to be good, except the buyer shall accept part of the goods so sold, and actually receive the same, or give something in earnest to bind the bargain, or in part payment, or that some note or memorandum in writing of the said bargain be made and signed by the party to be charged, or their agents thereunto lawfully authorized.

The adjudication of cases under the Statute of Frauds is often complicated. The major questions are: Does the transaction in question come under the statute? Was there a written memorandum signed by the parties? What was their intent?

For illustration, it is necessary to determine whether a certain contract is for a completed article or for the labor and materials necessary to make it. In the latter case, no writing is necessary; in the former, it depends on the price stipulated, the time required for delivery, the acceptance of part delivery or of part payment, or the presence of a signed memorandum.

Contracts for the sale of land or options on land must be in writing. Growing crops and portable tools are goods, and no writing is necessary to convey them. Standing timber is part of the land.

A lease of land or an easement for the use of land for specific purposes and for a specified time requires a writing.

Offer and Acceptance. The usual steps in making a contract are for one party to make an offer of so much goods or labor for a given sum. The offer may be made orally, by letter, telephone, telegraph, or other means of communication. The offer may be made subject to acceptance within a given time; if no time limit is set then it must be accepted within "a reasonable length of time" as the courts may decide how long is reasonable.

An offer may be withdrawn by any means of communication. An offer made by letter can be canceled by wire. An acceptance mailed before the offer is withdrawn constitutes a contract even though it had not been received at the time the offer was canceled. An acceptance, to be binding, must be unequivocal.

To answer, " I will accept your offer provided that you pay the costs of delivery " when no such offer was made is not an acceptance but a new offer. Thus one offer after another may be made until there is an agreement on all details. Not until then is there a contract.

An order for goods is a contract to pay a reasonable price—unless the price was specified. Be careful to specify price, quality, time and kind of delivery, and other items open to misunderstanding.

Mistakes may render a contract void. They include mistakes as to the person when one is contracting for personal, skilled services. A mistake about the person with whom one was contracting would not necessarily be void if the goods tendered were of the quality specified.

---

* John C. Waite, Engineering and Architectural Jurisprudence, p. 36.

Carelessness in reading or neglect to read a contract is not a ground on which to plead for the voiding of a contract. A mistake as to the nature of a contract not due to neglect may cause a contract to be declared void.

A contract made for the sale of a stack of hay was void when it was discovered that the hay had burned *before* the contract was made. If the contract was signed before the hay burned, the purchaser would suffer the loss unless there were other stipulations, such as delivery at a given place, which had not been fulfilled.

In interpeting a contract, the usual meaning of words and local customs will prevail.

Besides mistakes, contracts may be illegal because of fraud, duress, or undue influence.

Fraud. The reality of consent may be affected by a spoken or acted falsehood designed to induce one, and whereby one is induced, to agree to terms which are definitely detrimental. In other words:

There must be a misrepresentation or a false representation of pertinent facts, with intent to deceive.

The other party must be ignorant of the truth after using reasonable diligence in finding the facts.

The party claiming the contract to be void because of fraud must have suffered material injury as a result of such falsifications.

It is extremely difficult to prove intent to defraud.

In case of fraud the injured party may:

(*a*) plead the fraud as a defense against action taken to compel the injured party to perform his part of the contract; or
(*b*) proceed in court to have the contract declared void; or
(*c*) sue to recover damages caused him by the fraud.

Duress. Duress exists when compulsion by force or by threat is used to induce a party to sign a contract. Duress by force includes the use of actual physical force to a person or to a near relative, thus influencing a party to pay ransom, deliver property, or perform acts to obtain release or release of a relative, which acts would not normally be agreed to.

Duress by threat may consist of demands made on threat of bodily harm, exposure of illegal acts, or prosecution for crime.

The party intimidated may:

(*a*) ask the court to declare the agreement void; or
(*b*) plead duress as a defense if sued for performance; or
(*c*) sue for recovery of moneys or property transferred under duress.

Undue Influence is the misuse of mental power by one to change the purposes of another. In contesting wills, it is sometimes charged that a relative, a nurse, or other person in intimate and confidential relations with the ill or aged has used undue influence.

4. The Subject Matter Must Be Lawful

The courts can enforce only legal obligations. An agreement having an illegal object as its purpose cannot be enforced or is void. An illegal contract is not a contract in the eyes of the law.

An agreement in violation of a statutory law is illegal. Gambling is illegal; hence a contract to enforce payment of a gambling debt is void. A contract to commit a crime is likewise null.

In some states, an agreement entered into on Sunday or to be performed on Sunday is made illegal by statute. There are exceptions, such as acts of charity, to preserve property or life.

Licenses. For certain professions a license is required before a person may legally practice. In order to protect life and property, it is common to require physicians, lawyers, dentists, architects, and engineers to be licensed and registered. A contract requiring such licensed professional services is illegal if the party in question is not duly licensed. In states requiring architects and engineers to be licensed they may employ unlicensed designers, inspectors, and resident engineers, but the contracting principal for whom they work must be licensed except in certain governmental positions.

Public Policy. A contract against public interest may be declared illegal by the courts. As an illustration, suppose that a town council proceeds legally to buy or build a public utility or to sell a municipally owned plant. Citizens may ask for an injunction to forbid such act on the ground that it is against public policy, i.e., the best interests of the citizens, as expressed by their opinions and through expert opinion. The court may dissolve the injunction or make it permanent after due hearings.

It may be against public policy to let a contract for a public building or for repairs to the same to other than the lowest bidder.

Suppressing Competition. The common law (and statutes also) recognize competition in trade, and any contract in restraint of trade is illegal. Recent powers delegated by Congress to the President of the United States are amendatory to and in contradiction to English Common Law, the Clayton Act, and the Sherman Anti-Trust Law.

An agreement not to bid on a contract or to bid higher or lower than another or any form of collusion is illegal. In addition, parties to such illegal proceedings are liable under the criminal law.

5. Consideration

In deeds for the conveyance of lands, the price may be stated correctly or as "One Dollar and other considerations, receipt of which is hereby acknowledged." In land contracts, options on the purchase of real estate, and similar documents, including all executory contracts, it is customary to state the exact amount to be paid.

There must be a valuable consideration in a legal contract, but the courts are not concerned with adequacy of the consideration unless fraud is claimed.

The consideration may be something done, forborne, or suffered, or a promise to do, forbear, or suffer, or it may be money, goods, or real estate. The market value of the goods or land may be little under the common law injunction "Let the buyer beware"; that is, the buyer should take all reasonable means to inform himself that the exchange is to his advantage or that he is satisfied even though he will suffer a loss as a result of the bargain or contract.

The consideration should be something which the law esteems of value. A promise to pay the debt of a third party may create a moral obligation, but if there is no consideration, the law will not require the promisor to fulfil his promise. On the other hand, to say to a merchant, "Send A this bill of goods and if he does not pay for it, I will" is enforceable at law. The loss which would be suffered by the merchant in conveying the goods is sufficient consideration for the promise to pay for them. A promise to A that I will make him a gift of a bill of goods is a promise without a consideration and hence is not legal.

Sealed Instruments. A seal is a very old device for giving solemnity to a contract where there is no consideration. A promise to do or to refrain from doing a certain legal act is enforceable when it is a sealed contract. The seal serves notice on the parties to give the contract special consideration as the court will not "go behind the seal" to inquire into the justice of the bargain unless fraud is charged.

Wills, benefactions, trust fund agreements, freehold surety bonds, and similar documents should be sealed.

Originally, a seal ring impression was made in melted wax. The seal may now be made by sticking a piece of a stamp or writing the word "seal" or by a scroll following the signatures to a sealed instrument.

2. THE DISCHARGE OF A CONTRACT

The usual method of terminating a contract is to fulfil the terms of the same, and is called, 1, *performance*. But a contract may also be discharged by

2, breach of contract,
3, "impossibility" of performance,
4, a new agreement or consent, or
5, operation of law.

Performance is the normal method of discharging a contract, but in engineering and construction contracts it is rare for the original terms of the agreement to be carried out without change. All modifications of plans and extras call for supplementary contracts and a change in the consideration.

Where slight changes have been made and something "just as good" has been substituted, the courts will not usually interfere to require the substitution of that which may have been specified. The remedy is to prevent the substitution of other than that specified—unless the substitute is acceptable.

The meaning of a contract is a question of law, although the intent of the parties may be shown by evidence. Whether the contract has been completed is a question of fact for a jury to decide according to the evidence. "Substantial performance" will usually be accepted as full performance in litigation over that question.

Tender. If one party to a contract is obstructed by the other party in his purpose to perform, the obstructed party may "tender" the amount due in "legal tender," i.e., in bank notes (unless objected to at the time), U. S. Treasury notes, and coin, or he may offer to deliver the goods or do the labor as the contract specifies. Refusal to accept when the tender has been made in good faith and in accordance with the terms of the contract relieves the party making the tender of obligation under the contract.

Breach of Contract. Refusal or failure of a party to perform his part of a contract according to its terms constitutes a breach of contract and relieves the offended party of further obligations under the contract. The refusal must be absolute and unconditional. Mere objection or argument is not construed as refusal.

Failure to perform is sometimes difficult to establish. If a time is set for completion, the courts will often take into consideration weather conditions, strikes affecting the supply of or transportation of materials, the effect of fire, and the necessity for completion by a specific date.

The remedy for failure to complete the work on time may be by suit for damages *if* actual loss can be established and the amount of it can be determined. Otherwise the court will rarely enforce damages for non-completion by the specified time. See Liquidated Damages, page 16.

If no time for the completion of the contract is stated then the court will permit "a reasonable length of time" for performance. What is reasonable may depend on the factors of weather, etc., mentioned above.

The remedy for breach of contract may be a suit by the injured party for damages. Establishing by evidence the amount of damage suffered is usually difficult and expensive. It is therefore to be avoided so far as possible by requiring the contractor on engineering and construction work to provide a surety bond. The surety is usually a well-established bonding company, and in effect the bond ensures the completion of the contract by the bonding company if the contractor fails or refuses to perform. Litigation may follow to compel the bonding company to complete the work, or a settlement may be agreed to out of court. This involves a new contract.

There is another remedy for breach of contract called

Specific Performance. Specific performance, as a rule, deals only with lands or specific goods in existence where like goods cannot be acquired in the open market if money damages were awarded. If a person or contracting firm was engaged because of his or their particular skill and experience, and if the contract cannot be completed equally well by another contractor, then a court of equity might consider a suit for specific performance. If the court agrees that the particular skill and experience of the contractor were important considerations and that equal skill and experience cannot be obtained by reasonable effort, then the contractor may be required to perform the contract, but this is rare.

Impossibility of performance is the term applied when the conditions imposed were not contemplated in the contract and are onerous. It does not mean that it is actually impossible in the literal sense but that the difficulties and expense are much greater than was known or than existed when the contract was let. Ordinary difficulties do not comprise impossibility in the legal sense. The usual hazards of contracting are a part of the undertaking although they may involve extra work. Fire is a well-known danger, and insurance will save the contractor from a major part of the loss he would suffer. But a flood which washes away the site of a building which the contractor had agreed to build is an example of legal impossibility.

Acts of Providence. Certain catastrophies called "Acts of God," such as extremely high floods, tornadoes, earthquakes, and similar unforeseen acts of nature, are the basis of defense when contracts cannot be performed without much greater difficulty, time, and expense than was contemplated by the contracting parties. Such so-called Acts of God may create legal impossibility.

A contract for personal services is discharged by the death or incapacity of the party.

Contract Discharged by Agreement. Supplementary contracts to cover changes in the amount of work to be done and to cover extra work are usually provided for in the original contract. These do not affect the legality of the agreement.

Conditions may become such that changes greater than those contemplated by the contract may be necessary. The work may be abandoned at an uncompleted stage and the contract be discharged by a new contract which is in effect an amicable settlement of the case out of court.

Contract Discharged by Law. A legal contract cannot contain requirements or prohibitions contrary to law. A contract may have been entered into in good faith to perform a legal act. Subsequently, and before completion, a law may have been passed by a state or an ordinance by a city council which makes the contract illegal. It is discharged by law. A decision by the courts may have the same effect.

A contract to build a frame addition to a store may be made illegal by the passage of a zoning ordinance prescribing that frame buildings shall not be built in that zone.

3. AGENCY

An employee is one who is hired by the hour, day, week to perform such tasks as he may be directed to do in the way he is told. He may be employed on piece work.

An agent is given authority to act for and in the place of the principal in executing certain business transactions where he has more latitude than the employee as to the time, place, and manner in which he shall act. An employee may also be an agent when he performs certain specific acts.

The nature of the act will determine whether one was acting as employee or agent at the time.

An agent is one who acts for a principal within the powers expressly granted him and those which may reasonably be implied. An engineer for a railroad who is instructed to design and build a bridge has the authority delegated to him to carry out the usual steps customary with that railroad in contracting for materials and hiring the necessary force, or in advertising, receiving bids, accepting an offer, obtaining surety bond, and other details ready for the prescribed officers to sign the contract.

In addition to the authority which may be delegated to an agent in writing and the implied powers which follow as a consequence, there are cases where the courts have protected the third party from loss by holding the principal liable. Such are acts which might reasonably be expected to be within the powers of the agent. The test is thus stated: " Would a reasonably prudent person in like circumstances have been justified in assuming that the agent had the power to enter into the contract in behalf of his principal? "

The above does not apply to an agent of a public corporation. As in a contract with a municipality, it is necessary to observe strictly the powers granted by the government, and its agent has no *apparent* powers—only those specifically granted and those necessary to carry out the grant.

When a principal has ratified or has accepted by implication a contract not within the authority granted an agent, the principal is held liable.

When a principal promptly repudiates an unauthorized act of an agent and so notifies the third party, the principal is not liable.

The principal is liable for torts committed by the agent when carrying out the instructions of his principal and within the authority granted the agent. See Torts. The principal is not liable for criminal acts committed by an agent.

A minor may act as agent and thus bind his principal when he could not act as the principal because of being under twenty-one years of age.

When an agent has acted within the powers delegated to him or when the principal has ratified the contract executed by an agent, the third party is now liable to the principal the same as if he had negotiated directly with the principal.

It is the duty of the agent to carry out the instructions of his principal unless illegal, impossible, or unreasonable. He should exercise due care, act in good faith, and make regular accounting of his acts, receipts, and disbursements. The agent may not act for opposing interests or as principal when carrying out a commission.

The principal is bound by his contract with an agent and is liable to his agent as in any other contract.

4. LIENS AND LIABILITIES

Statutes in the majority of states provide that mechanics employed on building repairs or construction of a substantial character may file a mechanic's lien in a prescribed manner within a limited time. The owner is liable and the property may be sold to satisfy such claims.

Similar protection has also been provided for those supplying materials for such improvements even though the materials have not been used.

In some states a minimum cost of perhaps $100 is stipulated below which cost liens may not be legal.

The architect or engineer who prepares plans and specifications cannot recover under a mechanic's lien unless he has also supervised and inspected the work, in which latter case he may come under the law. The statute should be examined to determine its scope.

The only evidence admissible that the right to file a lien has been waived is a written agreement, known as a Release of Mechanic's Lien, which, properly signed and witnessed, becomes a quit claim against the property.

In large contracts the owner may require that the contractor furnish a bond with a proper surety company to indemnify against mechanic's and material dealer's liens.

If the owner has provided in the contract that amounts may be retained by him sufficient to meet all liens, the usual procedure is to file the lien in the prescribed manner.

The owner satisfies the lien, obtains an affidavit to that effect, withholds the sum or sums so paid, and in the final settlement with the contractor subtracts such sum or sums from the balance due. The prescribed procedure should be rigorously observed.

The lapse of time after the work in question is completed and within which a lien must be filed is usually not over ninety days. The contract may therefore provide for the withholding of sufficient funds until the expiration of the legal period within which liens must be filed. Such liens take precedence over all other claims.

The Lien of Wages is the term applied to statutes which provide for the payment of wages through a lien on the property of the employer or his interest in a property. There is usually a limit of $100 or $200 on the amount of each individual lien for wages.

5. WORKMEN'S COMPENSATION

Workmen's Compensation refers to statutes which provide for the recovery of damages for personal injury suffered while employed and while engaged on duties assigned by the employer or reasonably connected therewith.

Under the common law, the employer was expected to provide safe conditions and proper tools to employees. If a workman was injured, the recovery of damages depended on whether negligence of the employer could be proven and if negligence or contributory negligence could be proven against the employee, usually he could not recover.

Safety appliances were next specified and required with factory inspection by the state in order to improve working conditions.

Employer's Liability Acts were designed to remove the old defence of contributory negligence by the injured employee or that the act of a fellow employee such as foreman or superintendent, or some one to whom the injured employee was bound, was the act of a vice-principal and therefore relieved the employer of liability. There remained only the defense of culpable, intentional, or criminal neglect on the part of the injured.

The major weaknesses of the earlier acts were that no insurance was required by the employing company and that the amount of compensation to be received in case of an injury was not specified. In order to remedy these defects workmen's compensation acts were passed in most states.

Workmen's Compensation Acts provide that the employer, if he elects to operate under the statute, must carry insurance with the state, with an authorized company, or give evidence of financial ability to carry his own insurance and must receive permission so to do.

Under this act the defense is not admissible

(*a*) that the employee was negligent;
(*b*) that the injury was caused by the negligence of a fellow employee; or
(*c*) that the employee had assumed the risks and hazards of the task.

The statutes specify the amount of insurance to be received in case of temporary disability, the permanent loss of a member, and in case of death. Compensation is paid unless it can be proven that there was fraud, i.e., intent on the part of the workman to injure himself or to be injured and thereby obtain compensation.

6. THE ENGINEER'S LEGAL RELATIONS

The engineer may be an employee and as such should have a clear understanding of his duties, salary, and responsibilities. Correspondence, a memorandum signed by his employer, or a contract is desirable. If he is an employee on a day, week, or month basis, he may be given notice a day or two or a week or two before his time expires. Practices differ, but usually a two weeks' notice is given engineers on a monthly pay basis.

The engineer may be an agent either occasionally on special assignments or as a full-time job. He should observe strictly his instructions and the law of agency.

The engineer may be an employer and should then observe the law concerning safety devices, sanitary requirements, and workmen's compensation insurance; he should keep accurate records of all contracts, account for all receipts and disbursements, and prepare the necessary reports and legal statements required by law.

As a contractor he may contract to prepare plans and specifications on a percentage basis of about 5 per cent of the estimated cost for average buildings and more or less for structures of greater or less complexity. An additional charge is made for supervision and inspection.

He will not enter into collusion, nor will he prepare plans on a contingent fee which depends on his receiving the contract award or on whether the building is built.

He will observe the ethics of his profession—a moral not a legal obligation.

The engineer who contracts to prepare plans and specifications, supervise the construction, and inspect materials and workmanship agrees to bring to the job such skill as is usual and is necessary to prepare the designs so that the structure will be safe and equal to the loads and forces which it may reasonably be expected to carry or which are specified. Details should conform to all laws, building codes, and ordinances which may apply.

Although absolute accuracy is not required, neglect of plain duty renders him liable. The engineer who undertakes a contract for services agrees in the eyes of the law to supply reasonable knowledge, skill, and experience related to that specialty. He also agrees to use due care and diligence and to employ his best judgment. To receive commissions on materials, devices, or inventions used without the knowledge and consent of his principal is unfair, and absolute honesty is required in all relations with his principal and the contractor.

If the independent, practicing engineer also holds a public office such as city engineer —on a fee basis—or member of a board of public works, it is important that private and public business do not get mixed. It is necessary that they be kept strictly separate in order that he may not be charged with letting self-interest influence his judgment.

The engineer who prepares plans, like the architect, cannot obtain his compensation through a mechanic's lien unless he has also performed the labor of supervising and inspecting on something like a full-time basis similar to that of a mechanic.

7. ENGINEER AS EXPERT WITNESS

The engineer who accepts employment as an expert witness in cases involving contention over the quality of work, the quantity of work done, or the valuation of public utilities, or in other cases involving special knowledge and skill, must first be prepared to show by his education and experience that he can qualify as a specialist in the field in question. A recital of works designed or built by him similar to those under consideration or of valuations made is necessary. The opposing attorney may question his ability. The judge decides whether the witness qualifies as an expert.

Preparation for a case should include independent surveys, measurements, tests, computations, and such other steps as will provide full information concerning the facts at issue.

His estimates, judgments, and findings should be unswayed by the opinions of others. It is necessary that he be familiar with the evidence which is offered so far as it bears on the technical problems involved. Witnesses who are too anxious to help may do more harm than good if they have not been questioned carefully concerning the points at issue.

In preparation for the case, such maps, photographs, and plans as will be clear to the jury should be chosen for exhibit. Special drawings should be prepared to help make explanations clear to the jury. All pertinent facts upon which the engineer is asked to give testimony should be explained in language which is easily understood by the layman. Opinions should be fortified by illustrations drawn from similar cases.

The hypothetical case is used to introduce the opinion of an expert, for opinion evidence is looked upon askance, in fact, is admitted only under special circumstances in the ordinary case at law. The hypothetical question relates the facts of a similar but imaginary case and then asks the witness what, in his judgment, was the cause or effect.

Notes, computations, and tables of data may be used by the engineer acting as an expert witness in order to refresh his memory. He may also present as exhibits standard works of technology and may read from them in support of his method of analysis.

The witness should be prepared for an extensive, incisive cross-examination. That which is factual should be admitted. If differences arise the opposing attorney may insist on a "Yes" or "No" answer where neither is adequate in the judgment of the engineer. An appeal to the judge may be necessary in order to obtain the privilege of making an answer which is free from possible misinterpretation.

As a rule, engineers object to accepting a contingent fee for services as an expert witness and usually require a definite agreement concerning compensation.

8. TORT

A Tort has been defined as "An act or omission which unlawfully violates a person's right created by law, and for which the appropriate remedy is a common law action for damages by the injured person."

Torts are wrongs committed by one person against the person, property, business, or reputation of another. The liability which results from a tort is due either to intent or negligence; it is not based on contract or on a positive obligation such as is involved in a breach of contract.

Torts Are Classified as (1) those against the person; (2) those against personal property; and (3) those against real property.

The torts which most concern the engineer are, under (1), fraud, negligence, procuring breach of contract, slander, and libel. Under (2) or (3) there are infringement of patents, copyright, and trademark; violation of right of support; violation of water rights; nuisance.

Negligence

Negligence is a breach of duty which requires one to use due care, skill, diligence, and proper caution to avoid injury to another.

The owner or tenant of property must keep it in such repair that those who may lawfully enter may not suffer injury. There is an obligation to barricade pitfalls, trenches, and other excavations against the injury of those who may have the right to enter.

If a city permits the use of a part of a street or sidewalk for private improvements, the owner becomes liable if proper lights by night or barriers by day are not placed for the protection of the public.

The Engineer in the course of his practice must be reasonably prudent and careful in the exercise of his skill to protect property and life against damage due to his acts. The degree of skill which may be demanded depends on the difficulties and requirements of the situation.

If the injured party was negligent or was guilty of contributory negligence he may not recover.

Negligence on the part of the party sued for damages must be the primary cause of the accident and not an incidental circumstance.

Since the burden of proof is on the injured party it is necessary for him to show the conditions preceding, accompanying, and following the accident with a chain of evidence establishing the cause of weakness of the structure, the defect of its design or construction, and the usual good practice in such cases.

The determination of the cause of failure of complicated structures requires a special knowledge of the theory of design, the usual shop practice or method of construction, and a highly analytical skill in obtaining evidence.

Slander and Libel are torts against the reputation. Slander is oral defamation of character; and libel is a written communication designed to injure the name, business, or public estimate of the character of the party libeled.

Infringement of Patent Rights

The inventor or the party to whom rights have been assigned or a licensee may sue to recover damages for the use of a patented device for which rights have not been obtained or if the article has been manufactured by a party having no license. Infringement must be proven, and the prosecution or defense of patent suits is expensive and usually delays the use of the article.

Engineering contracts ordinarily require that the contractor shall provide the necessary license to use and shall be liable for damages for the use of patented devices and for infringement of patented devices, instruments, or machines.

Violation of Right of Support

By virtue of title to real estate the owner has the right to the lateral support of his land and thereby has the duty imposed on him to preserve the support of adjoining property. Excavations for walls, sewers, or basements which weaken the support of adjoining land renders liable the party who causes the excavation.

Support of the soil only is required. The owner of an adjoining building is obligated to shore, underpin, or otherwise protect his building. Otherwise the excavator may enter and protect at the owner's expense or proceed with his excavation, using ordinary care under the circumstances.

The Supreme Court of Massachusetts stated in one case: " If the owner of land makes an excavation in it so near to the adjoining of another proprietor that the soil of the latter breaks away and falls into the pit, he is responsible for all the damage thereby occasioned. Few principles of the law can be traced to an earlier or to a more constant recognition."

In Gildersleeve *vs.* Hammond, the Supreme Court of Michigan 1896, the court in summation said:

1. "While a landowner has the undoubted right to excavate close to the boundary line, he must take reasonable precautions to prevent his neighoor's soil from falling.

2. "If he has taken such reasonable precautions, and yet the soil falls from its own pressure, he is still liable for injury to the soil, but not for any injury to the superstructures.

3. "If the pressure of the superstructure causes the land to fall, he is not liable either for injury to the land or superstructure.

4. "If he fails to take such reasonable precautions to protect his neighbor's soil, and to preserve it in its natural state, he is liable for the injury to both the land and the superstructure if the pressure of the superstructure did not cause the land to fall, and it fell in consequence of the failure to take such reasonable precautions."

Good practice requires cooperation of adjoining owners, the engineers, and legal advisers to provide a proper contract covering shoring and other protective measures to save the interests of all concerned.

The lowering of the water table in the course of excavation may cause settlement. If due care has been used it is unlikely that damages can be obtained, but the problems of water rights and support of the soil may introduce legal complications.

Riparian Rights

The owner of lands adjoining a water course is entitled to the reasonable use of such water so long as he does not damage other riparian owners by the pollution of the stream or by damming it in such manner as to affect the interests above or so store and discharge the water as to injure those below.

The boundary of properties on non-navigable streams is often the streambed or thread of the stream, and the streambed is real property. The boundary may change as the stream slowly erodes and deposits, thus increasing or decreasing the area of a tract bounded by a stream. When land is made by deposit or by change of the channel of a stream or river, boundaries between adjoining properties are legally extended on lines at right angles to the water line, though in fact more frequently by extending the boundaries by mutual consent or custom.

If a lake recedes, the boundaries of adjoining properties are extended normally to the receding line, which action preserves a proportional water frontage and cuts off no one.

Irrigation. In the western states a different practice has grown up and is now recognized by statute in some of them. Prior use constitutes a right, and amounts of water are assigned to new projects according to need. See the law in such states. Congress has recognized priority of possession on public lands.

Pollution. Many of the industrial states have laws against pollution by city or trade wastes, but the laws were not passed until conditions under the common law had become so bad that the remedy is most difficult. Where statutes require it, plans for water supply and sewerage must be submitted for approval to the state board of health or similar authority. Plans not submitted or not approved, in those states, cannot be legally financed by bonds. The bonds are void. It is important that the engineer be familiar with the law and observe it. Failure to adopt changes suggested by the approving authority or to satisfy the same only delays the work.

Manufacturing Wastes constitute a serious source of pollution in the industrial states. Numerous cases have been carried through the courts with conflicting decisions, but the tendency is to view streams and rivers not as natural sewers but as property in which the public has an interest—especially on navigable streams—and to impose greater responsibility on the company contributing to serious pollution by requiring that screens, detention tanks, and treatment works be installed and operated.

Surface Waters is the term applied to run-off from storms, which is seeking a lower level in natural flow over lands on its way to recognized streams. The law of riparian rights does not apply, and in general an owner of lands may appropriate surface waters, but this is not true in all western states. In California a decision was against the storage of flood water to the detriment of users downstream.

The accumulation of excessive amounts of surface water added to normal stream flow produces floods. Floods overflow and damage farm lands and cities, and wash away bridges, railway embankments, and highways. Damages cannot be recovered for such losses unless it can be proven that dams have raised the water above its normal height for such volumes of flow or bridges have reduced the normal waterway and thus have raised the level artificially. Natural causes do not constitute a basis for action to recover damages.

Well Waters are the result of rainfall or surface waters percolating through the soil to porous strata above impervious strata of rock, hardpan, or other material where underground streams are formed.

In the construction of sewers such underground streams may be intercepted and wells rendered worthless. No recovery under such circumstances has been noted, but cities have been enjoined from pumping from wells which damaged private wells. No private owner has been prevented by law from sinking and using wells which interfered with the yield of neighboring wells.

Nuisance

A Nuisance is an offense which does harm or damage or creates inconvenience to private parties or to the public. Private parties are entitled to the comfortable use and enjoyment of their rights. The public likewise may be annoyed, inconvenienced, or damaged by the wrongful conduct of an owner, tenant, or trespasser who creates a material annoyance, offense, or damage. The pollution of streams; the dumping of offal on the banks of streams or in parks; smoke, odor, noise, and vibration caused by private acts, by utilities, or by cities may be the basis of suits by the public to abate or to pay damages.

Garbage incinerators, sewage treatment works, abattoirs, garbage disposal by feeding to hogs are sources of contention in which engineers are concerned.

Damages may be recovered by a private party if he can show depreciation of his property, injury to health, definite discomfort, or other real rather than prospective damages.

Trespass

"Trespass to real property is an unlawful entry upon the land of another, or unlawful acts committed subsequent to a lawful entry. The interest protected is that of possession, free from interference by physical intrusions of persons or things."

"Squatter's right" is established by continued, unchallenged possession of the real estate of another for a period of fifteen to twenty years. Such neglect by the owner may lead to loss of title through adverse possession, i.e., possession against the rights of the former owner who held title to the land in question. Numerous examples exist of title to valuable public or private lands being obtained in this manner.

Cattle roaming at large or breaking out of enclosures into the lands of others may do damage for which the owner may be sued.

The right to enter public buildings, parks, and other public places is granted so long as nuisance is not created or possession is not adverse.

The public has certain license to enter private property in the ordinary course of business, but permission may be revoked.

The law permits entry to control a conflagration and to destroy buildings to prevent loss to other property.

Surveyors and engineers who enter private property to lay out highways, sewers, or other public works, before easements, license, or title has been obtained, should obey the owner's instructions to get off, as otherwise trespass may be charged. The mere act of entry under those conditions is, in fact, trespass, but prompt respect for the rights of contestants or objecting owners rarely leads to suit.

In emergency, a temporary right of way may be established if a highway is blocked or impassable and several vehicles have already followed a specific path or route through a field and around such obstruction. Other vehicles may follow without trespassing until the condition has been cured and fences have been restored.

The engineer should see to it that license, easement, or other right to enter, construct, or repair a sewer, water main, or other public work crossing private property is obtained before entering thereon, unless by verbal agreement a temporary permit is obtained until such legal right has been consummated. A license is usually temporary, whereas an easement provides a permanent right to enter, perhaps for specific purposes.

9. PRELIMINARY STEPS IN LETTING A CONTRACT

1. Business Investigations. The engineer is frequently called upon to prepare reports covering the facts, estimates of cost, estimates of probable income, future prospects for business, probable competition, expected rate of income based on population growth, increase in usage, saturation point, and methods of financing.

In the last connection it is important that the engineer and his clients be thoroughly familiar with the Securities Act of 1933 and its amendments, if amended. Misrepresentation of facts or failure to obtain and divulge all facts related to the issue of securities is a serious offense.

2. Land Rights. The engineer may be called upon to obtain rights of way, options for the purchase of lands, or easements in order that power plants, water lines, transmission lines, highways, railways, sewers, or other constructions may be carried to completion.

Proper land rights should be obtained which will provide for the right to enter to repair or maintain such works.

3. Titles and Records. With the aid of legal advice, it will be necessary to prepare options, easements, deeds, and licenses for the use of patents, and other documents. It is necessary to see that transfers of title are properly "signed, sealed, and delivered" in order to consummate the act, and also to see that they are recorded in the correct office of record.

The engineer's records or the company records should show when deeds are submitted for legal record, at what office or offices, and by whom. Fees must be paid.

4. Issue of Securities. Incorporation of a corporation requires a specific legal procedure depending on the statutes of the state in which incorporation is proposed. Legal services are usually necessary in order to ensure full compliance with the law.

Certain business meetings, election of officers, and records are necessary before the company is in legal operation.

The issue of stocks and bonds involves the preparation of statements of facts and of necessity. Such prospectus must conform to the Securities Act of 1933 in full and with exactness in order that those making the statements may be free from liability.

5. Plans and Specifications must be prepared and made a part of the contract. Such plans and specifications constitute a description of the work to be done, the quality of the materials to be used, the quality of workmanship required, the time within which the work is to be done, the method of payment, provision for extra work, and protection for the contractor and for the owner against liens, suits, and disagreements.

6. Surety Bond. Provision should be made (*a*) for the deposit of a certified check to ensure that the contractor will sign the contract if awarded the same and (*b*) that he will indemnify the owner by a surety bond against loss in case of breach of contract by the contractor.

7. Instructions to Bidders define the basis on which bids must be submitted, i.e., whether on a unit cost basis for each class of material and work or by lump sum with a unit cost for extra work of each kind or a cost plus percentage of one type or another.

The time and place of receiving and opening bids will be stated. The amount of the certified check required from each bidder and the manner of returning the same to successful and unsuccessful bidders will also be stated. The amount and type of surety bond required will be stated.

The address where plans and specifications can be obtained and the cost of same will be given.

It is usual to state that any and all bids may be rejected.

The following is a short form of "Instructions to Bidders" which could be extended to meet the needs of more complicated jobs:

Sealed bids addressed to the Board of Public Works, ..., Pa., and endorsed "Bids for Sewers" will be received at their office in the City Building until 12 o'clock noon on February 5, 1935, and at that time all such bids will be publicly opened and read.

All bids must be on the blank forms provided for the purpose by the Board of Public Works.

A certified check for $. . . . . . must accompany the bid or bids submitted by each bidder.

Certified checks of unsuccessful bidders will be returned within three days after the contract has been signed and a satisfactory surety bond is provided.

The surety bond of a satisfactory bonding company must be provided in the sum of $. . . . . . within 10 days after the contractor is notified of the award or his certified check will be declared forfeited for failure to fulfil the terms of the contract. Likewise, the contract must be signed within the same ten days or the certified check may be declared forfeited.

The Board of Public Works reserves the right to reject any bid or all bids or to accept any bid which it deems for the best interests of the city.

Each bidder shall submit with his bid the names and addresses of parties for whom he has performed work of similar character to that on which he submits a bid.

The quantities of the various classes of work to be done are only approximate and may be increased or decreased by the Board of Works by an amount not to exceed 10 per cent, the increase or decrease to be made at the unit prices bid.

The contractor shall begin work within 30 days after the award of the contract, and the same shall be completed within 90 days after the award of the contract.

Where statutes or ordinances specify the maximum number of hours per day of work permitted or make other conditions, reference to or quotation from the statute should be included.

The instructions to bidders should be signed by a responsible officer such as the clerk or the engineer of the Board of Public Works.

Portions of the above do not apply verbatim where a private party or corporation is proposing to receive bids.

8. The Advertisement. In order to bring the letting of a contract to the attention of prospective bidders, a statement may be sent to a preferred list of bidders, as is often done by architects, or an advertisement may be inserted in a journal which appeals to the desired clientele.

Such notice or advertisement should contain certain pertinent facts, such as when, where, and by whom bids will be received; where plans and specifications can be obtained; conditions of bid such as certified check and surety bond required; the statement that "The right is reserved to refuse any or all bids or to let the contract to other than the lowest bidder."

Advertisements for bids by the U. S. Government may be brief, as in the following, taken from the *Engineering News-Record*, Dec. 13, 1934, p. 47.

UNITED STATES ENGINEER OFFICE, Room 710, Army Building, 39 Whitehall St., New York, N. Y. Sealed bids will be received until 12 m., December 18, 1934, and then publicly opened, for furnishing all labor and materials and performing all work for *dredging* approximately 10,830 cubic yards, place measurement, of material (maintenance) from Port Chester Harbor, N. Y. (225)

Longer and more detailed instructions may be seen in that and other engineering journals.

The following, from the *Engineering News-Record*, Nov. 29, 1934, p. 69, is a good example of a detailed statement designed to protect the state:

Bids: December 4.

State Highway Work

STATE DEPARTMENT OF PUBLIC WORKS—
DIVISION OF HIGHWAYS, ALBANY, N. Y.

Sealed proposals will be received by the undersigned at the State Office Building, 13th Floor, Albany, N. Y., until one o'clock p.m. on Tuesday, December 4, 1934, for the construction and reconstruction of highways and bridges in the following Counties, in accordance with the provisions of the National Industrial Recovery Act and Section 1 of the Act of June 18, 1934 (H.R. 8781):

Construction	Deposit Required
CLINTON (18′ Gravel Bituminous Treated, including 65′ Girder: 3.34 miles)	$5,000
COLUMBIA (18′ Gravel Surfacing: 2.85 miles)	1,700
DELAWARE (18′ Gravel Surfacing: 5.13 miles)	3,600
FRANKLIN (18′ Gravel Surfacing, including 55′ I-Beam: 2.88 miles)	1,900
KINGS & QUEENS (Prelim. Grading, including 56′–67′, 87.5′ Rigid Frame Structures: 0.82 mile)	33,000
MONROE (18′ Gravel Surfacing: 5.06 miles)	2,100
ORANGE (18′ Gravel Surfacing: 6.22 miles)	2,500
ORLEANS (18′ Gravel Surfacing: 4.38 miles)	2,000
ST. LAWRENCE (18′ Gravel Surfacing, including one 42′ and one 50′ Timber bridge: 5.53 miles)	2,500
SCHOHARIE (Broken stone—Bit. Treated: 4.25 miles)	4,000
Reconstruction	
ORANGE (30′ Concrete 8″ and 65.5′ Beam Elim. Structure: 0.27 mile)	3,500
OSWEGO (85.5′ Girder: 30′ Concrete Arch and Concrete Appr.: 0.12 mile)	4,500
ULSTER (Bit. Mac. M.M.O. & Concrete incl. 75′ Girder: 2.63 miles)	10,000
SCHENECTADY & ALBANY (Concrete: 7.58 miles)	21,000

Maps, plans, specifications, and estimates may be seen and proposal forms obtained at the office of the Division of Highways in Albany, N. Y., and at the office of the District Engineers in whose districts the roads are located, upon the payment of Five Dollars ($5.00) for plans and proposal forms. Standard specifications are Two Dollars ($2.00) per copy. No refund will be made on plans, specifications, or proposal forms. Plans and proposal forms may also be seen at the office of the State Department of Public Works, State Office Building, Worth & Center Streets, New York City. The addresses of the District Engineers and counties in each district will be furnished upon request.

Attention of Bidders is called to " General Information for Bidders " in the proposal, specifications, and contract agreement. The attention of bidders is also directed to the special provisions covering sub-letting or assigning the contract and to the use of domestic materials, when financed wholly or in part from funds apportioned under the National Industrial Recovery Act and

Section 1 of the Act of June 18, 1934 (H.R. 8781), and especially called to the fact that the funds for NRH, NRM, NRS (1935) projects were obtained from the provisions of the National Industrial Recovery Act, and Section 1 of the Act of June 18, 1934 (H.R. 8781), for the purpose of providing employment and hastening industrial recovery.

Proposals must be submitted in separate sealed envelopes with the name and number of contract plainly endorsed on the outside of the envelope. Each proposal must be accompanied by cash, draft or certified check payable to the New York State Department of Public Works, Division of Highways, for a sum of at least five per centum and not more than six per centum of the estimate accompanying the plans and specifications, and as specified in the advertisement for proposals and the proposal itself. The retention and disposal of such cash, draft or check by the State Division of Highways shall conform with Subdivision 2 of Section 130 of the Highway Law, as amended. The successful bidder will be required to execute the contract and comply in all respects with Section 130 of the Highway Law, as amended. The amount of the certified check accompanying the proposal of the bidder to whom the contract is awarded will be returned when ten per centum of the work under the contract has been completed. If Surety Bond is dispensed with, pursuant to the Highway Law, the amount of the bidding check will be returned when fifteen per centum of the contract work has been completed.

A certificate of compliance on the prescribed form which will be furnished for that purpose shall be signed and submitted by all bidders, in accordance with Executive Order No. 6646, issued by the President on March 14, 1934. Only bids accompanied by such certificate shall be considered or accepted. The contractor to whom award is made shall require subcontractors and dealers furnishing equipment, materials, and supplies to sign similar certificates before making awards to or purchases from such subcontractors or dealers, copies of which shall be furnished to the contracting officer.

On Federal Aid Contracts, when optional types are permitted for any one item of work, contractors must state in the space provided in the proposal for this purpose the exact designation of the optional type upon which the proposal is predicated. No one proposal shall contain more than one bid for an optional item. The award, if made, will be on the basis of the responsible proposal which for all items of work gives the lowest total cost for the project and the contract will call for the type designated in such proposal.

Skilled, intermediate grade, and unskilled labor on projects under the National Industrial Recovery Act, and Section 1 of the Act of June 18, 1934 (H.R. 8781) shall receive the minimum wage rate per hour as follows:

In New York City: skilled labor, eighty cents per hour; intermediate grade labor, sixty-five cents per hour; unskilled labor, fifty-five cents per hour; in the Counties of Nassau, Rockland, Suffolk, and Westchester, skilled labor, seventy-five cents per hour; intermediate grade labor, sixty cents per hour; unskilled labor, fifty-five cents per hour; in counties other than Nassau, Rockland, Suffolk, and Westchester, and New York City, skilled labor, seventy-five cents per hour; intermediate grade labor, fifty-five cents per hour; unskilled labor, forty-five cents per hour. The minimum hourly rate for the various types of operations and trades shall be set forth in the itemized proposal for each project.

The right is reserved to reject any or all bids.

A. W. BRANDT,
Commissioner of Highways.

9. Receiving Bids. A record should be prepared and kept of the time when each bid was received; the person, partnership, or corporation submitting it; and by whom submitted.

The bids should be opened by the duly authorized official in the case of a municipality, county, state, or federal unit of government.

The engineer should prepare on forms provided for the purpose a comparison of the bids submitted in order to determine the lowest bidder. The law recognizes the right of parties receiving bids to investigate the reliability, experience, and reputation of each bidder and to use their best judgment in selecting the " lowest and best bid," which may not be the lowest. All governmental authorities may be required to show that judgment without prejudice was used. Other things being equal, the courts have required that the lowest bid for public works shall be accepted.

This does not apply to private parties or corporations which may, barring fraud, award the contract as they see fit and usually without recourse on the part of disappointed bidders.

10. Awarding the Contract consists in formally accepting a bid and officially informing the bidder. The contract must be signed within a specified time or the certified check becomes the property of the owner, and he may proceed to notify another party that his bid has been accepted, or the certified check may be held pending the determination of damages sustained by accepting the next higher bid.

In addition to signing the contract, the successful bidder must provide a surety bond of approved form.

It is usual to hold in reserve a second or even a third best bid until the contract has been signed and a satisfactory bond has been submitted. When and if all details are satisfactory, then the certified checks are returned to the unsuccessful bidders.

If the contractor receiving the award in the first instance fails to sign the contract and/

or to supply a satisfactory bond, his certified check may be declared forfeited and another contractor may be notified that his bid is accepted. Or all bids may be rejected, changes may be made in conditions, and new bids advertised for.

10. FORM OF AGREEMENT

The following "Standard Form of Agreement between Contractor and Owner for Construction of Buildings" has received the approval of the National Association of Builders Exchanges, the Associated General Contractors of America, the Joint Conference on Construction Contracts, the National Association of Master Plumbers, and several other organizations. It is used with the approval of the American Institute of Architects. Comments, additions, and suggestions by the author are in smaller type.

"**THIS AGREEMENT** made the..

day of..............in the year Nineteen Hundred and..........................

by and between...

hereinafter called the Contractor, and.......................................

....hereinafter called the Owner, WITNESSETH, that the Contractor and the Owner for the considerations hereinafter named agree as follows:

"**Article 1. Scope of the Work**—The Contractor shall furnish all of the materials and perform all of the work shown on the Drawings and described in the Specifications entitled

" (*Here insert the caption descriptive of the work as used on the Drawings and in the other Contract Documents.*) "

prepared by...

acting as and in these Contract Documents entitled the Architect; and shall do everything required by this Agreement, the General Conditions of the Contract, the Specifications and the Drawings."

The word "Engineer" or "Chief Engineer" may be substituted for "Architect" where desirable.

"**Article 2. Time of Completion**—The work to be performed under this Contract shall

be commenced...
and shall be substantially completed..

" (*Here insert stipulation as to liquidated damages, if any.*)"

An alternative form is: The contractor shall begin active work not later than......days after the contract is signed. The work shall be substantially completed on or before............

It was customary to provide a penalty of $...... per day for each day thereafter that the work remained uncompleted.

The courts held that if no equal bonus was provided for completion before the specified date, the imposing of a penalty was an assumption of a legal authority which lay only in the courts. It was further required that the owner show that damages of the amount of the penalty was suffered. In many instances this was impossible.* Consequently resort has been made to a paragraph entitled " Liquidated Damages."

Whereas, time is of the essence of this contract and whereas the specific amount of damage suffered for each day that the work remains uncompleted after the specified date for completion is difficult or impossible of determination, it is hereby agreed between the Owner and the Contractor that the latter shall pay the sum of $...... per day for each day of delay, not as a penalty, but as liquidated damages for such delay except that the agreed shall not be due if the delay is caused by the owner, nor shall liquidated damages be paid for Sundays or legal holidays.

A " time charge " of similar import has been used by the Delaware State Highway Department.†

"**Article 3. The Contract Sum**—The Owner shall pay the Contractor for the performance of the Contract, subject to additions and deductions provided therein, in current funds as follows:..

---

* See The Elements of Specification Writing by Kirby, 1935, pp. 112 et seq.
† Ibid.

" (*State here the lump sum amount, unit prices, or both, as desired in individual cases.*) "

Where the quantities originally contemplated are so changed that application of the agreed unit price to the quantity of work performed is shown to create a hardship to the Owner or the Contractor, there shall be an equitable adjustment of the Contract to prevent such hardship."

The above article should contain the total of the contract, the agreed unit prices for extras such as excavation, concrete, etc.

Where the contract is on a unit basis the details of amounts of work to be done and unit costs should be given. If the owner supplies certain materials or equipment, this should be clearly stated.

If the contract is on a cost-plus basis, the details should be definite in order to avoid disputes.

" **Article 4. Progress Payments**—The Owner shall make payments on account of the Contract as provided therein, as follows:

On or about the....................day of each month........................per cent of the value, based on the Contract prices, of labor and materials incorporated in the work and of materials suitably stored at the site thereof up to the..............day of that month, as estimated by the Architect, less the aggregate of previous payments; and upon substantial completion of the entire work, a sum sufficient to increase the total payments to.......................per cent of the contract price.................
....

" (*Insert here any provision made for limiting or reducing the amount retained after the work reaches a certain stage of completion.*) "

On contracts for large sums it is usual to include two items under " Payments for Work in Progress." First, estimate the value of the work completed during the preceding month, and second, specify the payment of 75 or some other per cent of the estimated value of the work done.

If a payment is also made on the value of materials delivered during that month and not yet incorporated in the work, then a deduction will be made of the previous payments on materials *now* in the work completed. This requires careful bookkeeping, checking of bills of lading, and inventories of materials on hand. It is also necessary to check the amounts paid on materials received in order to ensure that payments do not exceed the agreed percentage of work done *and paid for*. It is important that the books of the contractor, bills, and receipts be open to inspection by the owner. See Art. 24.

" **Article 5. Acceptance and Final Payment**—Final payment shall be due.............. days after substantial completion of the work provided the work be then fully completed and the Contract fully performed.

Upon receipt of written notice that the work is ready for final inspection and acceptance, the Architect (or Engineer) shall promptly make such inspection, and when he finds the work acceptable under the Contract and the Contract fully performed he shall promptly issue a final certificate, over his own signature, stating that the work provided for in this Contract has been completed and is accepted by him under the terms and conditions thereof, and that the entire balance found to be due the Contractor, and noted in said final certificate, is due and payable.

Before issuance of final certificate the Contractor shall submit evidence satisfactory to the Architect (or Engineer) that all payrolls, material bills, and other indebtedness connected with the work have been paid.

If after the work has been substantially completed, full completion thereof is materially delayed through no fault of the Contractor and the Architect (or Engineer) so certifies, the Owner shall, upon certificate of the Architect (or Engineer) and without terminating the Contract, make payment of the balance due for that portion of the work fully completed and accepted. Such payment shall be made under the terms and conditions governing final payment, except that it shall not constitute a waiver of claims.

" **Article 6. The Contract Documents**—The General Conditions of the Contract, the Specifications and the Drawings, together with this Agreement, form the Contract, and they are as fully a part of the Contract as if hereto attached or herein repeated. The following is an enumeration of the Specifications and Drawings:

" **IN WITNESS WHEREOF**, the parties hereto have executed this Agreement, the day and year first above written.

" ....

" .... "

"Art. 1. Definitions.

"(a) The Contract Documents consist of the Agreement, the General Conditions of the Contract, the Drawings and Specifications, including all modifications thereof incorporated in the documents before their execution. These form the Contract.

"(b) The Owner, the Contractor and the Architect are those mentioned as such in the Agreement. They are treated throughout the Contract Documents as if each were of the singular number and masculine gender.

"(c) The term Subcontractor, as employed herein, includes only those having a direct contract with the Contractor and it includes one who furnishes material worked to a special design according to the plans or specifications of this work, but does not include one who merely furnishes material not so worked.

"(d) Written notice shall be deemed to have been duly served if delivered in person to the individual or to a member of the firm or to an officer of the corporation for whom it is intended, or if delivered at or sent by registered mail to the last business address known to him who gives the notice.

"(e) The term 'work' of the Contractor or Subcontractor includes labor or materials or both.

"(f) All time limits stated in the Contract Documents are of the essence of the Contract.

"(g) The law of the place of building shall govern the construction of this Contract.

"Art. 2. Execution, Correlation and Intent of Documents.—The Contract Documents shall be signed in duplicate by the Owner and the Contractor. In case the Owner and the Contractor fail to sign the General Conditions, Drawings or Specifications, the Architect shall identify them.

"The Contract Documents are complementary, and what is called for by any one shall be as binding as if called for by all. The intention of the documents is to include all labor and materials, equipment and transportation necessary for the proper execution of the work. It is not intended, however, that materials or work not covered by or properly inferable from any heading, branch, class or trade of the specifications shall be supplied unless distinctly so noted on the drawings. Materials or work described in words which so applied have a well-known technical or trade meaning shall be held to refer to such recognized standards.

"Art. 3. Detail Drawings and Instructions.—The Architect shall furnish with reasonable promptness, additional instructions, by means of drawings or otherwise, necessary for the proper execution of the work. All such drawings and instructions shall be consistent with the Contract Documents, true developments thereof, and reasonably inferable therefrom.

"The work shall be executed in conformity therewith and the Contractor shall do no work without proper drawings and instructions.

"The Contractor and the Architect, if either so requests, shall jointly prepare a schedule, subject to change from time to time in accordance with the progress of the work, fixing the dates at which the various detail drawings will be required, and the Architect shall furnish them in accordance with that schedule. Under like conditions, a schedule shall be prepared, fixing the dates for the submission of shop drawings, for the beginning of manufacture and installation of materials and for the completion of the various parts of the work."

In engineering work it is customary to submit all detail drawings with the general drawings to bidders. This paragraph may be omitted or a specific item can be incorporated where it is appropriate.

" **Art. 4. Copies Furnished.**—Unless otherwise provided in the Contract Documents the Architect will furnish to the Contractor, free of charge, all copies of drawings and specifications reasonably necessary for the execution of the work.

" **Art. 5. Shop Drawings.**—The Contractor shall submit with such promptness as to cause no delay in his own work or in that of any other Contractor, two copies of all shop or setting drawings and schedules required for the work of the various trades, and the Architect shall pass upon them with reasonable promptness. The Contractor shall make any corrections required by the Architect, file with him two corrected copies and furnish such other copies as may be needed. The Architect's approval of such drawings or schedules shall not relieve the Contractor from responsibility for deviations from drawings or specifications, unless he has in writing called the Architect's attention to such deviations at the time of submission, nor shall it relieve him from responsibility for errors of any sort in shop drawings or schedules."

This paragraph may be omitted from engineering work where detail and shop drawings are submitted to bidders. Where shop drawings are to be provided by the contractor, the paragraph should make clear that they are to be satisfactory to the engineer and approved by him when satisfactory.

" **Art. 6. Drawings and Specifications on the Work.**—The Contractor shall keep one copy of all drawings and specifications on the work, in good order, available to the Architect and to his representatives.

" **Art. 7. Ownership of Drawings and Models.**—All drawings, specifications and copies thereof furnished by the Architect are his property. They are not to be used on other work and, with the exception of the signed Contract set, are to be returned to him on request, at the completion of the work. All models are the property of the Owner.

" **Art. 8. Samples.**—The Contractor shall furnish for approval all samples as directed. The work shall be in accordance with approved samples.

" **Art. 9. Materials, Appliances, Employes.**—Unless otherwise stipulated, the Contractor shall provide and pay for all materials, labor, water, tools, equipment, light, power, transportation and other facilities necessary for the execution and completion of the work.

"Unless otherwise specified, all materials shall be new and both workmanship and materials shall be of good quality. The Contractor shall, if required, furnish satisfactory evidence as to the kind and quality of materials.

"The Contractor shall at all times enforce strict discipline and good order among his employes, and shall not employ on the work any unfit person or any one not skilled in the work assigned to him."

On engineering work it is usual to specify that workmanship shall be satisfactory in quality to the engineer. If any workman is judged by the engineer to be unfit for the work which is assigned him, he shall be discharged from that position upon written notice by the engineer to the contractor and shall not again be employed on this contract without the consent of the engineer.

" **Art. 10. Royalties and Patents.**—The Contractor shall pay all royalties and license fees. He shall defend all suits or claims for infringement of any patent rights and shall save the Owner harmless from loss on account thereof, except that the Owner shall be responsible for all such loss when a particular process or the product of a particular manufacturer or manufacturers is specified, but if the Contractor has information that the process or article specified is an infringement of a patent he shall be responsible for such loss unless he promptly gives such information to the Architect or Owner.

" **Art. 11. Surveys, Permits and Regulations.**—The Owner shall furnish all surveys unless otherwise specified. Permits and licenses of a temporary nature necessary for the prosecution of the work shall be secured and paid for by the Contractor. Permits, licenses and easements for permanent structures or permanent changes in existing facilities shall be secured and paid for by the Owner, unless otherwise specified.

"The Contractor shall give all notices and comply with all laws, ordinances, rules and regulations bearing on the conduct of the work as drawn and specified. If the Contractor observes that the drawings and specifications are at variance therewith, he shall promptly notify the Architect in writing, and any necessary changes shall be adjusted as provided in the Contract for changes in the work. If the Contractor performs any work knowing it to be contrary to such laws, ordinances, rules and regulations, and without such notice to the Architect, he shall bear all costs arising therefrom."

Engineering specifications often require the contractor to protect all grade stakes and bench marks. If they are damaged or removed by the contractor or his employees, the contractor shall be charged with the cost of replacing the same and shall be responsible for delays and expense caused thereby.

"**Art. 12. Protection of Work and Property.**—The Contractor shall continuously maintain adequate protection of all his work from damage and shall protect the Owner's property from injury or loss arising in connection with this Contract. He shall make good any such damage, injury or loss, except such as may be directly due to errors in the Contract Documents or caused by agents or employes of the Owner. He shall adequately protect adjacent property as provided by law and the Contract Documents. He shall provide and maintain all passage ways, guard fences, lights and other facilities for protection required by public authority or local conditions.

"In an emergency affecting the safety of life or of the work or of adjoining property, the Contractor, without special instruction or authorization from the Architect or Owner, is hereby permitted to act, at his discretion, to prevent such threatened loss or injury, and he shall so act, without appeal, if so instructed or authorized. Any compensation, claimed by the Contractor on account of emergency work, shall be determined by agreement or Arbitration.

"**Art. 13. Inspection of Work.**—The Architect and his representatives shall at all times have access to the work wherever it is in preparation or progress and the Contractor shall provide proper facilities for such access and for inspection.

"If the specifications, the Architect's instructions, laws, ordinances or any public authority require any work to be specially tested or approved, the Contractor shall give the Architect timely notice of its readiness for inspection, and if the inspection is by another authority than the Architect, of the date fixed for such inspection. Inspections by the Architect shall be promptly made, and where practicable at the source of supply. If any work should be covered up without approval or consent of the Architect, it must, if required by the Architect, be uncovered for examination at the Contractor's expense.

"Re-examination of questioned work may be ordered by the Architect and if so ordered the work must be uncovered by the Contractor. If such work be found in accordance with the Contract Documents the Owner shall pay the cost of re-examination and replacement. If such work be found not in accordance with the Contract Documents the Contractor shall pay such cost, unless he shall show that the defect in the work was caused by another Contractor, and in that event the Owner shall pay such cost.

"**Art. 14. Superintendence: Supervision.**—The Contractor shall keep on his work, during its progress, a competent superintendent and any necessary assistants, all satisfactory to the Architect. The superintendent shall not be changed except with the consent of the Architect, unless the superintendent proves to be unsatisfactory to the Contractor and ceases to be in his employ. The superintendent shall represent the Contractor in his absence and all directions given to him shall be as binding as if given to the Contractor. Important directions shall be confirmed in writing to the Contractor. Other directions shall be so confirmed on written request in each case.

"The Contractor shall give efficient supervision to the work, using his best skill and attention. He shall carefully study and compare all drawings, specifications and other instructions and shall at once report to the Architect any error, inconsistency or omission which he may discover, but he shall not be held responsible for their existence or discovery.

"**Art. 15. Changes in the Work.**—The Owner, without invalidating the Contract, may order extra work or make changes by altering, adding to or deducting from the work, the Contract Sum being adjusted accordingly. All such work shall be executed under the conditions of the original contract except that any claim for extension of time caused thereby shall be adjusted at the time of ordering such change.

"In giving instructions, the Architect shall have authority to make minor changes in the work, not involving extra cost, and not inconsistent with the purposes of the building, but otherwise, except in an emergency endangering life or property, no extra work or change shall be made unless in pursuance of a written order from the Owner signed or countersigned by the Architect, or a written order from the Architect stating that the Owner has authorized the extra work or change, and no claim for an addition to the contract sum shall be valid unless so ordered.

"The value of any such extra work or change shall be determined in one or more of the following ways:

(a) By estimate and acceptance in a lump sum.
(b) By unit prices named in the contract or subsequently agreed upon.
(c) By cost and percentage or by cost and a fixed fee.

"If none of the above methods is agreed upon, the Contractor, provided he receives an order as above, shall proceed with the work. In such case and also under case (c), he shall keep and present in such form as the Architect may direct, a correct account of the net cost of labor and materials, together with vouchers. In any case, the Architect shall certify to the amount, including reasonable allowance for overhead and profit, due to the Contractor. Pending final determination of value, payments on account of changes shall be made on the Architect's certificate.

" Art. 16. Claims for Extra Cost.—If the Contractor claims that any instructions by drawings or otherwise involve extra cost under this contract, he shall give the Architect written notice thereof within a reasonable time after the receipt of such instructions, and in any event before proceeding to execute the work, except in emergency endangering life or property, and the procedure shall then be as provided for changes in the work. No such claim shall be valid unless so made.

" Art. 17. Deductions for Uncorrected Work.—If the Architect and Owner deem it inexpedient to correct work injured or done not in accordance with the Contract, an equitable deduction from the contract price shall be made therefor.

" Art. 18. Delays and Extension of Time.—If the Contractor be delayed at any time in the progress of the work by any act or neglect of the Owner or the Architect, or of any employe of either, or by any other Contractor employed by the Owner, or by changes ordered in the work, or by strikes, lockouts, fire, unusual delay in transportation, unavoidable casualties or any causes beyond the Contractor's control, or by delay authorized by the Architect pending arbitration, or by any cause which the Architect shall decide to justify the delay, then the time of completion shall be extended for such reasonable time as the Architect may decide.

"No such extension shall be made for delay occurring more than seven days before claim therefor is made in writing to the Architect. In the case of a continuing cause of delay, only one claim is necessary.

"If no schedule or agreement stating the dates upon which drawings shall be furnished is made, then no claim for delay shall be allowed on account of failure to furnish drawings until two weeks after demand for such drawings and not then unless such claim be reasonable.

"This article does not exclude the recovery of damages for delay by either party under other provisions in the contract documents.

" Art. 19. Correction of Work Before Final Payment.—The Contractor shall promptly remove from the premises all materials condemned by the Architect as failing to conform to the Contract, whether incorporated in the work or not, and the Contractor shall promptly replace and re-execute his own work in accordance with the Contract and without expense to the Owner and shall bear the expense of making good all work of other contractors destroyed or damaged by such removal or replacement.

"If the Contractor does not remove such condemned work and materials within a reasonable time, fixed by written notice, the Owner may remove them and may store the material at the expense of the Contractor. If the Contractor does not pay the expenses of such removal within ten days' time thereafter, the Owner may, upon ten days' written notice, sell such materials at auction or at private sale and shall account for the net proceeds thereof, after deducting all the costs and expenses that should have been borne by the Contractor.

" Art. 20. Correction of Work After Final Payment.—Neither the final certificate nor payment nor any provision in the Contract Documents shall relieve the Contractor of responsibility for faulty materials or workmanship and, unless otherwise specified, he shall remedy any defects due thereto and pay for any damage to other work resulting therefrom, which shall appear within a period of one year from the date of substantial completion. The Owner shall give notice of observed defects with reasonable promptness. All questions arising under this article shall be decided by the Architect subject to arbitration.

"**Art. 21. The Owner's Right to Do Work.**—If the Contractor should neglect to prosecute the work properly or fail to perform any provision of this contract, the Owner, after three days' written notice to the Contractor may, without prejudice to any other remedy he may have, make good such deficiencies and may deduct the cost thereof from the payment then or thereafter due the Contractor, provided, however, that the Architect shall approve both such action and the amount charged to the Contractor.

"**Art. 22. Owner's Right to Terminate Contract.**—If the Contractor should be adjudged a bankrupt, or if he should make a general assignment for the benefit of his creditors, or if a receiver should be appointed on account of his insolvency, or if he should persistently or repeatedly refuse or should fail, except in cases for which extension of time is provided, to supply enough properly skilled workmen or proper materials, or if he should fail to make prompt payment to subcontractors or for material or labor, or persistently disregard laws, ordinances or the instructions of the Architect, or otherwise be guilty of a substantial violation of any provision of the contract, then the Owner, upon the certificate of the Architect that sufficient cause exists to justify such action, may, without prejudice to any other right or remedy and after giving the Contractor seven days' written notice, terminate the employment of the Contractor and take possession of the premises and of all materials, tools and appliances thereon and finish the work by whatever method he may deem expedient. In such case the Contractor shall not be entitled to receive any further payment until the work is finished. If the unpaid balance of the contract price shall exceed the expense of finishing the work including compensation for additional managerial and administrative services, such excess shall be paid to the Contractor. If such expense shall exceed such unpaid balance, the Contractor shall pay the difference to the Owner. The expense incurred by the Owner as herein provided, and the damage incurred through the Contractor's default, shall be certified by the Architect.

"**Art. 23. Contractor's Right to Stop Work or Terminate Contract.**—If the work should be stopped under an order of any court, or other public authority, for a period of three months, through no act or fault of the Contractor or of anyone employed by him, or if the Architect should fail to issue any certificate for payment within seven days after it is due, or if the Owner should fail to pay to the Contractor within seven days of its maturity and presentation, any sum certified by the Architect or awarded by arbitrators, then the Contractor may, upon seven days' written notice to the Owner and the Architect, stop work or terminate this contract and recover from the Owner payment for all work executed and any loss sustained upon anv plant or materials and reasonable profit and damages.

"**Art. 24. Applications for Payments.**—The Contractor shall submit to the Architect an application for each payment, and, if required, receipts or other vouchers, showing his payments for materials and labor, including payments to subcontractors as required by Art. 37.

"If payments are made on valuation of work done, such application shall be submitted at least ten days before each payment falls due, and, if required, the Contractor shall, before the first application, submit to the Architect a schedule of values of the various parts of the work, including quantities, aggregating the total sum of the contract, divided so as to facilitate payments to subcontractors in accordance with Article 37 (e), made out in such form as the Architect and the Contractor may agree upon, and, if required, supported by such evidence as to its correctness as the Architect may direct. This schedule, when approved by the Architect, shall be used as a basis for certificates of payment, unless it be found to be in error. In applying for payments, the Contractor shall submit a statement based upon this schedule, and, if required, itemized in such form and supported by such evidence as the Architect may direct, showing his right to the payment claimed.

"If payments are made on account of materials delivered and suitably stored at the site but not incorporated in the work, they shall, if required by the Architect, be conditional upon submission by the Contractor of bills of sale or such other procedure as will establish the Owner's title to such material or otherwise adequately protect the Owner's interest.

"**Art. 25. Certificates of Payments.**—If the Contractor has made application as above, the Architect shall, not later than the date when each payment falls due, issue to the Contractor a certificate for such amount as he decides to be properly due.

"No certificate issued nor payment made to the Contractor, nor partial or entire use or occupancy of the work by the Owner, shall be an acceptance of any work or materials not in accordance with this contract. The making and acceptance of the final payment shall constitute a waiver of all claims by the Owner, other than those arising from unsettled liens, from faulty work appearing after final payment or from requirement of the specifications, and of all claims by the Contractor, except those previously made and still unsettled.

"Should the Owner fail to pay the sum named in any certificate of the Architect or in any award by arbitration, upon demand when due, the Contractor shall receive, in addition to the sum named in the certificate, interest thereon at the legal rate in force at the place of building.

"**Art. 26. Payments Withheld.**—The Architect may withhold or, on account of subsequently discovered evidence, nullify the whole or a part of any certificate to such extent as may be necessary to protect the Owner from loss on account of:

(a) Defective work not remedied.
(b) Claims filed or reasonable evidence indicating probable filing of claims.
(c) Failure of the Contractor to make payments properly to subcontractors or for material or labor.
(d) A reasonable doubt that the contract can be completed for the balance then unpaid.
(e) Damage to another Contractor.

"When the above grounds are removed payment shall be made for amounts withheld because of them.

"**Art. 27. Contractor's Liability Insurance.**—The Contractor shall maintain such insurance as will protect him from claims under workmen's compensation acts and from any other claims for damages for personal injury, including death, which may arise from operations under this Contract, whether such operations be by himself or by any subcontractor or anyone directly or indirectly employed by either of them. Certificates of such insurance shall be filed with the Owner, if he so require, and shall be subject to his approval for adequacy of protection.

"**Art. 28. Owner's Liability Insurance.**—The Owner shall be responsible for and at his option may maintain such insurance as will protect him from his contingent liability for damages for personal injury, including death, which may arise from operations under this contract.

"**Art. 29. Fire Insurance.**—The Owner shall effect and maintain fire insurance upon the entire structure on which the work of this contract is to be done and upon all materials, in or adjacent thereto and intended for use thereon, to at least eighty per cent of the insurable value thereof. The loss, if any, is to be made adjustable with and payable to the Owner as Trustee for whom it may concern.

"All policies shall be open to inspection by the Contractor. If the Owner fails to show them on request, or if he fails to effect or maintain insurance as above, the Contractor may insure his own interest and charge the cost thereof to the Owner. If the Contractor is damaged by failure of the Owner to maintain such insurance, he may recover as stipulated in the contract for recovery of damages.

"If required in writing by any party in interest, the Owner as Trustee shall, upon the occurrence of loss, give bond for the proper performance of his duties. He shall deposit any money received from insurance in an account separate from all his other funds and he shall distribute it in accordance with such agreement as the parties in interest may reach, or under an award of arbitrators appointed, one by the Owner, another by joint action of the other parties in interest, all other procedure being as provided elsewhere in the contract for Arbitration. If after loss no special agreement is made, replacement of injured work shall be ordered and executed as provided for changes in the work.

"The Trustee shall have power to adjust and settle any loss with the insurers unless one of the Contractors interested shall object in writing within three working days of the occurrence of loss, and thereupon arbitrators shall be chosen as above. The Trustee shall in that case make settlement with the insurers in accordance with the directions of such arbitrators, who shall also, if distribution by arbitration is required, direct such distribution.

"**Art. 30. Guaranty Bonds.**—The Owner shall have the right, prior to the signing of the Contract, to require the Contractor to furnish bond covering the faithful performance of the Contract and the payment of all obligations arising thereunder, in such form as the Owner may prescribe and with such sureties as he may approve. If such bond is required by instructions given previous to the submission of bids, the premium shall be paid by the Contractor; if subsequent thereto, it shall be paid by the Owner."

It is customary to require the deposit of a certified check, payable to the owner, by each bidder to ensure that the contract if awarded to a bidder will be signed by him, and also to ensure that a satisfactory bond is submitted by a surety company covering the completion of the contract. A bond by freeholders, i.e., individual holders of real estate, is not usually acceptable except on small contracts awarded to local bidders. Even then a bond supplied by material dealers may not be desirable.

"**Art. 31. Damages.**—If either party to this Contract should suffer damage in any manner because of any wrongful act or neglect of the other party of or anyone employed by him, then he shall be reimbursed by the other party for such damage.

"Claims under this clause shall be made in writing to the party liable within a reasonable time at the first observance of such damage and not later than the time of final payment, except as expressly stipulated otherwise in the case of faulty work or materials, and shall be adjusted by agreement or arbitration.

"**Art. 32. Liens.**—Neither the final payment nor any part of the retained percentage shall become due until the Contractor, if required, shall deliver to the Owner a complete release of all liens arising out of this Contract, or receipts in full in lieu thereof and, if required in either case, an affidavit that so far as he has knowledge or information the releases and receipts include all the labor and material for which a lien could be filed; but the Contractor may, if any subcontractor refuses to furnish a release or receipt in full, furnish a bond satisfactory to the Owner, to indemnify him against any lien. If any lien remain unsatisfied after all payments are made, the Contractor shall refund to the Owner all moneys that the latter may be compelled to pay in discharging such a lien, including all costs and a reasonable attorney's fee.

"**Art. 33. Assignment.**—Neither party to the Contract shall assign the Contract or sublet it as a whole without the written consent of the other, nor shall the Contractor assign any moneys due or to become due to him hereunder, without the previous written consent of the Owner.

"**Art. 34. Mutual Responsibility of Contractors.**—Should the Contractor cause damage to any other contractor on the work the Contractor agrees, upon due notice, to settle with such contractor by agreement or arbitration, if he will so settle. If such other contractor sues the Owner on account of any damage alleged to have been so sustained, the Owner shall notify the Contractor, who shall defend such proceedings at the Owner's expense and, if any judgment against the Owner arise therefrom, the Contractor shall pay or satisfy it and pay all costs incurred by the Owner.

"**Art. 35. Separate Contracts.**—The Owner reserves the right to let other contracts in connection with this work. The Contractor shall afford other contractors reasonable opportunity for the introduction and storage of their materials and the execution of their work, and shall properly connect and coordinate his work with theirs.

"If any part of the Contractor's work depends for proper execution or results upon the work of any other contractor, the Contractor shall inspect and promptly report to the Architect any defects in such work that render it unsuitable for such proper execution and results. His failure so to inspect and report shall constitute an acceptance of the other contractor's work as fit and proper for the reception of his work, except as to defects which may develop in the other contractor's work after the execution of his work.

"To insure the proper execution of his subsequent work the Contractor shall measure work already in place and shall at once report to the Architect any discrepancy between the executed work and the drawings.

"**Art. 36. Subcontracts.**—The Contractor shall, as soon as practicable after the signature of the contract, notify the Architect in writing of the names of subcontractors proposed for the principal parts of the work and for such others as the Architect may direct and shall not employ any that the Architect may within a reasonable time object to as incompetent or unfit.

"If the Contractor has submitted before signing the contract a list of subcontractors and the change of any name on such list is required in writing by the Owner after signature of agreement, the contract price shall be increased or diminished by the difference in cost occasioned by such change.

"The Architect shall, on request, furnish to any subcontractor, wherever practicable, evidence of the amounts certified on his account.

"The Contractor agrees that he is as fully responsible to the Owner for the acts and omissions of his subcontractors and of persons either directly or indirectly employed by them, as he is for the acts and omissions of persons directly employed by him.

"Nothing contained in the contract documents shall create any contractual relation between any subcontractor and the Owner.

"**Art. 37. Relations of Contractor and Subcontractor.**—The Contractor agrees to bind every Subcontractor and every Subcontractor agrees to be bound by the terms of the Agreement, the General Conditions, the Drawings and Specifications as far as applicable to his work, including the following provisions of this article, unless specifically noted to the contrary in a subcontract approved in writing as adequate by the Owner or Architect.

"This does not apply to minor subcontracts.

"The Subcontractor agrees—

"(a) To be bound to the Contractor by the terms of the Agreement, General Conditions, Drawings and Specifications, and to assume toward him all the obligations and responsibilities that he, by those documents, assumes toward the Owner.

"(b) To submit to the Contractor applications for payment in such reasonable time as to enable the Contractor to apply for payment under Article 24 of the General Conditions.

"(c) To make all claims for extras, for extensions of time and for damages for delays or otherwise, to the Contractor in the manner provided in the General Conditions for like claims by the Contractor upon the Owner, except that the time for making claims for extra cost is one week.

"The Contractor agrees—

"(d) To be bound to the Subcontractor by all the obligations that the Owner assumes to the Contractor under the Agreement, General Conditions, Drawings and Specifications, and by all the provisions thereof affording remedies and redress to the Contractor from the Owner.

"(e) To pay the Subcontractor, upon the issuance of certificates, if issued under the schedule of values described in Article 24 of the General Conditions, the amount allowed to the Contractor on account of the Subcontractor's work to the extend of the Subcontractor's interest therein.

"(f) To pay the Subcontractor, upon the issuance of certificates, if issued otherwise than as in (e), so that at all times his total payments shall be as large in proportion to the value of the work done by him as the total amount certified to the Contractor is to the value of the work done by him.

"(g) To pay the Subcontractor to such extent as may be provided by the Contract Documents or the subcontract, if either of these provides for earlier or larger payments than the above.

"(h) To pay the Subcontractor on demand for his work or materials as far as executed and fixed in place, less the retained percentage, at the time the certificate should issue, even though the Architect fails to issue it for any cause not the fault of the Subcontractor.

"(j) To pay the Subcontractor a just share of any fire insurance money received by him, the Contractor, under Article 29 of the General Conditions.

"(k) To make no demand for liquidated damages or penalty for delay in any sum in excess of such amount as may be specifically named in the subcontract.

"(l) That no claim for services rendered or materials furnished by the Contractor to the Subcontractor shall be valid unless written notice thereof is given by the Contractor to the Subcontractor during the first ten days of the calendar month following that in which the claim originated.

"(m) To give the Subcontractor an opportunity to be present and to submit evidence in any arbitration involving his rights.

"(n) To name as arbitrator under arbitration proceedings as provided in the General Conditions the person nominated by the Subcontractor, if the sole cause of dispute is the work, materials, rights or responsibilities of the Subcontractor; or, if of the Subcontractor and any other subcontractor jointly, to name as such arbitrator the person upon whom they agree.

"The Contractor and the Subcontractor agree that—

"(o) In the matter of arbitration, their rights and obligations and all procedure shall be analogous to those set forth in this contract.

"Nothing in this article shall create any obligation on the part of the Owner to pay to or to see to the payment of any sums to any Subcontractor.

"**Art. 38. Architect's Status.**—The Architect shall have general supervision and direction of the work. He is the agent of the Owner only to the extent provided in the Contract Documents and when in special instances he is authorized by the Owner so to act, and in such instances he shall, upon request, show the Contractor written authority. He has authority to stop the work whenever such stoppage may be necessary to insure the proper execution of the Contract.

"As the Architect is, in the first instance, the interpreter of the conditions of the Contract and the judge of its performance, he shall side neither with the Owner nor with the Contractor, but shall use his powers under the contract to enforce its faithful performance by both.

"In case of the termination of the employment of the Architect, the Owner shall appoint a capable and reputable Architect, whose status under the contract shall be that of the former Architect.

"**Art. 39. Architect's Decisions.**—The Architect shall, within a reasonable time, make decisions on all claims of the Owner or Contractor and on all other matters relating to the execution and progress of the work or the interpretation of the Contract Documents.

"The Architect's decisions in matters relating to artistic effect, shall be final, if within the terms of the Contract Documents.

"Except as above or as otherwise expressly provided in the Contract Documents, all the Architect's decisions are subject to arbitration.

"**Art. 40. Arbitration.**—All questions subject to arbitration under this Contract shall be submitted to arbitration at the choice of either party to the dispute.

"The Contractor shall not cause a delay of the work during any arbitration proceedings, except by agreement with the Owner.

"The demand for arbitration shall be filed in writing with the Architect, in the case of an appeal from his decision, within ten days of its receipt and in any other case within a reasonable time after cause thereof and in no case later than the time of final payment, except as otherwise expressly stipulated in the Contract. If the Architect fails to make a decision within a reasonable time, an appeal to arbitration may be taken as if his decision had been rendered against the party appealing.

"No one shall be nominated or act as an arbitrator who is in any way financially interested in this Contract or in the business affairs of either the Owner, Contractor or Architect.

"Unless otherwise provided by controlling statutes, the parties may agree upon one arbitrator; otherwise there shall be three, one named in writing, by each party to this Contract, to the other party and to the Architect and the third chosen by these two arbitrators, or if they fail to select a third within fifteen days, then he shall be chosen by the presiding officer of the Bar Association nearest to the location of the work. Should the party demanding arbitration fail to name an arbitrator within ten days of his demand, his right to arbitration shall lapse. Should the other party fail to choose an arbitrator within said ten days, then such presiding officer shall appoint such arbitrator. Should either party refuse or neglect to supply the arbitrators with any papers or information demanded in writing, the arbitrators are empowered by both parties to proceed ex parte.

"If there be one arbitrator his decision shall be binding; if three the decision of any two shall be binding. Such decision shall be a condition precedent to any right of legal action, and wherever permitted by law it may be filed in Court to carry it into effect.

"The arbitrators, if they deem that the case demands it, are authorized to award to the party whose contention is sustained such sums as they shall deem proper for the time, expense and trouble incident to the appeal and, if the appeal was taken without reasonable cause, damages for delay. The arbitrators shall fix their own compensation, unless otherwise provided by agreement, and shall assess the costs and charges of the arbitration upon either or both parties.

"The award of the arbitrators shall be in writing and it shall not be open to objection on account of the form of the proceeding or the award, unless otherwise provided by the controlling statutes.

"In the event of such statutes providing on any matter covered by this article otherwise than as hereinbefore specified, the method of procedure throughout and the legal effect of the award shall be wholly in accordance with the said statutes, it being intended hereby to lay down a principle of action to be followed, leaving its local application to be adapted to the legal requirements of the jurisdiction having authority over the arbitration."

Arbitration is increasingly recognized as a quicker way of settling disputes than resort to court action. It is also cheaper and as just. It should apply to all disagreements such as those which may arise under Arts. 15 and 17.

New York, in 1920, was the first state to recognize arbitration and " made agreements to arbitrate irrevocable. New Jersey, Pennsylvania, Massachusetts, California, Oregon, Louisiana, Connecticut, New Hampshire, Rhode Island, and Arizona have similar laws while all the other states have passed arbitration laws of one kind or another." The American Arbitration Association, organized in 1926 by Chief Justice Hughes and others, was designed to speed justice and reduce the cost of litigation. See *Harper's Magazine*, December, 1931.

It is generally accepted that the engineer should have power " to reject or condemn any work or material which does not conform to the contract."

The clause formerly specifying that " the decision of the chief engineer shall be final " is less frequently used.

"**Art. 41. Cash Allowances.**—The Contractor shall include in the contract sum all allowances named in the Contract Documents and shall cause the work so covered to be done by such contractors and for such sums as the Architect may direct, the contract sum being adjusted in conformity therewith. The Contractor declares that the contract sum includes such sums for expenses and profit on account of cash allowances as he deems proper. No demand for expenses or profit other than those included in the contract sum shall be allowed. The Contractor shall not be required to employ for any such work persons against whom he has a reasonable objection.

"**Art. 42. Use of Premises.**—The Contractor shall confine his apparatus, the storage of materials and the operations of his workmen to limits indicated by law, ordinances, permits or directions of the Architect and shall not unreasonably encumber the premises with his materials.

"The Contractor shall not load or permit any part of the structure to be loaded with a weight that will endanger its safety.

"The Contractor shall enforce the Architect's instructions regarding signs, advertisements, fires and smoking.

"**Art. 43. Cutting, Patching and Digging.**—The Contractor shall do all cutting, fitting or patching of his work that may be required to make its several parts come together properly and fit it to receive or be received by work of other contractors shown upon, or reasonably implied by, the Drawings and Specifications for the completed structure, and he shall make good after them as the Architect may direct.

"Any cost caused by defective or ill-timed work shall be borne by the party responsible therefor.

"The Contractor shall not endanger any work by cutting, digging or otherwise, and shall not cut or alter the work of any other contractor save with the consent of the Architect.

"**Art. 44. Cleaning Up.**—The Contractor shall at all times keep the premises free from accumulations of waste material or rubbish caused by his employees or work, and at the completion of the work he shall remove all his rubbish from and about the building and all his tools, scaffolding and surplus materials and shall leave his work 'broom clean' or its equivalent, unless more exactly specified. In case of dispute the Owner may remove the rubbish and charge the cost to the several contractors as the Architect shall determine to be just."

ADDITIONAL CLAUSES which should be given consideration if the character of the work to be done suggests their fitness:

Contractor's Understanding.—The Contractor agrees that he by careful examination satisfied himself as to the nature and location of the work, the conformation of the ground, the character, quality, and quantity of the materials to be excavated and moved, and the conditions affecting all the work to be done, and that his conclusion to execute this contract is based on such investigation, and not on the estimates of the quantities or other information supplied by the Engineer, and that the Contractor will make no claim against the Owner because of any estimates, tests, borings, or representations of any kind affecting the work to be done which have been or may be made by any agent of the Owner and which may prove to be in error.

Rejected Material.—" Any materials condemned or rejected by the Engineer as not conforming to the specifications may be (so) branded or otherwise marked, and shall, on demand, be at once removed by the Contractor (at his expense) to a satisfactory distance from the work."

Report Errors and Discrepancies.—" If the Contractor, in the course of the work, finds any discrepancy between the plans (specifications) and the physical conditions of the locality, or any errors on plans or in the layout as given by said points and instructions, it shall be his duty to immediately inform the Engineer, in writing, and the Engineer shall promptly verify the same. Any work done after such discovery shall be done at the Contractor's risk."

If the Engineer's decision concerning the responsibility for the error and the cost of correction, if any, is refused by the Contractor, the question at issue shall be referred to the Board of Arbitration.

"**Indemnity.**—The Contractor shall indemnify and save harmless the Company from and against all losses and all claims, demands, payments, suits, actions, recoveries, and judgments of every nature and description brought or recovered against it, by reason of any act or omission of the said Contractor, his agents, or employees, in the execution of the work or in consequence of any negligence or carelessness in guarding the same.*

"**Liens.**—If at any time there shall be evidence of any lien or claim for which the Company might become liable and which is chargeable to the Contractor, the Company shall have the right to retain out of any payment then due or thereafter to become due, an amount sufficient to completely indemnify the Company against such lien or claim, and if such lien or claim be valid, the Company may pay and discharge the same, and deduct the amount so paid from any moneys which may be or become due and payable to the Contractor."†

Legal Restrictions.—Specifications should contain clauses calling the attention of the contractor to, or quoting, statutes which may require citizenship to be established, restrict hours of labor, or stipulate minimum wage rates.

Unforeseen Difficulties.—The justice of such clauses should be carefully studied as any attempt to make the contractor responsible for the damage resulting from so-called " Acts of God " will defeat itself—and should. Ordinary risks are covered by the article entitled " Contractor's Understanding." The following may be inserted if it makes clearer the legitimate risks which the Contractor assumes. "All loss or damages arising out of the nature of the work to be done under this contract on account of unforeseen obstructions or difficulties, from the action of the elements, from strikes, lockouts, or from incumbrances on the work, shall be at the expense of the Contractor."

---

* Business Law for Engineers, by Allen, 1929, pp. 16–38.

† Ibid., pp. 16–40.

Intoxicating Liquors Prohibited.—" The Contractor, in so far as his authority extends, shall not permit the sale, distribution or use of intoxicating liquors upon or adjacent to the work, or allow any such to be brought upon, to or near the property of the Company."

Note. Neither the above contract nor any other form should be used without examining each clause to see if it is pertinent and adequate.

In order to ensure the completeness of the specifications, especially on complicated or unusual jobs, additional or substitute clauses should be examined as they are presented in

Business Law for Engineers, by C. F. Allen, published by McGraw-Hill Book Company, New York.

Elements of Specification Writing, by R. S. Kirby, published by John Wiley & Sons, New York.

Specification details can best be studied from office copies which represent good practice. All construction firms have files of specifications designed to meet general and particular cases.

Advertisement of contract, 13–13 to 13–15
Aerodynamics, 4–02, 6–05
  airfoils, characteristics of, 6–42
  coefficients of, 6–42
  ideal-fluid theory in, 6–24 to 6–26
  of viscous incompressible fluids, 6–41 to 6–44
    applications of, 6–44 to 6–48
Aeronautical symbols, 1–04 to 1–11

- **Aerostatics,** 6–05, 6–11 to 6–12
- **Agency** (contracts), 13–07
- **Agent** (contracts), 13–07
- **Aggregate** (concrete), 12–04 to 12–06
- **Aggregation,** symbols of, 1–02
- **Agreement** (contracts), 13–03, 13–04
  - contract discharged by, 13–06
  - form of, 13–16, 13–17
- **Air,** columns, vibration of, 9–44
  - compressibility of, 6–10
  - compression system, refrigeration, 7–82 to 7–84
  - conditioning, 7–94, 7–95
    - abbreviations, 7–85, 7–86
    - equipment, 7–94
    - examples, 7–95
    - symbols, 7–85, 7–86
  - constituents of, 10–25
  - density of, 6–06
  - furnace melting, 11–16
  - index of refraction of, 9–15
  - injection (Diesel engine), 7–76
  - insulating properties of, 12–74
  - magneto-optic rotation of, 9–18
  - preheaters 7–71
  - properties of, 1–121, 7–16, 10–24
  - purity of, 7–94
  - resistance of automobiles, 9–69
  - resistance of trains, 9–69
  - -slaked lime, 12–12
  - spaces, conductivity of, 12–37
    - thermal conductances of, 12–33
  - specific heat of, 7–17
  - standard analyses of, 7–74
  - velocity of sound in, 9–37
  - viscosity of, 6–08
  - weight of, 10–11
- **Aircraft,** gas-filled, lift of, 6–12
- **Airfoils,** characteristics of, 6–41 to 6–43
  - combinations, 6–26
  - lift of, in two-dimensional flow, 6–24
  - moment of, in two-dimensional flow, 6–24
  - plan forms of, 6–41
  - in three-dimensional flow, 6–24
- **Airless injection** (Diesel engine), 7–76
- **Airplanes,** fixed pitch propeller, 6–45
  - in flight, loads on, 6–47
  - performance of, 6–47
  - propellers, full-scale tests on, 6–41
    - velocity increase due to, 6–23
  - testing models of, 6–52
  - variable pitch propellers, 6–45
- **Alaska cedar,** allowable unit stress, 5–29, 5–31
  - properties of, 12–44
- **Alclad products,** 11–65
- **Alcohol,** composition of, 10–11
  - compressibility of, 6–10
  - density of, 1–123, 6–06
  - molecular weight of, 10–11
  - properties of, 1–123
  - specific gravity of, 10–11
  - surface tension of, 6–09
  - viscosity of, 1–123, 6–07
- **Aldehyde,** properties of, 1–123
- **Alder,** red, properties of, 12–44
- **Algebra,** 2–06 to 2–22
- **Alignment charts,** 2–116 to 2–122
  - definitions, 2–116
  - functions of four variables, 2–120 to 2–122
  - functions of three variables, 2–117 to 2–120
  - use of, 2–116
- **Alkali** earth metals, 10–14, 10–15
  - metals, 10–12 to 10–14
- **Alkyd,** 12–54
- **Allotropic modifications (metals),** 11–05
- **Allowable** safe loads, cast-iron columns, 5–46, 5–47
  - unit stresses, 5–10
    - reinforced concrete under static loads, 5–62
    - riveted joints, 5–58
    - structural steel, 5–24
    - timber, 5–29, 5–31
- **Alloy,** *see* name of alloy in question
- **Alloys,** conductivity of, 8–66
  - definition of, 11–03
  - and metals, general properties of, 11–02 to 11–05
- **Allyl alcohol,** properties of, 1–123
- **Alpha**-particles, 9–04
  - -rays, 9–05, 10–06
- **Alternating** current, 8–12
  - -current circuits, 8–45 to 8–57
    - current and voltage relationships, 8–50 to 8–53
    - definitions, general, 8–45 to 8–47
    - non-sinusoidal currents and voltages, 8–49, 8–50
    - sinusoidal currents and voltages, 8–47 to 8–49
    - steady-state solution, 8–53 to 8–57
  - quantity (electricity), 8–45
- **Alum,** 10–19
  - ammonium, properties of, 10–11
  - potassium, properties of, 10–11
- **Alumina,** properties of, 10–11
- **-Alumina,** high, brick, 12–20
  - properties of, 12–20, 12–22 to 12–25
  - uses of, 12–28 to 12–31
- **Aluminum,** 10–19, 11–58 to 11–60
  - alloys, 11–60 to 11–70
    - castings, 11–60 to 11–64
      - properties at elevated temperatures, 11–63, 11–64
    - design stresses for, 11–68
    - die-casting, 11–62, 11–63
    - effect of cold working, 11–65, 11–66
    - effect of heat treatment, 11–66
    - fabrication of, 11–69
    - permanent mold castings, 11–62, 11–63
    - sand-cast, 11–60 to 11–63
    - specific gravity of, 11–67, 11–68
    - structural uses of, 11–70
    - weight of, 11–67
    - wrought, 11–64 to 11–70
      - composition of, 11–65
      - mechanical properties of, 11–67, 11–68
      - temper designation of, 11–64
  - bronze, properties of, 11–41, 11–48
    - properties under repeated stress, 5–15
  - castings, 11–60 to 11–64
  - -chromium-iron, properties of, 11–99
  - conductors, 11–96 to 11–98
  - and copper wires, comparison, 11–97
  - corrosion-resistant characteristics of, 11–59
  - effects of cold working on, 11–65
  - electric conductivity of, 11–96, 11–97
  - electrode potentials, values of, 10–37
  - fabrication of, 11–69
  - foil, 11–65
    - with air spaces, thermal conductivity, 12–37
  - hydroxide, 10–19
  - non-aqueous solutions, 10–39
  - optical constants 9–16
  - oxide, 10–19
  - paint, 12–52
  - permanent mold castings, 11–62, 11–63
  - plate, weight of, 1–150

- **Aluminum,** pressure die castings, 11–62, 11–63
  - properties of, 1–125, 1–127, 11–59
    - under repeated stress, 5–14
  - relation of cold working to temper, 11–66
  - resistivity, temperature coefficient of, 11–97
  - sand-castings, 11–60 to 11–63
  - sheet, weight of, 1–150
  - soldering of, 11–69
  - structural sections, 1–153
  - sulfate, 10–19
  - surface, thermal conductivity, 12–37
  - welding of, 11–69
  - wire tables, 11–96, 11–98
- **Amalgam (mercury),** 10–17
- **Ambrac (alloy),** properties of, 11–43, 11–48
- **American** Elm, allowable unit stresses, 5–29, 5–31
    - properties of, 12–45
  - standard steel beam, properties of, 1–157
    - channels, properties of, 1–158
  - wire gage, 1–150 to 1–152
- **Ammonia,** 10–26
  - density of, 6–07
  - properties of, 1–121, 7–16, 7–82, 10–11, 10–24
  - viscosity of, 6–08
  - weight of, 10–11
- **Ammonium** chloride, properties of, 10–11
  - nitrate, properties of, 10–11
  - sulfate, properties of, 10–11
- **Amortization fund,** 2–29
- **Ampere,** 3–33
  - international, 3–34
- **Ampere's law,** 3–20
- **Ampere-turn,** international, 3–34
- **Ampere-turns,** 8–22
- **Amplitude** resonance, 8–57
  - simple harmonic motion, 4–29
  - sinusoidal current, 8–47
- **Amsler testing machine,** 5–82
- **Amyl alcohol,** properties of, 1–123
  - specific optical rotation, 9–18
- **Analysis** of colors, 9–28
  - determination of chemical formula from, 10–10
  - dimensional, 3–36 to 3–45
  - harmonic, 8–49
  - of materials by x-rays, 9–25
  - qualitative, preliminary examination, 10–31 to 10–33
    - systematic, of the metals, 10–33 to 10–36
  - truss, 4–14, 4–15
  - vector, 2–112 to 2–116
    - symbols for, 1–02
- **Analytic** geometry, plane, 2–61 to 2–70
  - solid, 2–70 to 2–75
  - symbols for, 1–02
- **Anemometers,** 9–64 to 9–66
- **Angle** between two lines, 2–63, 2–71
  - complex, functions of, 2–60, 2–61
  - degree, minutes, radians, conversion of, 1–54
  - dihedral, 2–34
  - of friction (axle), 4–45
  - geometrical construction of, 2–45, 2–46
  - hyperbolic, 2–58
    - functions, table of, 1–102 to 1–112
  - imaginary, functions of, 2–60, 2–61
  - kinetic friction, 4–44
  - measurement of, 2–34
  - non-planar, 2–34, 2–35
  - phase, 4–29
  - plane, 2–32
    - circular functions of, 2–53 to 2–56
      - table of, 1–57 to 1–101
    - units of, conversion of, 1–134
- **Angle,** polygonal, table of, 2–50
  - polyhedral, 2–34
  - power-factor, 8–48
  - solid, 2–34, 2–116
    - units of, conversion of, 1–134
  - spherical, 2–35
  - stalling, 6–43
  - static friction, 4–44
  - steel, equal legs, properties of, 1–159, 1–160
    - unequal legs, properties of, 1–161, 1–162
  - trigonometric functions, tables of, 1–57 to 1–101
  - trim, 6–49
  - of twist, 5–49 to 5–51
  - vectorial, 2–70
- **Angular** acceleration, 4–32
    - units of, conversion of, 1–136
  - degrees, minutes, radians, conversion of, 1–54
  - displacement, 4–32
  - impulse, 4–36
  - momentum, 4–36
  - velocity, 4–32
    - alternating current, 8–45
    - and rectangular velocity, relation between, 4–32
    - units of, conversion factor, 1–136
- **Aniline,** properties, 1–123
- **Annealing,** steel, 11–33
- **Annuities** and sinking funds, 2–26 to 2–32
- **Annuity,** amount of 1 per annum, 2–27
  - life, 2–30
    - present value of, 2–32
  - present value of 1 per annum, 2–28
  - which 1 will purchase, 2–28, 2–29
  - which will amount to 1 (sinking fund), 2–30
- **Annulus,** mensuration formulas, 2–39
  - properties of, 4–22
- **Anode,** nickel, 11–71
- **Anodizing,** 11–10
- **Anthracite coal,** 12–77
- **Anti**-hyperbolic functions, 2–60
  - -trigonometric functions, 2–55, 2–56
- **Antimony,** 10–27
  - electrode potentials, values of, 10–37
  - properties, 1–125, 1–127
  - trioxide, 10–27
  - trisulfide, 10–27
- **Apjohn's** equation, 7–93
- **Apothecaries'** fluid measure, 1–133
  - weight, 1–138
- **Apparent power,** 8–47
- **Appliances** (contracts), 13–19
- **Aqua regia,** 10–18
- **Aqueous solutions (electrochemistry),** 10–36 to 10–39
- **Arabic numbers,** numeration of, 2–02
- **Arbitration** (contracts), 13–26
- **Arc,** 2–33
  - circular, mensuration formulas, 2–38
    - properties of, 4–20
    - table of, 1–28, 1–29
  - of a curve, length of, 2–96
  - electric, 9–31
  - furnace, 10–39
  - welding electrodes, 11–90, 11–91
- **Archimedes'** law, 6–13
  - spiral of, 2–69
    - mensuration formulas, 2–40
- **Architect's** decisions, 13–26
  - measure, 1–131
  - status, 13–25
- **Architectural acoustics,** 9–50 to 9–53
- **Area** of circles, table of, 1–12 to 1–28
  - of contact, two surfaces, 5–57

Area of curved surface, 2–94
  effective, reinforced-concrete column, 5–73
  expressed as a line integral, 2–93
  metric multiples, 1–131
  plane, 2–97
  reduction of, in tensile test, 5–07
    bronze bearing alloys, 11–87
    copper-base alloys, 11–41 to 11–43
    copper-nickel alloys, 11–72
    determination of, 5–88
    iron, 11–20, 11–25
    metals, 1–127
    molybdenum, 11–81
    Monel metal, 11–73, 11–74
    nickel, 11–71
    stainless steel, 11–38
    steel, 11–25
    structural alloy steel, 11–36
  of similar figures, 2–36
  steel bars, 1–164
  steel pipe, 1–165
  steel sections, 1–153 to 1–163
  of a surface of revolution, 2–97
  units of, conversion of, 1–131
  yard lumber, 1–167, 1–168
Argon, properties, 1–121
Arithmetic, 2–02 to 2–06
  mean, 2–20, 2–126
  progression, 2–20
Arm of a couple, 4–07
Armco ingot iron, 11–21
  properties of, 11–25
    under repeated stress, 5–13
Arsenic, 10–27
  acid, 10–27
  properties of, 1–125, 1–127
  sulfide, 10–27
Arsenious acid, 10–27
  oxide, 10–27
    properties, 10–11
  sulfide, 10–27
Arsine, properties, 1–121
Articulation, 9–49
Asbestos, 12–59
  boards, thermal conductivity of, 12–36
  cloth, dielectric strength of, 12–64
  paper, 12–62
    dielectric strength of, 12–64
    electrical properties of, 12–60
  tape, dielectric strength of, 12–64
Ash (wood), 12–39
  allowable unit stresses, 5–29, 5–31
  properties of, 12–44
Aspen, allowable unit stresses, 5–29, 5–31
  properties of, 12–44
Asphaltic gums, 12–70
  varnishes, 12–71
Asphalts, 12–70
  electrical properties, 12–60
Aston process, 11–20
Astroid, 2–68
Astronomical refracting telescope, 9–14
Astrophysical dimension system, 3–06
Asymptotes, 2–52, 2–65
Atmosphere, density of, 7–93
  isothermal, 6–12
  normal, 3–25
  partial pressure of vapor in, 7–93
  polytropic, 6–12
  practical, 3–25
Atmospheric corrosion of zinc, 11–53
    protection from, 11–08 to 11–10
  pressure, standard, 3–25
  regions, 6–12
Atom, 10–02
  Bohr's model, of, 9–06
Atomic disintegration, 10–06
  forces, 10–05
  number, chemical elements, 10–02, 10–03
  weight, chemical elements, 10–02, 10–03
    metals, 1–125, 1–126
Austenite, 11–27
Austenitic cast iron, 11–19
Automobiles, air resistance of, 9–69
  ground effect on, 6–53
Automotive oils, 12–76
Availability of energy, 7–08
Average value (alternating current), 8–46
Avialite, properties, 11–48
Avoirdupois, weight, 1–137
Axes, instantaneous, 4–33
  parallel, theorems, 4–18, 4–19
  principal, of inertia of a body, 4–19
    of a plane surface, 4–17
  rotated, theorem, 4–18, 4–19
Axial impact on bars, 5–17
Axially end-loaded beams, 5–35, 5–36
Axle friction, 4–45

Babbitt metals, 11–85, 11–86
Bakelite, 12–68
  electrical properties of, 12–60
Ballistic pendulum, 4–37
Balmer series, 9–20
Balsa (wood), 12–39
  thermal conductivity of, 12–37
Balsam fir, allowable unit stresses, 5–29, 5–31
  properties of, 12–45
Bar (unit of pressure), 3–25
Barium, 10–15
  carbonate, 10–15
    properties of, 10–11
  properties of, 1–125
  sulfate, 10–15
    properties of, 10–11
  sulfide, 10–15
Barkhausen effect, 8–19
Barometer height, mean, 9–61
  indications, 9–56
Barometric observations, 9–60, 9–61
Bars, reinforcement, *see* reinforcement
  steel, size and weight of, 1–164
Barye, 3–25
Basalt, strength, 12–15
Bases, 10–06
  diacid, 10–07
  properties of, 10–11
  triacid, 10–07
Basic Bessemer steel, 11–23
  open-hearth steel, 11–23
    uses of, 11–33
  pig iron, 11–15
    analysis of, 11–13
Basswood, allowable unit stresses, 5–29, 5–31
  plywood, 12–49
  properties of, 12–44
Batteries, electric storage, 10–37 to 10–39
Bead tests (chemistry), 10–32
Beams, 5–19 to 5–36
  axially end loaded, 5–35, 5–36
  bending moment of, 5–20, 5–21, 5–26 to 5–28
  cantilever, 5–19
    example, 5–23
  constrained, 5–19
  continuous, 5–19, 5–33, 5–35
  curved, 5–33, 5–34
  dangerous section of, 5–21

Beams, deflection of, 5-26 to 5-28
    due to shear, 5-23
  design of, use of tables, 5-30
  elastic curve of, 5-19
    deflection of, 5-22, 5-23
  fixed, 5-19
  flexure formula, 5-21
    theory, 5-19 to 5-23
  horizontal shear, 5-21
    in timber, 5-25
  impact on, 5-18
  lateral deflection, 5-25
  moment diagram of, 5-21, 5-26 to 5-28
  neutral axis, 5-19
    surface, 5-19
  reactions at supports of, 5-19
  rectangular, reinforced concrete, 5-63 to 5-68
    of uniform strength, 5-32
  reinforced concrete, 5-62 to 5-72
    anchorage of reinforcement, 5-66
    bending moments, 5-66, 5-67
    bond, 5-66
    external shears, 5-66, 5-67
    flexure formulas, 5-63 to 5-65
    shearing stress, 5-65
    web reinforcement, 5-65
  resisting moment, 5-20, 5-21
    shear, 5-20
  restrained, 5-19, 5-25
  sections of, properties of, 5-22
  shear diagrams of, 5-26 to 5-28
  simple, 5-19
    safe loads on, 5-28
  steel, American standard, properties of, 1-157
  -T, reinforced concrete, 5-64, 5-65, 5-69 to 5-71
  timber, example, 5-30, 5-36
    horizontal shear in, 5-25
  types of, 5-19
  of uniform cross-section, 5-23 to 5-31
    design, procedure, 5-23
  of uniform strength, 5-32
  vertical deflection, 5-24
  vertical shear of, 5-20, 5-26 to 5-28
  web, buckling of, 5-25
    shear, 5-23
Bearing metals, properties and uses of, 11-84 to 11-89
  stress, allowable unit, aluminum alloys, 11-68
    riveted joints, 5-58
    structural steel, 5-24
Beats, 9-48
Beaufort scale (windspeed), 9-59
Beech, allowable unit stress, 5-29, 5-31
  properties of, 12-44
Beeswax, 12-69
Bell metal, properties of, 11-42
Belt friction, 4-47
Bend, cold, concrete reinforcement bars, 5-61
  test, wrought copper-base alloys, 11-45 to 11-51
Bending, allowable unit stresses for timber in, 5-29
  impact of wood, 12-44 to 12-47
  moment, 5-20, 5-21
    of beams of uniform cross-section, 5-26 to 5-28
    in rectangular flat slabs, 5-56
    reinforced concrete, 5-66
  reversed, 5-12
  static, wood, 12-44 to 12-47
  test for determining ductility, 5-91
Benedict metal, properties of, 11-43
Benzene, density of, 6-06
  index of refraction of, 9-15
  magneto-optic rotation of, 9-18
  properties of, 1-123
  surface tension of, 6-09
  viscosity of, 6-07
Benzol, properties of, 1-123
Bernoulli's equation, 2-100, 6-19
  theorem, 6-22
Beryllium copper, 11-50
  properties, 1-125
Bessemer iron, analysis of, 11-13
  steel, 11-22
    uses of, 11-33
Beta-rays, 9-04, 10-06
Bidders, instructions to, 13-13
Bids, receiving, 13-15
Binary alloy steels, 11-34, 11-35
  -fluid cycle, 7-61
Binocular, prism, 9-14
Binomial theorem, 2-19
Biplanes, 6-26
Biquadratic equations, 2-14
Birch, allowable unit stresses, 5-29, 5-31
  plywood, 12-49
  properties of, 12-44
Birmingham wire gage, 1-151, 1-152
Bismuth, 10-27
  electrode potentials, values of, 10-37
  optical constants of, 9-16
  properties of, 1-125
  subnitrate, 10-27
Bituminous coal, 12-77
  coatings, 11-11
Black ash (wood), allowable unit stresses, 5-29, 5-31
    properties of, 12-44
  body, 9-03
    luminous efficiency and brightness of, 9-31
    radiation of, 9-22
  cherry, properties of, 12-45
  cottonwood, allowable unit stresses, 5-29, 5-31
    properties of, 12-45
  gum (wood), allowable unit stresses, 5-29 5-31
    properties of, 12-45
  -heart iron, 11-17
  locust, properties of, 12-46
  maple, allowable unit stresses, 5-29, 5-31
    properties of, 12-46
  oak, 12-40
  walnut, 12-40
    properties of, 12-47
Blast furnace, 11-14
Bleaching powder, 10-14
Blowpipe tests (chemistry), 10-32
Blue heat, 11-31
  working steel at, 11-29
Bluestone, durability of, 12-16
Board measure, 1-132
Bodies, angular acceleration of rigid, 4-32
  angular displacement of rigid, 4-32
  angular velocity of rigid, 4-32
  black, 9-03
  center of gravity of, 4-15, 4-16
  center of gyration of, 4-19
  definitions of, 4-16, 4-19
  in equilibrium, 4-11
  falling, 4-27
  magnetic, in magnetic field, forces on, 8-35
  moment of inertia of, 4-19
  motions of, 4-31, 4-32
  plane motion of rigid, 4-31

Bodies, principal axes of inertia of, 4–19
  product of inertia of, 4–19
  properties of, 4–23 to 4–26
  radius of gyration of, 4–19
  of revolution, properties, 4–23
  rotation of rigid, 4–31
  stability of completely immersed, 6–14
  three-dimensional motion of rigid, 4–31
  transformation formulas, 4–19
  translation of rigid, 4–31
Bohr's model of atoms, 9–06
Boiler energy balance, 7-63 to 7-66
Boiling point, 10–24
  gases, 1–121, 1–122, 10–24
  liquids, 1–123, 1–124
  metals, 1–125, 1–126
  substances, *see* substance in question
Bolometer, 9–23
Bolts, standard, 1–166
Bond, guaranty (contracts), 13–23
  in reinforced concrete, 5–66
  stresses, allowable unit, in reinforced concrete, 5–62
  surety (contract), 13–06
Bonderizing, 11–09
Borax, 10–30
Boric acid, 10–30
  properties of, 10–11
Boron, 10–30
Boundary, conditions (electrical networks), 8–58
  layer, Prandl theory (fluid dynamics), 6–27
Boyle's law, 7–15, 10–24
Brackett series, 9–20
Bragg's law, 9–24
Brake horsepower, 7–67
  mean effective pressure, 7–68
Branch currents (electrical networks), 8–51
Brass, 11–40, 11–55
  corrosion of, 11–52
  fabrication of, 11–40
  modulus of resilience of, 5–08
  plate, weight of, 1–150
  properties under repeated stress of, 5–14, 5–15
  roughness number of, 6–51
  sand-cast, properties of, 11–41 to 11–43
  sheet, weight of, 1–150
  toughness, relative, 5–08
  wrought, properties of 11–44 to 11–47
Brazing brass, properties of, 11–44
  materials, 11–89 to 11–92
Breach of contract, 13–06
Breakaway of flow, 6–28
Brick, 12–16 to 12–18
  absorption by, 12–18
  acid-resisting, 12–26
  building, grades of, 12–17
    standard sizes of, 12–17
    strength of, 12–18
  chrome, 12–21
  clay, 12–16 to 12–18
  digester, 12–26
  factor of safety of, 5–11
  fireclay, 12–20
  Forsterite, 12–26
  high-alumina, 12–20
  insulating refractory, 12–27
  magnesite, 12–21
  piers, tests of, 12–18
  refractory, application of, 12–28 to 12–31
    mortars for laying, 12–26
    properties of, 12–22 to 12–25
    types of, 12–20, 12–21
  sand-lime, 12–17
  silica, 12–21
Brick, silicon carbide, 12–27
  thermal conductivity of, 12–34 to 12–38
Bridled cup anemometer, 9–66
Briggs logarithms, 2–10
Brightness, 9–29
  of a color, 9–27
  luminous, of light sources, 9–31
  units of, interrelations between, 9–29
Brinell hardness, 5–89 to 5–91
  (*see also* Hardness, Brinell)
British thermal unit (Btu), 3–25, 3–28, 7–03
    relation to other units, 3–28
  wire gage, 1–151, 1–152
Brittleness, definition of, 5–07
Brodhun and Lummer photometer, 9–30
Bromine, 10–28
  index of refraction of, 9–15
  properties of, 1–123
Bronze, 11–40
  bearing alloys, 11–85, 11–88, 11–89
    composition and properties of, 11–87
    thermal expansion of, 11–89
  copper-aluminum-iron, 11–110
  corrosion of, 11–52
  fabrication of, 11–40
  modulus of resilience of, 5–08
  properties under repeated stress, 5–15
  sand-cast, properties of, 11–41, 11–42
  toughness, relative, 5–08
  wrought, properties of, 11–44 to 11–51
Brown & Sharpe gage, 1–150 to 1–152, 11–56
Brownstone, durability of, 12–16
Brushes, carbon, 11–99, 11–100
Btu, *see* British thermal unit
Buckingham, method of E. (dimensional analysis), 3–42
  example, 3–43
Buckling of web, 5–25
Building brick, grades of, 12–17
    standard sizes of, 12–17
    strength of, 12–18
  materials, thermal conductivity of, 12–34 to 12–38
    thermal resistivity of, 12–34 to 12–38
  ordinances, reinforced concrete, 5–62
Buildings, protection against lightning, 9–62
Bulk modulus (mechanics of fluid), 6–02
Bunsen photometer, 9–30
Bureau of Standards, tests of steel columns, 5–42 to 5–44
Bushel, 3–21
Business investigations, 13–12
Butane, properties of, 1–121, 7–82
Butt brass, properties of, 11–46, 11–47
  joints, riveted, 5–58
Butternut (wood), 12–39
  properties of, 12–44
Butyl alcohol, properties of, 1–123
Butyric acid, properties of, 1–123

Cable (unit of length), 1–130
Cadmium, 10–16
  electrode potentials, values of, 10–37
  electroplating with, 11–09
  properties of, 1–125, 1–127
Calcite, grating spacings of, 9–25
Calcium, 10–14, 10–15
  acetate, properties of, 10–11
  bicarbonate, 10–14
  carbide, properties of, 10–11
  carbonate, 10–15
    properties of, 10–11
  electrode potentials, values of, 10–37

Calcium, hydroxide, 10–06, 10–14
    properties of, 10–11
  hypochlorite, 10–14
  lime, 12–11
  oxide, 10–14
    properties of, 10–11
  phosphate, properties of, 10–11
  properties of, 1–125, 1–127
  sulfate, 10–14
    properties of, 10–11
Calculus, differential, 2–75 to 2–85
  Heaviside operational, 2–108 to 2–111
  integral, 2–86 to 2–99
  integrals, table of, 1–113 to 1–120
  symbols for, 1–02
Calendar, history of the, 3–23
California redwood, 12–40
  thermal conductivity of, 12–37
Caloric unit system, 3–15
Calorie, 3–28, 7–03
  gram, 3–26, 3–28
  international steam-table, 3–26
  kilo–, international, 3–26, 3–28
  Ostwald, 3–26, 3–28
Calorimeter, throttling, 7–46
Calorimetric equivalent, 3–28
Calsun bronze, properties of, 11–50
Cambric, dielectric strength of, 12–64
Canal rays, 8–06, 9–05
Candle, 9–28
  foot–, 9–29
  international, 9–28
Candlepower, 9–28, 9–29
Cantilever beam, 5–19
  diagrams, uniform cross-section, 5–26 to 5–27
    uniform strength, 5–32
  example of, 5–23
Cap gilding (alloy), properties, 11–46
Capacitance, condensers, and induction, electrostatic, 8–40 to 8–43
  dimensions, 3–08, 3–09
  units of, 3–30, 3–32, 3–33, 3–34
    conversion of, 1–145
Capacity, electric, specific inductive, of insulating materials, 12–60
      of rubber, 12–67
  thermal, 7–13
    dimensions, 3–06
    units of, 3–15, 3–28
  unit of, dry, 3–21
    electric, 3–18
    liquid, 3–21, 3–23
Capillary depression of mercury, 9–60
  rise, 6–08, 6–09
Carbides, cemented, 11–81
Carbolic acid, properties of, 1–123
Carbon, 10–30, 11–99 to 11–101, 12–77
  brushes, 11–99, 11–100
  contact material, 11–101
  dioxide, 10–30
    density of, 6–07
    dielectric strength of, 12–74
    effect on zinc, 11–53
    index of refraction of, 9–15
    insulating properties of, 12–74
    magneto-optic rotation of, 9–18
    properties of, 1–121, 7–16, 7–82, 10–24
    specific heat of, 7–17
    viscosity of, 6–08
    weight of, 10–11
  disulfide, 10–30
    properties of, 1–123, 10–11
  effect on cast iron, 11–17
Carbon, and hardness of steel, 11–32
  monoxide, density of, 6–07
    index of refraction of, 9–15
    properties of, 1–121, 7–16, 10–24
    specific heat of, 7–17
    viscosity of, 6–08
    weight of, 10–11
  oxychloride, properties of, 1–121
  oxysulfide, properties of, 1–121
  per cent of, iron and steel, 11–22, 11–25
  steel, magnetic properties of, 11–108
    uses of, 11–33, 11–34
  tetrachloride, 10–30
    compressibility of, 6–10
    density of, 6–06
    properties of, 1–123, 10–11
    surface tension of, 6–09
    viscosity of, 6–07
Carborundum, 10–30
Carburetor, 7–72
Cardioid, 2–68
Carelessness in contracts, 13–04
Carnot cycle, 7–07, 7–09, 7–53
    reversed, 7–77
  -Kelvin relation, 7–07
  principle, 7–07
  refrigeration cycle 7–77
Cartesian coordinates, 2–61
Cartridge brass, properties of, 11–44
Cast iron, 11–15 to 11–19
    alloy, 11–18
      properties, 11–25
    analyses of, 11–13
    austenitic, 11–19
    "chilling," 11–18
    column, 5–46, 5–47
    column formula constants, 5–39, 5–40
    effect of ingredients on, 11–17
    endurance ratio, 5–15
    factor of safety for, 5–11
    growth of, 11–18
    heat-treated, 11–19
    magnetic induction, 11–103
    magnetic properties, 11–102
    magnetization characteristics, 8–25
    malleable, 11–19
      properties of, 11–25
    modulus of resilience of, 5–08
    non-magnetic, 11–18
    pearlitic, 11–18
    permeability, 8–26
    properties of, 11–18, 11–25
      under repeated stress, 5–13
    shrinkage of, 11–18
    specimens for test, 5–84, 5–85, 5–86
    toughness, relative, 5–08
    use of, 11–19
  sand-, aluminum alloys, properties of, 11–61
    copper-base alloys, 11–41 to 11–43, 11–52
  steel, endurance ratio of, 5–15
    magnetic inductance of, 11–103
    magnetic properties of, 11–102
Casting alloys, permanent mold, aluminum, composition and properties of, 11–62
Castings, aluminum alloy, 11–60 to 11–64
    properties at elevated temperatures, 11–63, 11–64
  die-, alloys, *see* Die-casting alloys
  direct iron, 11–15
  slush, of zinc, 11–56
  x-ray examination of, 5–92
Castor oil, critical velocity in smooth tubes, 6–29
  properties of, 1–123
  viscosity of, 6–07

Catenary, 2–70
  mensuration formulas, 2–40
Cathode rays, 8–06
Cauchy-Riemann differential equations, 2–112
Caustic soda, electrolytic, 10–37
Cedar, 12–39
  allowable unit stresses for, 5–29, 5–31
  column formula constants, 5–41
  properties of, 12–44, 12–45
Cell, electric storage, 10–37 to 10–39
  Kerr, 9–18
Cellophane, 12–63
  electrical properties of, 12–60
Celluloid, electrical properties of, 12–60
Cellulose acetate, 12–63
    electrical properties of, 12–60
  cements, 12–80
Celsius degree, 3–27
Cement, 12–02, 12–03
  cellulose, 12–80
  high, early-strength, 12–03
  -lime mortar, 12–13
  mortar, natural, 12–13
    Portland, 12–12
    thermal conductivity of, 12–34
  natural, 12–02
  neat, 12–02
  plaster, Portland, 12–13
  Portland, 12–02
  Puzzolan, 12–03
  roughness number of, 6–51
  used in concrete, 12–04
Cemented carbides, 11–81
Cementite, 11–26
Center of gravity, 2–98, 4–15 to 4–17
    of lines, surfaces, volumes, and bodies, 4–20 to 4–26
  of gyration, 4–19
  of inertia, 4–15
  of mass, 4–15
  of percussion, 4–41
  of pressure, 2–99
Centigrade scale, international, 3–27
  thermodynamic, 3–27
Centimeter, 3–22
  -gram-second system of units, 3–14 to 3–21
  (*see also* Cgs system of units)
Centrifugal force, 4–41
Centripetal force, 4–41
Centroid, 4–15
Ceresin, electrical properties of, 12–60
Cerium, properties of, 1–125, 1–127
Cesium, 10–14
  properties of, 1–125
Cgs system, derived units in the, 3–35
    electromagnetic units, 3–16 to 3–18
    electrostatic units, 3–16 to 3–18
    rationalized electromagnetic units, 3–16, 3–17
    symmetric units, 3–16, 3–17
    thermal unit, 3–15
    of units, 3–14 to 3–21
Cgss system of units, 3–16, 3–19
Channels, circular, turbulent flow through, 7–24
  flow in open, 6–51, 6–52
  steel, American Standard, properties of, 1–158
Characteristic determinant, 8–57
  of logarithms, 2–10
Charcoal, 12–77
  pig iron, 11–14
Charge, electric, 8–09, 8–39
    of a condenser, 8–42
    density, units of, surface, 3–18
Charge, electric, dimensions of, 3–08, 3–09
    exponential, 8–52
    residual, 8–43
    surface density of, 8–39
    units of, 3–16, 3–18, 3–29, 3–31, 3–33
      conversion of, 1–142
Charles' law, 6–05, 7–15, 10–24
Charpy impact testing machine, 5–83
Charts, alignment, 2–116 to 2–122
Check (wood), 12–41
Chemical calculations, 10–10 to 10–12
  compounds, 10–03
  elements, 10–02 to 10–04
  equation, 10–04

Chemistry, Section 10
Cherry, black, properties of, 12–45
Chestnut, 12–39
  allowable unit stresses, 5–29, 5–31
  oak, 12–40
  properties of, 12–45
Chezy's formula, 6–52
Chile saltpeter, properties of, 10–11
Chilled iron, 11–17
" Chilling " cast iron, 11–18
China wood oil, 12–55
Chlorine, 10–27
  electrolytic, 10–37
  monoxide, properties of, 1–121
  properties of, 1–121, 10–24
Chloroform, properties of, 1–123
  surface tension of, 6–09
Chords, 1–28, 1–29, 2–33
Chromatic aberration, 9–12
Chrome brick, 12–21
    uses of, 12–28 to 12–31
  -molybdenum steel, 11–37
    mechanical properties of, 11–36
  -nickel steel, 11–35
    mechanical properties of, 11–36
  steel, mechanical properties of, 11–36
  -vanadium steel, 11–37
    mechanical properties of, 11–36
Chromel, properties of, 11–99
Chromic anhydride, 10–21
  oxide, 10–21
  sulfate, 10–21
Chromium, 10–20, 10–21
  acetate, 10–21
  effect on hardness of steel, 11–37
  electrode potentials, values of, 10–37
  electroplating with, 11–09
  nickel-, alloys, 11–75
  properties of, 1–125, 1–127
  steels, 11–35
    magnetic properties of, 11–108
Cinder blocks, thermal conductivity of, 12–34
  concrete, thermal conductivity of, 12–34
Circle, 2–33, 2–64
  area of, 1–12 to 1–28
  circumference of, 1–12 to 1–28
  geometrical construction of, 2–46 to 2–49
  inertia, 4–18
  involute of, 2–53, 2–69
    geometrical construction of, 2–53
  mensuration formulas, 2–38
  properties of, 4–22
Circuits, alternating-current, 8–45 to 8–57
  breaker oil, 12–71
  complicated, 8–56
  dielectric, and electrostatics, 8–35 to 8–45

- **Circuits, direct-current,** 8–09 to 8–16
  - electric, magnetic energy of, 8–30, 8–31
  - magnetic, 3–20
    - and electrokinetics, 8–18 to 8–35
    - and magnetizing force, 8–21 to 8–27
  - parameters of electric, 8–50
  - stability of 8–59 to 8–61
- **Circular arcs,** 1–28, 1–29, 2–32
    - mensuration formulas, 2–38
    - properties of, 4–20
  - flat plates, stresses and deflection of, 5–53, 5–54
  - functions of plane angles, 2–53 to 2–56
    - relation to hyperbolic function, 2–60
  - inch, 1–131
  - lamina, properties of, 4–25
  - mil, 1–131
  - sector, mensuration formulas, 2–39
    - properties of, 4–22
  - segment, mensuration formulas, 2–39
    - properties of, 4–22
- **Circumference** of circles, 1–12 to 1–28
  - of similar figures, 2–36
- **Clapeyron's equation,** 7–14

  - cross-bending loads on, 5–45
  - definitions, 5–36, 5–37
  - eccentric loads on, 5–44, 5–45
  - end conditions, 5–37
  - footings, reinforced concrete, 5–75 to 5–77
  - formulas, 5–37 to 5–40
  - length of, 5–37
  - radius of gyration of, 5–37
- **Column, reinforced concrete,** 5–72 to 5–75
    - effective area of, 5–73
    - formulas, 5–73
    - types of, 5–72
  - slenderness ratio of, 5–37
  - spiraled, reinforced-concrete, 5–73 to 5–75
  - square-tied, reinforced concrete, 5–74
  - steel, 5–40 to 5–44
    - Bureau of Standards tests of, 5–42 to 5–44
    - design of, guiding principles, 5–41
    - example, 5–42
    - formula constants, 5–39, 5–40
    - formulas, 5–41, 5–42
    - slenderness ratio, maximum values, 5–42
    - types of, 5–40
  - tied, reinforced concrete, 5–73, 5–74
  - timber, 5–40, 5–41
  - transverse loads on, 5–45, 5–46
  - wooden, 5–40, 5–41
    - formulas, 5–40
- **Combinations,** 2–21
- **Combined elementary stresses,** 5–09, 5–10
- **Combustion,** internal-, engine, 7–71 to 7–77
- **Commercial brass,** bronze, properties of, 11–44
  - elastic limit of, 5–04
  - properties of, 11–44
- **Common** logarithms, 2–10
    - of hyperbolic functions, 1–102 to 1–112
    - of numbers, 1–30 to 1–51
  - of trigonometric functions, 1–57 to 1–101
  - lumber, 12–48
- **Compensation, workmen's,** 13–08
- **Competence** of parties to a contract, 13–02
- **Complementary function,** 2–102
- **Complex** angle functions of, 2–60, 2–61
  - numbers, 2–06, 2–111
    - flows obtained by, 6–21
    - inverse functions of, 2–61
    - solutions of electrical networks, 8–54
  - variables, 2–112
- **Composite** functions, differentiation of, 2–78
  - number, 2–03
- **Composition** of concurrent forces, 4–03 to 4–05
  - of nonconcurrent forces, 4–07 to 4–10
  - percentage, by weight, 10–10
  - of substances, *see* substance in question
  - of various industrial compounds, 10–11
- **Compound,** chemical, definition, 10–03
  - discount, 2–26
  - industrial, composition, etc., of, 10–11
  - interest, 2–24
    - amount of 1, 2–24
  - lever testing machines, 5–81
  - microscope, 9–13, 9–14
- **Comprehensive unit systems,** 3–13
  - fundamental units, 3–16
  - metric, 3–15 to 3–21
  - natural, 3–19 to 3–21
  - practical, 3–19
  - theoretical, 3–16 to 3–18
- **Compressed liquid,** 7–32, 7–40
  - properties of, 7–40
  - region, 7–41
- **Compressibility, fluids,** 6–03
  - of liquids and gases, 6–09 to 6–10
- **Compression,** adiabatic, multistage, 7–31
    - single-stage, 7–30
  - axial, definition of, 5–03
  - definition of, 5–02
  - of gases in compressors, 7–30, 7–31
  - isothermal, 7–30
  - load, bronze bearing alloys, 11–87

- **Compression,** members, eccentric loads on, 5–44, 5–45
    - transverse loads on, 5–45, 5–46
  - ratio (Otto cycle), 7–74
  - and shear, combined, 5–10
  - system, air, refrigeration, 7–82 to 7–84
  - test, 5–88
    - of metals, specimens for, 5–85
  - vapor, system, 7–79 to 7–82
    - examples of, 7–81
- **Compressional wave,** 9–35
- **Compressive** strength, aluminum alloys, sand-cast, 11–61
    - brick, 12–17, 12–18
      - piers, 12–18
    - concrete, 12–06
    - magnesium alloys, 11–78
    - stone, 12–15
    - tile, 12–20
    - wood, 12–44 to 12–47
    - zinc-base die-casting alloys, 11–83
  - stress, allowable, unit, 5–10
      - due to shear, 5–09
      - reinforced concrete, 5–62
      - structural steel, 5–24
      - timber, 5–31
    - design, aluminum alloys, 11–68
- **Compressors,** gas, 7–30
- **Compton effect,** 9–08
- **Computations,** approximate, 2–05, 2–06
- **Concave spherical** lenses, 9–12
  - mirrors, 9–10
- **Concentrated loads,** beam design, example, 5–30
- **Concrete,** 12–04 to 12–11
  - aggregates, 12–04 to 12–06
  - cement used in, 12–04
  - classes for different degrees of exposure, 12–06
  - colored, 12–09
  - conveying, 12–07
  - corrosion protection by, 11–11
  - curing, 12–08
  - depositing, 12–07
  - forms for, 12–08
  - high early-strength, 12–09
  - light weight, 12–09
  - mixing, 12–07
  - mixtures, assumed strength, 12–06
  - proportionment, 12–05
  - quantities of materials, 12–10
  - reinforced, *see* Reinforced concrete
  - surfaces, finishing, 12–09
  - thermal conductivity of, 12–34
  - trial mixtures, 12–07
  - water proofing of, 12–10
- **Concurrent forces,** composition and resolution of, 4–03 to 4–05
- **Condensers,** electric, 8–40 to 8–45
  - steam, 7–69, 7–70
- **Conductance,** electric, 8–12 to 8–14
    - and capacitance, relation between, 8–42
    - effective, 8–17
    - units of, 3–18, 3–34
      - conversion of, 1–144
  - thermal, 12–32
- **Conduction,** electric, current, 8–37
    - in fluids, 8–67 to 8–69
    - in solids, 8–62 to 8–67
  - thermal, 7–02, 12–32
- **Conductivity,** electric, 8–13
    - aluminum, 11–59, 11–96, 11–97
    - alloys, 8–66
    - bronze bearing alloys, 11–87
    - copper, 11–92 to 11–94
    - copper-base alloys, wrought, 11–45 to 11–51
- **Conductivity,** electric, gases, 8–67
    - iron, wrought, 11–20
    - magnesium, 11–76
    - per cent, 11–96
    - and resistivity, 8–38
    - units, 3–18
      - conversion of, 1–145
    - zinc-base die-casting alloys, 11–83
  - thermal, *see* Thermal conductivity
- **Conductor materials,** electrical, 11–92 to 11–101
- **Conductors (electric),** 8–11, 8–63
  - aluminum, 11–96 to 11–98
  - copper, 11–92 to 11–96
  - current-carrying, force between, 8–34
  - dielectric flux density due to, 8–39
- **Cone,** 2–35, 2–73
  - mensuration formulas, 2–42
  - properties of, 4–24, 4–25
  - pyrometric, 12–24
- **Confluent forces,** 4–03
- **Conformal mapping,** 2–112
- **Conic sections,** 2–64 to 2–66
- **Conical horn,** 9–47
- **Conjugate** diameters, 2–64, 2–65
  - hyperbolas, 2–65
- **Connecting-rod and crank mechanism,** 4–28
- **Conpernik,** 11–109
- **Conservation** of angular momentum, principle of, 4–36
  - of energy, principle of, 4–35, 7–05
  - of linear momentum, principle of, 4–36
- **Consideration** (contracts), 13–05
- **Constantan,** properties of, 11–99
    - under repeated stress, 5–14
- **Constant-**entropy process, 7–04
  - pressure, gases, property, energy relations, 7–20
    - process, 7–04
      - example, 7–44
  - temperature, gases, property, energy relations, 7–20
  - volume, gases, property, energy relations, 7–20
    - process, 7–04
      - example, 7–44
- **Constants** containing e and π, 1–11
  - electrical, determination of, 8–04
  - proportionality, 3–04
- **Constrained** beam, 5–19
  - rotation, 4–39 to 4–42
- **Contact** drop, carbon brushes, 11–100
  - electromotive force, 8–10
  - material, carbon, 11–101
- **Continuity,** equation of (dynamics of ideal fluids), 6–19
- **Continuous** beams, 5–19, 5–33 to 5–35
  - electric current, 8–12
- **Contraction** joints in reinforced concrete, 5–60
  - lateral, factor of, 5–06
- **Contractor and subcontractor,** relations of, 13–24
- **Contractor's** liability insurance, 13–23
  - mutual responsibility, 13–24
  - right to terminate, 13–22
  - understanding, 13–27
- **Contracts,** Section 13
  - advertisement of, 13–13 to 13–15
  - agreement in, 13–03, 13–04
  - competence of parties to, 13–02
  - consideration in, 13–05
  - discharge of a, 13–05, 13–06
  - form of agreement, 13–16, 13–17
  - general conditions, articles of, 13–18 to 13–28
    - index of, 13–18

Contracts, parties to, 13–02
  preliminary steps in letting, 13–12 to 13–16
  separate, 13–24
  subject matter must be lawful in, 13–04, 13–05
Contractual relationships, conditions of, 13–02 to 13–05
Convection, 7–03, 12–32
Convergence of integrals, uniform, 2–91
  of series, 2–80 to 2–82
Conversion factors, tables of, 1–130 to 1–147
Convex spherical lenses, 9–11
  mirrors, 9–10
Coordinates, 2–61, 2–70
  cylindrical, 2–115
  polar, 2–73
  rectangular, 2–113
  spherical, 2–73, 2–115
  transformation of, plane analytic geometry, 2–63
    solid analytic geometry, 2–73
Copel (alloy), properties, 11–99
Coplanar forces, 4–03
  concurrent, composition of, 4–04, 4–05
    resolution of, 4–05
  non-concurrent, composition of, 4–07, 4–08
Copper, 10–17, 10–18, 11–39 to 11–40
  -aluminum-iron bronze, 11–110
  and aluminum wires, comparison, 11–97
  base alloys, 11–40 to 11–52
    corrosion of, 11–52
    die-casting, 11–83, 11–84
    fabrication of, 11–40, 11–52
    sand-cast, 11–41 to 11–43, 11–52
    wrought, 11–44 to 11–52
  commercial, composition of, 11–39
  conductors, 11–92 to 11–96
  corrosion of, 11–39
  effect on steel, 11–26
  electrical conductivity of, 11–92
  electrode potentials, values of, 10–37
  electroplating with, 11–09
  fabrication of, 11–40
  hardening of, 11–40
  and nickel, alloys of, 11–72 to 11–75
  -nickel alloys, properties of, 11–72
  nickel, properties of, 11–99
  nickel and zinc, alloys of, 11–75
  optical constants, 9–16
  oxygen-free high-conductivity, 11–40
  plate, weight of, 1–150
  properties of, 1–125, 1–127, 11–39, 11–40, 11–41, 11–44
    under repeated stress, 5–14
  roughness number of, 6–51
  sheet, weight of, 1–150
  temperature coefficient of resistivity of, 11–96
  wires, allowable current-carrying capacities, 11–95
    specifications, 11–94, 11–95
    table of, 11–93, 11–96
Core loss, aging, of non-retentive magnetic materials, 11–102
  factors for non-retentive magnetic materials, 11–104, 11–105
  of non-retentive magnetic materials as a function of gage, 11–106
  total, 8–33
Cored columns, reinforced concrete, 5–73
Cork, 12–82
  regranulated, thermal conductivity of, 12–35
Corkboard, thermal conductivity of, 12–35, 12–36
Corona, theory of, 8–09
Corporation, competence of (contracts), 13–02
Corpuscle, 9–08
Corpuscular aspects of radiation, 9–08, 9–09
  radiations, 9–04
Corrosion, atmospheric, protection from, 11–08 to 11–10
  copper-base alloys, 11–52
  established facts regarding, 11–05
  factors controlling, 11–06
  -fatigue, 5–16, 11–07
  magnesium alloys, 11–77
  metals, 11–05 to 11–11
  molybdenum, 11–82
  in presence of water, 11–05
  prevention of, 11–08 to 11–11
  principles of, 11–05 to 11–08
  -resistant characteristics of aluminum, 11–59
  -resistant steels, 11–37
  soil, 11–10
  testing, principles of, 11–08
  tungsten, 11–80
  undersoil, protection against, 11–10, 11–11
  underwater, protection against, 11–10
  zinc, 11–53
Corrosiron, 11–110
Cosecant, 2–54
  hyperbolic, 2–59
Cosine, 2–53
  hyperbolic, 2–59
  law of, 2–57, 2–58
Coslettizing, 11–09
Cosmic rays, 8–07, 9–04
Cosmical magnetism, 8–18
Cotangent, 2–54
  hyperbolic, 2–59
Cotton, 12–62
Cottonseed oil, density of, 6–06
  viscosity of, 6–07
Cottonwood, allowable unit stresses, 5–29, 5–31
  properties of, 12–45
Coulomb, 3–33, 8–09
  international, 3–34
Coulomb's law, 3–20
Couple, 4–03, 4–06, 4–07
Couplings, steel pipe, dimensions of, 1–165
Coversine, 2–54
Crank and connecting-rod mechanism, 4–28
Creep limit, 5–07
  metal, 5–07
  steel, 11–31
  stress, Monel metal, 11–74
  tests, 5–92
Crest factor, 8–46
Critical damping, 8–62
  -point curves of steel, 11–29
  pressure, gases, 10–25
    vapors, 7–41
    ratio, 7–27
    ratio steam, 7–49
  temperature, 7–41
    gases, 10–25
  velocity (fluid dynamics), 6–29, 6–32
Cross-bending loads, columns, 5–45
Crucible steel, 11–24
  uses of, 11–33
Crude oil, petroleum, 12–78
  surface tension, 6–09
Crushing strength of refractories, 12–22
Crystal form, of aluminum, 11–59
    of magnesium, 11–76
  structure, 8–19
Crystallizing varnish, 12–56
Crystallography, x-ray, 9–25
Crystals of solid solution, decomposition of 11–27

Crystals, transparent, 9–16
    various, grating spacings of, 9–25
Cube, mensuration formulas of, 2–41
  properties of, 4–23
  roots, 1–12 to 1–28
    to extract, 2–04
Cubes, 1–12 to 1–28
Cubic equation, 2–12
  measure, 1–132
Cucumber magnolia (wood), properties of, 12–46
Cumarone resin, 12–54
Cupola, 11–15
Cupping tests for determining ductility, 5–91
Cupric arsenite, properties of, 10–11
  hydroxide, 10–17
  oxide, 10–17
    properties of, 10–11
  sulfate, 10–17
    properties of, 10–11
  sulfide, 10–17
Cupron, properties of, 11–99
Cupro-nickel, properties of, 11–48
Cuprous oxide, 10–17
  sulfide, 10–17
Curl (vector analysis), 2–114
Current (electric), 8–09, 8–36
  allowable, carrying capacities of copper wires, 11–95
  alternating, 8–12
    circuits, 8–45 to 8–57
  branch, 8–51
  -carrying conductors, force between, 8–34
  charging (of a condenser), 8–42
  coil carrying, force produced in magnetic field, 8–33
  conduction, 8–37
  continuity of, 8–37
  continuous, 8–12
  density of, 8–37
    units of, conversion of, 1–142
  dimensions of, 3–08, 3–09
  direct, 8–12
    circuits, 8–09 to 8–16
  direction of, 8–36
  displacement, 8–37, 8–51
  due to a varying electric field, 8–37
  eddy, 8–32
  equivalent sinusoidal, 8–46
  exponential, 8–52
  leakage, 8–42
  magnetic fields due to, 8–20
  mesh, 8–51
  non-oscillatory, 8–12
  non-sinusoidal periodic, 8–49, 8–50
  oscillatory, 8–12
  pulsating, 8–12
  simple harmonic, 8–47
  sinusoidal, 8–47 to 8–49
  stream lines of, 8–37
  theoretical electrodynamic unit of, 3–32
  theoretical electromagnetic unit of, 3–31
  theoretical electrostatic unit of, 3–30
  transient, 8–12, 8–58
  units of, 3–16, 3–18, 3–30 to 3–34
    conversion of, 1–142
  and voltage relationships, 8–50 to 8–53
Curtate trochoid, 2–68
Curvature of curve, 2–67
  radius of, 2–67, 5–22
Curved beams, 5–33, 5–34
Curves, curvature of, 2–67
  higher plane, 2–66 to 2–70
  length of arc of, 2–96
  normal to, 2–67
Curves, plane, 2–66
    properties of, 4–20
  tangent to, 2–67
Curvilinear figures, plane, 2–33, 2–34
    mensuration formulas, 2–38 to 2–40
  motion, 4–27, 4–30, 4–31
    formulas, 4–38, 4–39
Cusp, 2–67
Cyanogen, properties of, 1–121
Cycle, alternating current, 8–45
  thermodynamics, 7–06
    binary-fluid, 7–61
    Carnot, 7–07, 7–09, 7–53
      refrigeration, 7–77
    Diesel, 7–72, 7–73, 7–76, 7–77
    efficiency, 7–06
    four-stroke, 7–72, 7–73
    heat power, 7–06
    irreversible, 7–11
    modern vapor, 7–60 to 7–62
    Otto, 7–72, 7–74, 7–75
    Rankine, 7–52 to 7–55
    regenerative feed-heating, 7–61
    reheating, 7–61
    reversed Carnot, 7–77
    reversible, 7–06, 7–11
    semi-Diesel, 7–73
    two-stroke, 7–72, 7–73
Cycloid, 2–53, 2–67
  geometrical construction of, 2–53
  mensuration formulas, 2–40
Cyclops metal, properties under repeated stress, 5–13
Cylinders, 2–35, 2–74
  drag of, 6–39
  flow around, 6–38
  mensuration formulas, 2–42
  under pressure, 5–52, 5–53, 5–57
  properties of, 4–24
  shrinkage fits, 5–53
Cylindrical coordinates, 2–115
  rollers, 5–55
Cypress, 12–39
  allowable unit stresses, 5–29, 5–31
  properties of, 12–45
  thermal conductivity of, 12–37, 12–38

Damage, windstorm, 9–64
Damages (contracts), 13–12, 13–24
Damping, critical, 8–62
  factor, 8–62
Day, solar, 3–23
Days between same dates of different months, 2–23
Debye's model of molecules, 9–07
Debye-Scherrer pattern, 9–25
Decane, properties of, 1–123
Decarbonization, surface, of steel, 11–30
Decay of timber, 12–41, 12–42
Decibel, 9–41
Decimal equivalents, 1–12 to 1–28
Decimals of a degree in minutes and seconds, 1–54
Defects, timber, 12–41, 12–42
Definite integral, 2–86, 2–88 to 2–92
Definition, mathematical, of a physical quantity, 3–03
Definitive dimension system, 3–09
  system of units, 3–16, 3–19
Deflection of beams of uniform cross-section, 5–26 to 5–28
  elastic, of beams, 5–22, 5–23
  lateral, 5–25

- **Deflection,** due to shear, 5–23
  - transverse, zinc-base die-casting alloys, 11–83
  - vertical, 5–24
- **Deformation,** definition of, 5–03
  - drag, 6–37
  - due to normal stresses at right angles, 5–09, 5–10
  - factor, 8–46
  - limit, sand-cast copper-base alloys, 11–41 to 11–43
  - stress-, diagram, 5–05
  - ultimate, unit, 5–04
  - unit, 5–03
- **Deforming steel,** 11–30
- **Degree,** angle, 2–32
  - decimals of, in minutes and seconds, 1–54
  - in radians, 1–54
  - of differential equation, 2–99
  - on various temperature scales, 3–27
- **De Laval turbine,** 7–68
- **Del (vector analysis),** 2–114
- **Demulsibility,** mineral oils, 12–71
- **Density,** 6–02, 6–03
  - acoustic, 9–38
  - aluminum, 11–59
    - casting alloys, 11–61, 11–62
    - wire, 11–97
  - building materials, 12–34 to 12–38
  - carbon brushes, 11–100
  - copper, 11–40
  - copper-base alloys, wrought, 11–45 to 11–51
  - copper-nickel alloys, 11–72
  - current, 8–37
    - units of, conversion of, 1–142
  - dielectric flux, 8–38, 8–39
    - units of, 3–29, 3–31, 3–33
      - conversion of, 1–142
  - gases, 1–121, 1–122, 6–05 to 6–07, 10–24
  - liquids, 1–123, 1–124, 6–05, 6–06
  - magnesium, 11–76
  - magnetic flux, units of, 3–18, 3–30, 3–31
    - conversion of, 1–146
  - mass, definition of, 6–02
  - metals, 1–125, 1–126
  - molybdenum, 11–81
  - Monel metal, 11–73
  - nickel, 11–71
  - of radiation, 9–02
  - specific (fluids), 6–03
  - surface charge, 8–39
    - units of, 3–18
  - thermal insulating materials, 12–34 to 12–38
  - per unit volume, units of, conversion of, 1–138
  - weight, definition of, 6–02
  - weld metal, 11–90, 11–91
  - wood, 12–37, 12–38
  - zinc, 11–53
  - zinc-base, die-casting alloys, 11–83
- **Depth,** steel sections, 1–153 to 1–163
- **Derivatives** and functions, 2–75 to 2–77
  - partial, 2–78, 2–79
- **Derived units,** 2–13, 2–33, 3–35
- **Descartes' rule of signs,** 2–15
- **Determinants,** 2–16, 2–17
  - characteristic, 8–57
- **Detonation,** 7–73
- **Detonator,** 12–80
- **Deviation,** standard (measurements), 2–123
  - of arithmetic mean, 2–126
  - interpretation of, 2–127
- **Dew point,** 7–92, 7–93, 9–61
- **Diacid base,** 10–07
- **Diamagnetic substances,** 8–25
- **Diameters,** conjugate, 2–64, 2–65
- **Diaphragms,** 9–44
- **Dibasic acid,** 10–07
- **Dichlorodifluoromethane,** properties of, 7–82
- **Dichloromethane,** properties of, 7–82
- **Die-casting** alloys, 11–82 to 11–84
  - aluminum-base, 11–62, 11–63
  - copper-base, 11–83, 11–84
  - lead-base, 11–82
  - magnesium-base, 11–84
  - tin-base, 11–82
  - zinc-base, 11–82, 11–83
  - of zinc, 11–55
- **Dielectric** circuit and electrostatics, 8–35 to 8–45
  - coefficient, 8–38, 8–43
  - constant, 3–20, 8–38
    - absolute, 3–29, 3–32
      - dimensions, 3–08 to 3–09
    - units, 3–16, 3–18
  - flux, 8–38, 8–39
    - units of, 3–29, 3–31, 3–33
      - conversion of, 1–141
  - flux density, 8–38, 8–39
    - units of, 3–29, 3–31, 3–33
      - conversion of. 1–142
  - hysteresis, 8–43
  - loss factor, phenolic sheet materials, 12–68
  - losses, 8–43, 8–44
  - strength, 8–44
    - fiber, 12–65
    - fish paper, 12–65
    - of gases, 12–74
    - insulating materials, 12–60
    - insulating varnishes, 12–72
    - laminated tubing, 12–69
    - phenolic sheet material, 12–68
    - rubber, 12–66
- **Diesel cycle,** 7–72, 7–73, 7–76, 7–77
  - semi-, 7–73
- **Di-ethyl ether,** properties of, 1–123
- **Differential,** 2–75
  - calculus, 2–75 to 2–85
  - equations, 2–99 to 2–108
    - definitions, 2–99
    - of first order, 2–99 to 2–101
    - fundamental types, 2–99
    - linear, 2–102 to 2–104
    - partial, 2–99, 2–104 to 2–108
    - second order, 2–101, 2–102
  - exact, 2–78, 2–96
  - operators, 2–114
- **Differentiation** formulas, 2–77
  - under integral sign, 2–91
  - of vectors, 2–114, 2–115
- **Diffracting grating,** 9–04
- **Diffraction** of radiation, 9–04
  - of sound, 9–40
  - of x-rays, 9–24
- **Diffuse reflecting power,** non-metallic materials, 9–16
- **Diffuser of fluids,** 7–29, 7–50
  - example, 7–52
- **Diffusion of light,** 9–32
- **Digester brick,** 12–26
- **Dihedral angle,** 2–34
- **Diluents in lacquers,** 12–57
- **Dimension,** 3–03
  - of electromagnetic quantities, 3–08, 3–09
  - of mechanical quantities, 3–05
  - systems, 3–03 to 3–05
    - absolute electrical, so-called, 3–10, 3–11
    - complete, 3–37
    - of electromagnetism, 3–07 to 3–12
    - fractional electrical, 3–09, 3–10
    - of heat, 3–06, 3–07

Dimension, systems, of mechanics, 3–05, 3–06
natural electrical, 3–07 to 3–09
practical, 3–12
of thermal quantities, 3–06
Dimensional analysis, 3–36 to 3–45
application to fluid dynamics, 6–16 to 6–18, 6–28
equations, 3–04
homogeneity of physical equations, 3–36, 3–37
Dimensionless products, 3–38
example, 3–40
Dimensions and units, 3–12
Dines tube anemometer, 9–65
Diorite, average strength, 12–15
Direct current, 8–12
circuits, 8–09 to 8–16
Direction of sound, 9–48
Directrix (conic sections), 2–35, 2–51, 2–64
Discharge, coefficient of (nozzles), 7–27
of a condenser, 8–42
of a contract, 13–05
Discount, 2–26
Discriminant of quadratic equation, 2–13
Disintegration, atomic, 10–06
Disk, Rayleigh, 9–53
Dispersion, 9–04
Displacement, angular, 4–32
current, 8–37, 8–51
dielectric flux density, dimensions, 3–08 to 3–09
units of, 3–18, 3–29, 3–31, 3–33
conversion of, 1–141
law, Wien's, 9–22
of a particle, 4–27
Dissociation constant, 10–07
ionic, 10–05
Distance between two points, 2–70
formula for (rectilinear motion), 4–27
optical, 9–10
perpendicular, of point to line, 2–62
of point to plane, 2–71
Div (vector analysis), 2–114
Divergence theorem, 2–115
Divergent series, 2–80
Dividend, 2–03
Division, 2–03, 2–05, 2–07
by logarithms, 2–10
by slide rule, 2–11
symbols for, 1–02
synthetic (equations), 2–15
Divisor, 2–03, 2–43
greatest common, 2–03
Documents, contract, 13–18, 13–19
Domain, magnetic, 8–19
Doppler effect, light, 9–20
sound, 9–38
Dosage of x-rays, 9–34
Double point, 2–67
refraction, 9–17
Douglas fir, 12–39
allowable unit stresses, 5–29, 5–31
column formula constants, 5–41
properties of, 12–45
thermal conductivity, 12–37
Drag coefficient (fluid flow), 6–38, 6–42
of a cylinder, 6–39
of a sphere, 6–40
induced (aerodynamics), 6–25
of a streamlined strut, 6–39
types of, 6–37
Drawing brass (alloy), properties of, 11–44
Driers, function of, in varnish, 12–52
" Drop of the beam " method, 5–87
Drop-weight testing machine, 5–83
Dry measure, 1–133
surfaces, laws of friction for, 4–44
Ductility, definitions of, 5–06
dynamic, of zinc, 11–57
index, non-retentive magnetic material, 11–102
of steel at various temperatures, 11–31
tests, 5–91
Ducts, flow of gas through, 7–23 to 7–25
Duhamel integral, 8–59
Duprene, 12–67
Durability of stone, 12–16
Duralumin, modulus of resilience and toughness, 5–08
properties under repeated stress, 5–14
Durand's rule, 2–40
Duress in contracts, 13–04
Duriron, 11–109, 11–110
Dynamic ductility of zinc, 11–57
Dynamical dimension system, 3–05
similarity, fluid dynamics, 6–15, 6–17
example, 6–18
units, 3–24
Dynamics (*see also* Kinetics), 4–02
of fluids, 6–05, 6–15 to 6–54
Dynamite, 12–79
Dyne, 3–25
-centimeter, 3–26

e, constants containing, 1–11
Ear, human, 9–48
Earth walls, roughness number, 6–51
Eastern cedar, red, properties of, 12–44
cotton wood, allowable unit stresses, 5–29, 5–31
properties of, 12–45
hemlock, allowable unit stresses, 5–29, 5–31
properties of, 12–45
thermal conductivity, 12–37
spruce, properties of, 12–47
Eccentric loads on compression members, 5–44, 5–45
Eccentricity (conic section), 2–64
Echo, 9–39
Economizer, 7–71
Eddy currents, 8–32
Edison storage cell, 10–38, 10–39
wire gage, 1–151
Effective resistance and conductance, 8–17
temperature (air conditioning), 7–94
value, alternating current, 8–46
Efficiency, actual thermal, 7–57
cycle, 7–06
heat engine cycle, 7–55 to 7–57
luminous, of light sources, 9–31
measures of, 7–55 to 7–58
example, 7–58
mechanical, 4–35
nozzle, 7–27
propeller, 6–44
of steam-generating unit, 7–62
thermal, 7–55
Diesel cycle, 7–76
ideal, of steam engine, 7–68
Otto cycle, 7–74
type, 7–56
Einstein's relation, 9–23
Ejector, 7–29, 7–50 to 7–52
Elastic curve of beams, 5–19
deflection of beams, 5–22, 5–23
Elastic limit, 5–04
bronze bearing alloys, 11–87

Elastic limit, commercial, 5-04
  Johnson's apparent, 5-04
    white metal bearing alloys, 11-86
    wrought copper-base alloys, 11-44 to 11-50
  nickel, 11-71
  proportional-, 5-04
Elasticity, 5-06
  modulus of, *see* Modulus of elasticity
Electric (electrical) absorption, 8-43
  admittance, 8-55, 8-58
  anemometers, 9-66
  -arc furnaces, 1-23
  arcs, luminous efficiency and brightness, 9-31
  cells and batteries, 10-37 to 10-39
  charge, 8-09, 8-39
    density, units of surface, 3-18
    dimensions of, 3-08, 3-09
    exponential, 8-52
    residual, 8-43
    surface density of, 8-39
    units of, 3-16, 3-18, 3-29, 3-31
      conversion of, 1-142
  circuit, alternating-current, 8-45 to 8-57
    direct current, 8-09 to 8-16
    magnetic energy of, 8-30, 8-31
    parameters, 8-50
    stability of, 8-59 to 8-61
  condenser, 8-40 to 8-45
  conductance, *see* Conductance, electric
  conduction, in fluids, 8-67 to 8-69
    in solids, 8-62 to 8-67
  conductivity, *see* Conductivity, electric
  conductor materials, 11-92 to 11-101
  conductors, 8-11
  constants, determination of, 8-04
  current, *see* Current, electric
  dimension systems, 3-07 to 3-12
  energy, 8-16, 8-17
  engineering symbols, 1-04 to 1-11
  entities, 8-02
    properties of, 8-03 to 8-05
  equipotential surfaces, 8-35
  field energy, 3-20
    of force, 8-35
    intensity of, 8-35
      dimensions of, 3-08 to 3-09
      units of, conversion of, 1-143
    mechanical forces in, 8-44
    strength, units of, 3-18
    varying, current due to, 8-37
  force, lines, of, 8-35
  furnace steel, 11-23
  furnaces, 10-39
  horsepower, 3-26
  images, 8-41
  insulating materials, 12-58 to 12-74
  insulator, 8-11, 8-63
  intensity, lines of, 8-35
  lamps, incandescent, characteristics, 9-31
  networks, steady state solution, 8-53 to 8-57
  pig iron, 11-15
  potential coefficients, 8-40, 8-41
    difference of, 8-10, 8-11, 8-36
    units of, 3-29, 3-32, 3-33
    gradient, 8-35, 8-36
      units of, 3-30
        conversion of, 1-143
    units of, 3-18
      conversion of, 1-143
  power, 8-16, 8-17
  resistance, *see* Resistance, electric
  resistivity, *see* Resistivity, electric
  steel, uses of, 11-33
Electric (electrical) units most commonly used, 3-18
    and standards, historical, 3-35, 3-36
      international, 3-34 to 3-36
    theoretical or absolute, 3-29 to 3-33
  voltage, difference of, 8-10
    (*see also* Voltage)
Electricity, conduction of, in fluids, 8-67 to 8-69
    in solids, 8-62 to 8-67
  flow of, 8-36
  and magnetism, Section 8
  and matter, 8-02, 8-03
  quantity of, differential equations in terms of, 8-52
    units of, conversion of, 1-141
  systems of units, 8-02, 8-03
Electroacoustical methods, 9-54
Electrochemistry of solutions, 10-36 to 10-39
Electrode materials, arc melting, 11-90, 11-91
  potentials of metals, value of, 10-37
Electrodeposition, 10-37
Electrodynamic units, theoretical, 3-32
Electrogalvanizing, 11-55
Electrokinetics and magnetic circuit, 8-18 to 8-35
Electrolysis (corrosion), 11-11
Electrolyte, 8-12
Electrolytic caustic soda and chlorine, 10-37
  iron, 11-21
Electromagnetic dimension system, 3-09
    absolute (so-called), 3-10
  equations, writing of, 3-35
  induction, 8-27 to 8-33
  origin, mechanical forces of, 8-33
  quantities, dimensions of, 3-08, 3-09
  relations, writing of, 3-20, 3-21
  right-handed screw law, 8-20
  spectrum of radiation, 9-06 to 9-08
  theory of light, 9-06
  unit system, cgs, 3-16, 3-17, 3-18
    rationalized cgs, 3-16, 3-17
  units, theoretical, 3-30 to 3-32
  waves, 8-07, 9-05
Electromagnetism, 8-20, 8-21
  dimension systems of, 3-07 to 3-12
Electromotive force (emf), 8-10, 8-36, 8-51
  exponential, 8-52
  induced, 8-21
  sinusoidal, 8-53
  sources of, 8-10
  units of, 3-30, 3-32
    conversion of, 1-143
Electron, free, 8-62
  mass of the, 8-05
  metal, properties under repeated stress, 5-14
  negative, 8-02, 8-03
  positive, 8-02, 8-04
  production of, in gases, 8-67, 8-68
  radiation, 9-04
  and radiation, collision of, 9-08
  spinning, 8-18
  theory, 8-02 to 8-09
  thermionic emission of, 8-05, 8-65
  tubes, 8-06
Electronics, 10-40
Electrophysical dimension system, 3-07, 3-08
  unit system, 3-16, 3-19
Electroplating, 10-37
  with other metals, 11-09
Electrorefining, 10-37
Electrostatic capacitance, condensers and induction, 8-40 to 8-43
  and dielectric circuit, 8-35 to 8-45

Electrostatic dimensions system, 3-08, 3-09
    absolute (so-called), 3-10
  energy and mechanical forces, 8-44, 8-45
  fields, potentials and currents, 8-35 to 8-38
  flux, dimensions, 3-08, 3-09
    units of, 3-18
  induction, 3-20
    coefficients, 8-40, 8-41
  unit system, cgs, 3-16, 3-17, 3-18
  units, theoretical, 3-29, 3-30
Electrotechnical dimension system, 3-07, 3-08
  unit system, 3-16, 3-19
Electrothermics, 10-39
Electrowinning, 10-37
Elements, chemical, 10-02 to 10-04
Ellipse, 2-50, 2-64
  geometrical construction, of, 2-50, 2-51
  mensuration formulas for, 2-39
  properties of, 4-22
Ellipsoids, 2-73
  flow around, 6-39, 6-40
  mensuration formulas for, 2-43
  properties of, 4-26
Elliptic cylinder, 2-74
  paraboloid, 2-74
Elliptical flat plates, 5-53
Elm, 12-39
  allowable unit stress, 5-29, 5-31
  properties of, 12-45
  thermal conductivity, 12-38
Elongation, aluminum, 11-59
  aluminum-base alloys, 11-61, 11-62, 11-67
    at elevated temperatures, 11-64
  bronze bearing alloys, 11-87
  copper-base alloys, 11-40 to 11-42, 11-44 to 11-50, 11-84
  copper-nickel alloys, 11-72
  copper wire, 11-94, 11-95
  determination of, 5-88
  iron, 11-20, 11-25

  Navier-Stokes, 6–15
  *n*th degree, 2–14 to 2–16
    special systems of, 2–19
  physical, 3–03, 3–13
    dimensional homogeneity of, 3–36, 3–37
    style of writing, 3–37
  quadratic, 2–12, 2–13
  Riccati's, 2–101
  unitary homogeneous, 3–37
  writing of the electromagnetic, 3–35
Equiangular spiral, 2–69
Equilateral triangle, 2–32
Equilibrant, 4–03
Equilibrium, conditions of, 5–20
  diagram of iron and steel, 11–27 to 11–29
  principles of, 4–10, 4–11
  problems, 4–11 to 4–15
Equipment, air-conditioning, 7–94
  materials testing, 5–81 to 5–84
Equipotential surfaces, electric, 8–35
  magnetic, 8–26
Equivalent sinusoidal current, 8–46
Erg, 3–25, 3–28
Erichsen draw, non-retentive magnetic materials, 11–102
Errors, 2–05
  and observations, 2–123
  probable, 2–123 to 2–126
    applications, 2–126 to 2–128
    interpretation of, 2–127, 2–128
Ester gum, 12–55
Ethane, properties of, 1–121, 7–82
Ether, density of, 6–06
Ethyl acetate, properties of, 1–123
  alcohol, density of, 6–06
    index of refraction of, 9–15
    magneto-optic rotation of, 9–18
    properties of, 1–123
    surface tension of, 6–09
  bromide, properties of, 1–123
  chloride, properties of, 1–121, 1–123, 7–82
  ether, index of refraction of, 9–15
  iodide, properties of, 1–123
Ethylene bromide, properties of, 1–123
  chloride, properties of, 1–123
  properties of, 1–121, 7–82
Euler's column formula, 5–38
  homogeneous equation, 2–103
Evaporation and rainfall, 9–58, 9–59
  test (lubricants), 12–75
Everdur, properties of, 11–41, 11–50
Evergreen magnolia, properties of, 12–46
Exact differential equation, 2–10
  simple interest on $1000, 2–23
Exchange (magnetism), 8–19
Excitation of line spectra, 9–20
Expansion, actual, of a vapor, 7–49
  of functions, series, 2–79 to 2–85
  ratio (Otto cycle), 7–74
  thermal coefficient of, aluminum, 11–59
    bearing bronzes, 11–89
    copper, 11–40
    copper-base alloys, wrought, 11–45 to 11–51
    copper-nickel alloys, 11–72
    electrical resistance materials, 11–90
    gases, 1–121, 1–122
    iron, 11–20, 11–25
    magnesium, 11–76
    metals, 1–125, 1–126
    molybdenum, 11–81
    Monel metal, 11–73
    nickel, 11–71
    non-metallic solids, 1–129
    refractories, 12–22, 12–23
    stainless steel, 11–38
    steel, 11–25
    tungsten, 11–80
    zinc, 11–53
    zinc-base die-casting alloys, 11–83
Expert witness, engineer as, 13–09
Explosives, 12–79, 12–80
Exponential charge, 8–52
  current, 8–52
  emf, 8–52
  horn, 9–47
  impedance, 8–53
  values and logarithms, 1–102 to 1–112
Extensometers, 5–83
External shear, reinforced concrete, 5–66
Eye, 9–26
Eyelet brass, properties of, 11–44
Eyepieces, optical instruments, 9–13
Eyring's formula, 9–50

Fabrication aluminum and aluminum alloys, 11–69
  copper, and copper alloys, 11–40
  of rolled zinc, 11–57
Fabrics, insulating, dielectric strength of, 12–64
Factor, integrating, 2–101
  of safety, 5–10, 5–11
  shape (wind pressure), 9–66 to 9–69
Factorials, 1–11, 2–03
Factoring (algebra), 2–08
Factors (arithmetic), 2–03
  conversion, tables of, 1–130 to 1–147
Factory lumber, 12–43
Fahrenheit temperature scale, 3–27
Failure, character of **(repeated stress),** 5–12
Fan, characteristics of, 6–46
  drag, 6–37
  and propellers, 6–44
  propeller-type, 6–46
Farad, 3–33, 8–40
  international, 3–34
Faraday, 3–34, 10–36
  effect, 9–18
Faraday's induction law, 3–20
  law, 10–36
Fatigue, corrosion, 5–16, 11–07
  of metals, 5–12
Fechner's law, 9–26
Feedwater heaters, 7–70
Fermat's principle, 9–10
Fermi-Dirac statistics, 8–64

- **Ferrel psychrometric formula,** 7–91
- **Ferric** chloride, magneto-optic rotation, 9–18
  - ferrocyanide, 10–20
  - hydroxide, 10–20
  - oxide, 10–19
    - properties of, 10–11
  - sulfate, 10–20
- **Ferrite,** 11–26
- **Ferroalloys,** manufacture of, 11–15
- **Ferromagnetic substances,** 8–25
- **Ferromagnetism,** 8–18
- **Ferromanganese,** 11–13, 11–18
- **Ferrophosphorus,** 11–13
- **Ferrosilicon,** analysis of, 11–13
- **Ferrous** carbonate, 10–19
  - chloride, magneto-optic rotation of, 9–18
  - ferricyanide, 10–20
  - hydroxide, 10–20
  - metals, endurance ratios for, 5–15
    - under repeated stress, 5–13
    - values of endurance limit, 5–12
  - oxide, 10–19
    - properties of, 10–11
  - sulfate, 10–20
    - properties of, 10–11
  - sulfide, 10–20
- **Fiber (insulating material),** 12–64
  - electrical properties of, 12–60
  - hard, NEMA specifications, 12–65
  - thermal conductivity of, 12–35, 12–36
- **Fiber stress, allowable,** reinforced concrete, 5–62
  - structural steel, 5–24
- **Field,** electric, current due to varying, 8–37
    - intensity of, 8–35
    - mechanical forces in, 8–44
  - electrostatic, 8–35 to 8–38
  - energy, electric, 3–20
    - magnetic, 3–20
  - of force, electric, 8–35
    - magnetic, 8–18
  - intensity, electric, dimensions, 3–08
      - electric, units of, conversion of, 1–143
    - magnetic, 8–22
      - lines of, 8–23
      - units of, conversion of, 1–147
  - magnetic, energy of, 8–30
    - mechanical forces in, 8–33 to 8–35
    - torque on a coil in, 8–33, 8–34
  - strength, electric, units of, 3–18, 3–30, 3–32
- **Fifth roots,** table of, 1–12 to 1–28
- **Figures,** irregular, mensuration formulas, 2–40
  - plane curvilinear, 2–33, 2–34
    - mensuration formulas, 2–38 to 2–40
  - plane rectilinear, mensuration formulas, 2–37, 2–38
  - significant, 2–05
  - similar, areas of, 2–36
    - perimeters or circumferences, 2–36
- **Films,** surface (corrosion), 11–07
- **Filter,** acoustic, 9–46
- **Finance,** mathematics of, 2–22 to 2–32
- **Finery process,** 11–20
- **Finishing of aluminum,** 11–69
- **Fir,** 12–39
  - allowable unit stresses, 5–29, 5–31
  - column formula constants, 5–41
  - properties of, 12–45
  - thermal conductivity of, 12–37, 12–38
- **Firebrick,** *see* Refractories
- **Fireclay** brick, 12–20
    - properties of, 12–22 to 12–25
    - uses of, 12–28 to 12–31
  - mortars, 12–26
- **Fire point,** 12–75
  - mineral oils, 12–71
- **First law** energy balance, 7–58
  - of thermodynamics, 7–05
- **Fish** oil, 12–55
  - paper, 12–62
    - dielectric strength of, 12–64, 12–65
- **Fixed beam,** 5–19
  - diagrams, 5–27, 5–28
- **Flag signal,** 9–55
- **Flame tests (chemistry),** 10–33
- **Flash point,** 12–75
  - mineral oils, 12–71
- **Flat slab** construction, rectangular, bending moments in, 5–56
  - reinforced concrete, 5–78 to 5–80
- **Flexural strength,** phenolic sheet material, 12–68
- **Flexure,** formula for, 5–21
    - rectangular beams, reinforced concrete, 5–63
    - solid slabs, reinforced concrete, 5–63
    - T-beams, reinforced concrete, 5–64
  - phenomena of, 5–19
  - tests of cast iron, machines for, 5–82
    - specimens for, 5–85
  - theory of, 5–19 to 5–23
- **Floor,** ribbed, reinforced concrete, 5–71
      - example, 5–72
  - tile, 12–18 to 12–20
- **Flooring,** thermal conductivity, 12–36
- **Flow,** adiabatic, 7–11
  - breakaway of, 6–28
  - of energy in speech, 9–49
  - of ideal fluids, two-dimensional, 6–18 to 6–22
      - applications of results, 6–22 to 6–26
  - of gases, through orifices and nozzles, 7–25 to 7–30
    - through pipes and ducts, 7–23 to 7–25
  - over notches, 6–52
  - in open channels, 6–51, 6–52
  - point, silver solders, 11–92
  - stationary, of a viscous fluid through a pipe, 3–39
  - throttling, 7–11
  - of vapors through nozzles and orifices, 7–47 to 7–52
  - of viscous incompressible fluids, 6–27
    - around bodies, 6–37 to 6–40
    - near boundaries, 6–48
    - through nozzles, 6–35, 6–36
    - through orifices, 6–34, 6–35
    - in rough tubes, 6–32, 6–33
    - in smooth pipes or tubes, 6–28 to 6–33
    - through venturi tubes, 6–36
    - over weirs, 6–52
- **Fluid,** conduction of electricity in a, 8–67 to 8–69
  - dynamics, 6–05, 6–15 to 6–53
  - flow of, *see* Flow
  - ideal, dynamics of, 6–18 to 6–22
      - applications of results, 6–22 to 6–26
  - incompressible, *see* Viscous incompressible fluids
  - kinds of, 6–04, 6–05
  - measure, apothecaries', 1–133
  - mechanics of, Section 6
    - definitions, 6–02
    - division of, 6–05
  - media, causes of sound absorption in, 9–41, 9–42
  - motion, laws of, 6–15 to 6–18
  - pressure, 6–11
  - properties of, 6–02 to 6–10
  - and solids, 6–02

- **Fluid,** statics, 6–05, 6–11 to 6–14
  - viscous, incompressible, *see* Viscous incompressible fluids
    - aerodynamics of, 6–41 to 6–48
    - dynamics of, 6–27, 6–28
    - flow of, *see* Flow
- **Fluorescence,** 9–04, 9–21
- **Fluorine,** 10–28
  - properties of, 1–121
- **Flux** density, dielectric, 8–38, 8–39
      - units of, 3–29, 3–31, 3–33
        - conversion of, 1–142
    - magnetic, 8–20
      - units of, 3–18, 3–30, 3–31
        - conversion of, 1–146
  - dielectric, 8–38, 8–39
    - units of, 3–29, 3–31, 3–33
      - conversion of, 1–141
  - electrostatic, dimensions, 3–08
    - units of, 3–18
  - linkages, 8–21
  - luminous, 9–28
  - magnetic, 8–19
    - dimensions, 3–08
    - international unit of, 3–34
    - lines, 8–20
    - units of, 3–18, 3–30, 3–31, 3–32, 3–34
      - conversion of, 1–146
    - work done by varying, 8–22
  - soldering, 11–91
- **Foci of ellipse,** 2–50
  - of hyperbola, 2–52
- **Focus of conic section,** 2–64
  - of parabola, 2–51
- **Foil, aluminum,** 11–65
  - thermal conductivity of, 12–37
- **Foot,** 3–21
- **Foot-candle,** 9–29
- **Footings,** reinforced concrete, 5–75 to 5–77
- **Foot-pound** (force), 3–24
- **Foot-poundal,** 3–24
- **Force,** 4–02
  - atomic, 10–05
  - centrifugal, 4–41
  - centripetal, 4–41
  - classification of, 4–03
  - coefficient (fluid dynamics), 6–16
  - coercive, 8–31
    - high-purity iron, 11–22
    - non-retentive magnetic materials, 11–102
    - permanent magnet materials, 11–108
  - concurrent, composition and resolution of, 4–03 to 4–05
  - coplanar, 4–03
    - concurrent, composition of, 4–04, 4–05
      - resolution of, 4–05
    - non-concurrent, composition of, 4–07, 4–08
  - between current-carrying conductors, 8–34
  - dimensions, 3–05, 3–08, 3–09
  - electric field of, 8–35
  - electromotive, *see* Electromotive force
  - energy, power, 3–24 to 3–26
  - in equilibrium, 4–10
  - graphical representation of, 4–02, 4–03
  - lines of electric, 8–35
  - lines of magnetic, 8–23
  - on magnetic bodies in a magnetic field, 8–35
  - magnetic field of, 8–18
  - magnetizing, *see* Magnetizing force
  - magnetomotive, *see* Magnetomotive force
  - mass, acceleration, relation between, 4–34
  - mechanical, of electromagnetic origin, 8–33 to 8–35
      - in electric field, 8–44
- **Force, mechanical, of electromagnetic origin in magnetic field, 8–33**
  - moment of, about a line, 4–06
    - about a point, 4–05
    - units of, conversion of, 1–139
  - nonconcurrent, 4–03
    - composition of, 4–07 to 4–10
    - resultant of, 4–10
  - noncoplanar, 4–03
    - composition of, 4–05, 4–09
    - resolution of, 4–05
  - polygon, 4–04, 4–07, 4–08
  - power of, 4–35
  - produced by a magnetic field on a coil carrying a current, 8–33
  - single and couple, composition and resolution of, 4–07
  - systems of, 4–03
  - transmissibility of, 4–02
  - per unit area, units of, conversion of, 1–139
  - units of, 3–14, 3–16, 3–24, 3–25, 4–34
    - conversion of, 1–138
  - vs. weight, 3–24
  - on wire in magnetic field, 8–34
  - work of a, 4–34
- **Forge pig iron,** 11–15
- **Forging** aluminum, 11–69
  - brass, properties of, 11–46
  - steel, 11–29
- **Form factor,** 8–46
- **Formic acid,** properties, 1–123
- **Forms for concrete,** 12–08
- **Formulas,** approximate, 2–20, 2–21
  - chemical, determination of, 10–10
- **Forsterite brick,** 12–26
- **Fossil gums,** 12–70
- **Foucault currents,** 8–32
- **Foundry pig iron,** 11–14
- **Four-cycle engine,** 7–73
- **Fourdrinier wire,** properties of, 11–46
- **Fourier series,** 2–82, 8–49
- **Four-stroke cycle,** 7–72, 7–73
- **Fractional electrical dimension system,** 3–09, 3–10
  - roots, 2–15
- **Fractions,** 2–06
  - partial, 2–08
  - rational, 2–08, 2–09
    - integration of, 2–86
- **Fracture,** types of, 5–07
- **Frame,** building, thermal conductivity, 12–36
- **Frames,** redundant, 4–14
- **Fraud** in contracts, 13–04
- **Frauds,** statute of, 13–03
- **Fraunhofer lines,** 9–19
- **Free electrons,** 8–62
  - oscillations, 9–42
- **Free-cutting** phosphor bronze, properties of, 11–46
  - rod, properties of, 11–46
- **Freezing point,** aluminum, 11–59
  - diagram, alloys, 11–03, 11–04
  - magnesium, 11–76
- **French units and standards,** 3–22, 3–23
- **Freon,** *P–H* diagram for, 7–82
- **Frequency,** change of velocity with, 9–37
  - of errors, relative, 2–123
  - mass and energy relation, 8–03
  - of periodic quantity, 8–45
  - resonance (sound), 9–43
  - simple harmonic motion, 4–29
  - of sound, 9–48
  - threshold, 8–66
- **Friction,** 4–44 to 4–47
  - axle, 4–45

Friction, belt, 4–47
  coefficient of, carbon brushes, 11–100
    tubes, 6–33
  coil, 4–47
  drag, skin, 6–37
  kinetic, 4–44
  pivot, 4–45, 4–46
  rolling, 4–44, 4–45
  static, 4–44, 4–45
  tape, dielectric strength, 12–64
Froude's formula, 6–49
  number, 3–40, 3–43, 6–15
Frustum of a cone, 2–35
  of a pyramid, 2–35
Fuels, 12–77, 12–78
  injection (Diesel engine), 7–76
  liquid and gaseous, 12–78, 12–79
Fullerboard, 12–60, 12–62
  dielectric strength of, 12–64
Functional relationships, trigonometric, 2–55, 2–56
Functions, circular, of plane angles, 2–53 to 2–56
    values and logarithms of, 1–57 to 1–101
  complementary, 2–102
  of complex variables, 2–111, 2–112
  composite, differentiation of, 2–78
  continuity of, 2–75
  definition of, 2–75
  and derivatives, 2–75 to 2–77
  of four variables, alignment charts for, 2–120 to 2–122
  gravitational, 4–38
  hyperbolic, 2–59 to 2–61
    values and logarithms of, 1–102 to 1–112
  of imaginary and complex angles, 2–60, 2–61
  implicit, 2–79
  inertia, 4–38
  irrational, integration of, 2–86
  relation of hyperbolic to circular, 2–60
  of Routh and Hurwitz, test, 8–60
  series expansion of, 2–79 to 2–85
  stream, 6–18 to 6–21
  of three variables, alignment charts for, 2–117 to 2–120
  trigonometric, 2–53 to 2–56
    values and logarithms of, 1–57 to 1–101
  of two variables (partial derivatives), 2–78
Fund, sinking, 2–29, 2–30
Fundamental (Fourier series), 8–50
Funicular polygon, 4–07
Furnace, air, melting, 11–16
  electric-arc, 11–23
  innovations in, 11–16
Fusible alloys, 11–110
Fusion, latent heat of, aluminum, 11–59
    gases, 1–121, 1–122
    liquids, 1–123, 1–124
    magnesium, 11–76
    metals, 1–125, 1–126
    zinc, 11–53

Gages, rain, 9–58
  sheet metal, 1–148 to 1–150
  wire, 1–150 to 1–152
  zinc, comparison with other gages, 11–56
Galileo's telescope, 9–14
Gallon, 3–21
  imperial, 3–22
  United States, 3–21
Galvanizing, 11–54, 11–55
Gamma-rays (**γ-rays**), 9–04, 10–06
Gas calculations, 10–10
Gases, characteristic properties of, 7–16
Gases, chemistry of, 10–23 to 10–25
  coal, 12–78
  in compressors, compression of, 7–30, 7–31
  constant, 7–15, 7–16
    equivalent, for gas mixture, 7–87
  definitions of, 6–04, 6–05
  diatomic, *T–S* and *H–S* diagrams for, 7–22
  dielectric strength of, 12–74
  dynamics, 6–05
  electric conduction in, 8–67, 8–68
  energy equations for, 7–19 to 7–21
  flow of, through pipes, nozzles and orifices, 7–23 to 7–30
  H-S curves for a, 7–21
  index of refraction of (light), 9–15
  insulating properties of, 12–74
  ionization of, 8–09
  kinetics of, 10–23
  laws, 7–15, 7–16, 10–23 to 10–25
  magneto-optic rotation of, 9–18
  mixtures, 7–85 to 7–87
  natural, 12–78
  perfect, definition of, 6–05
    P–V–T relation for, 7–15
    velocity of sound in, 9–37
  photon, 9–08
  processes, energy equations for, 7–20, 7–21
  producer, 12–78
  properties of, 1–121, 1–122, 6–07 to 6–10, 7–17, 10–24
  property relations of, 7–19 to 7–21
  P–V curves for, 7–21
  specific heat of, 7–16 to 7–18
    charts of, 7–18
  state changes, 7–21 to 7–23
  thermodynamics of, 7–15 to 7–31
  T–S curves for, 7–21
  vapor mixtures, 7–87 to 7–89
  viscosity of, 6–04
  water, 12–78
  weights of common, 10–11
Gas-filled air craft, lift of, 6–12
Gaskets and packings, 12–83
Gasoline, 12–78
  properties, 1–123
  viscosity, 6–07
Gauss, 3–31, 3–32, 8–20
  -Laplace law, 2–123
  theorem, 2–115
Gaussian dimension system, 3–10
  unit system, 3–17
Gear bronze, properties, 11–42
Generating unit, steam, 7–62 to 7–66
Generatrix, 2–35
Geometric concepts, 2–32 to 2–36
  mean, 2–20
  progression, 2–20
Geometrical construction, 2–44 to 2–53
    angles, 2–45, 2–46
    circles, 2–46 to 2–49
    ellipse, 2–50, 2–51
    hyperbola, 2–52
    involute of a circle, 2–53
    lines, 2–44, 2–45
    parabola, 2–51, 2–52
    polygons, 2–49, 2–50
  optics, principles of, 9–09, 9–10
Geometry, 2–32 to 2–53
  analytic, symbols for, 1–02
  plane, symbols for, 1–02
  plane analytic, 2–61 to 2–70
  of radiation, 9–09 to 9–14
    bibliography, 9–14
  solid analytic, 2–70 to 2–75

German silver, properties, 11–99
    under repeated stress, 5–14
Gilbert, 3–31, 8–22
Gilding (alloy), properties, 11–44
Girderless construction, reinforced concrete, 5–78 to 5–80
Glare, 9–32
Glass, 12–61
  electrical properties, 12–60
  index of refraction of, 9–15
  magneto-optic rotation, 9–18
  roughness number, 6–51
  wool, thermal conductivity, 12–35
Glauber salt, properties of, 10–11
Glues, properties of, 12–81
Glycerin, index of refraction of, 9–15
  properties of, 1–123
Glyptal, 12–54, 12–68
Gneiss, 12–14
  durability of, 12–16
Gold, 10–18
  electrode potentials, values of, 10–37
  optical constants of, 9–16
  properties of, 1–125, 1–127
Goods, contracts for, 13–03
Grad (vector analysis), 2–114
Gradient, electric potential, 8–35
    units of, 3–30
      conversion of, 1–43
  magnetic potential, units of, 3–32
      conversion of, 1–147
  voltage, 8–35, 8–36
Grain, growth in iron and steel, 11–32
  of wood, 12–41
  unit of mass, 3–22
Gram, 3–23
Gram-calorie, 3–26
  conversion, 3–28
Granite, 12–14
  durability of, 12–16
  strength of, 12–15
Granodizing, 11–10
Graph, motion, 4–28, 4–29, 4–31, 4–32
Graphic transformation, plane surfaces, 4–18
Graphical representation, of forces, 4–02
    of gas state changes, 7–21
    of vapor properties, 7–41
  solution of equations, 2–16
Graphite brushes, 11–99, 11–100
  in steel, 11–26
Grating, diffracting, 9–04
  spacings of various crystals, 9–25
Gravitation constant, 3–05
  functions, 4–38
Gravitational dimension system, 3–05
  system of units, 3–24, 4–02
Gravity, center of, 2–98, 4–15 to 4–17
    of various lines, surfaces, volumes, and bodies, 4–20 to 4–26
  force (fluid dynamics), 6–15
  specific, *see* Specific gravity
Gray iron, 11–17
Greases, properties of, 12–76
Greek alphabet, 1–02
Green ash (wood), 12–39
Greenheart (wood), 12–39
Green's theorem, 2–95, 2–115
Ground effect on automobiles and trains, 6–53
Grouping (algebra), 2–06
" Growth " of cast iron, 11–18
Guaranty bonds (contracts), 13–23
Gum, ester, 12–55
Gum (wood), 12–39
  allowable unit stresses, 5–29, 5–31
Gum (wood), plywood, 12–49
  properties of, 12–45
Gums (resin), 12–70
Guncotton, 12–79
Gunpowder, 12–79
Gusts, load multiples due to, 6–48
Gutta percha, 12–67
Gypsum boards, grating spacings, 9–25
  plaster, neat, 12–14
  thermal conductivity of, 12–35, 12–36
Gyration, center of, 4–19
  polar radius of, in shafts, 5–48
  radius of, beam section, 5–22
    of a body, 4–19
    columns, 5–37
    of a plane surface, 4–17
    steel pipe, 1–165
    steel sections, 1–153 to 1–163
    various surfaces, volumes, bodies, 4–20 to 4–26

Hackberry (wood), properties of, 12–45
Hagen-Poiseuille law, 6–28, 6–30
Hallwachs' effect, 9–23
Halogen elements, acids of, 10–06
Halogens, 10–27, 10–28
Halowax, 12–69
Hardening of copper, 11–40
  of steel by quenching, 11–32
    theory of, 11–33
  strain, 11–31
Hardness, alloy steels for, 11–37
  Brinell, aluminum, 11–59
    aluminum alloys, wrought, 11–67
    aluminum-base, casting alloys, 11–61, 11–62, 11–64
    bronze bearing alloys, 11–87
    copper-base alloys, die casting, 11–84
      sand-cast, 11–40 to 11–42
      wrought, 11–44 to 11–51
    copper-nickel alloys, 11–72
    ferrous metals, 5–13
    fiber, 12–65
    iron, 11–25
    magnesium, 11–76
    magnesium alloys, 11–78
    metals, 1–127
    Monel metal, 11–74
    nickel, 11–71
    non-ferrous metals, 5–14, 5–15
    steel, 11–25
    testing machine, 5–89
    white metal bearing alloys, 11–86
    zinc-base die-casting alloys, 11–83
  definition of, 5–07
  numbers, relationship between, 5–90, 5–91
  Moh's scale of, 5–90
  Rockwell, aluminum alloys, sand-cast, 11–61
    copper-base alloys, wrought, 11–44 to 11–51
    magnesium alloys, 11–78
    nickel, 11–71
    testing machine, 5–89
  scleroscope, aluminum alloys, wrought, 11–67
    carbon brushes, 11–100
    nickel, 11–71
    testing machine, 5–90
  tests, 5–89 to 5–91
  Vicker's pyramid testing machine, 5–89
  of water, 10–14, 10–15
  of wood, 12–44 to 12–47
Harmonic analysis, 8–49
  current, simple, 8–47

- **Harmonic mean,** 2–20
  - motion, simple, 4–29
  - progression, 2–20
- **Harmonics,** 8–49, 8–50
- **Haversine,** 2–54
- **Hearths,** charcoal, 11–20
- **"Heat" (energy) balance,** 7–58 to 7–60
- **Heat** conductivity, 12–32
  - content, 7–06
  - definition of, 7–02
  - dimension systems of, 3–06, 3–07
  - effect on steel, 11–30 to 11–33
  - equivalent, specific, for gas mixture, 7–87
  - flow, internal resistance to, 12–32
  - of fusion, latent, aluminum, 11–59
    - gases, 1–121, 1–122
    - liquids, 1–123, 1–124
    - magnesium, 11–76
    - metals, 1–125, 1–126
    - zinc, 11–53
  - latent, 7–13
  - mechanical equivalent of, 7–03
  - power cycle, 7–06
  - quantity of, dimensions of, 3–06
  - radiation, measurement of, 9–23
  - rate, 7–57
  - -resisting alloy steels, 11–39
  - specific, *see* Specific heat
  - symbols for, 1–04 to 1–11
  - transfer, 12–32
  - transmission, coefficients of, 12–33
  - -treated cast iron, 11–19
  - treatment, effect on aluminum alloys, 11–66
    - structural alloy steel, 11–36
  - unit systems (thermal), 3–15
  - units of, conversion of, 1–140
    - quantity of, 3–28
  - of vaporization, latent, aluminum, 11–59
    - gases, 1–121, 1–122, 10–24
    - liquids, 1–123, 1–124
    - magnesium, 11–76
    - metals, 1–125, 1–126
    - zinc, 11–53
  - waves, 8–07
- **Heaviside operational calculus,** 2–108 to 2–111
- **Hefner,** 9–28
- **Height, mean barometer,** 9–61
- **Helium,** compressibility of, 6–10
  - density of, 6–07
  - properties of, 1–121, 7–16
  - viscosity of, 6–08
- **Helix,** mensuration formulas for, 2–40
- **Hemisphere,** mensuration formulas for, 2–42
  - properties of, 4–25
- **Hemlock,** 12–39
  - allowable unit stresses, 5–29, 5–31
  - column formula constants, 5–41
  - properties of, 12–45, 12–46
  - thermal conductivity of, 12–38
- **Hempseed oil,** 12–56
- **Henry,** 3–33, 8–28
  - international, 3–34
- **Heptane,** properties of, 1–124
- **Hertz equations,** 5–55
- **Hexagon,** geometrical construction, 2–49
- **Hexane,** properties of, 1–124, 7–82
- **Hickory,** 12–39
  - allowable unit stresses, 5–29, 5–31
  - properties of, 12–46
- **Hiding** power, pigments, 12–51
  - units, pigments, 12–51
- **High-conductivity copper,** oxygen free, 11–40
- **High-frequency** electric furnace, 9–23
  - magnetic materials, 11–109
- **High-purity iron,** 11–21, 11–22
  - properties of, 11–99
- **High-speed steel,** 11–37
- **High-strength bronze,** properties of, 11–46
- **Hipernik,** induction, 11–103
  - magnetic properties, 11–102
- **Hitenso,** properties of, 11–50
- **Hodograph,** 4–30
- **Holes, effect of, in members under simple stress,** 5–03
- **Homogeneity, dimensional, of physical equations,** 3–36, 3–37
- **Homogeneous equations,** 2–100, 2–103, 2–107
- **Honey locust,** properties of, 12–46
- **Hooke's law,** 5–04
- **Horizontal** candlepower, mean, 9–29
  - shear, 5–21
    - beam design, example, 5–30
    - in timber beams, 5–25
- **Horner's method,** 2–16
- **Horns,** 9–47
- **Horsepower,** 3–25, 7–03
  - brake, 7–67
  - electrical, 3–26
  - indicated, 7–77
  - metric, 3–26
- **Hot-wire microphone,** 9–54
- ***H–S* curves for a gas,** 7–21
- ***H–S* diagram,** 7–42
  - Carnot refrigeration cycle, 7–78
  - for diatomic gases, 7–22
  - of diffuser process, 7–50
  - for ejector process, 7–51
  - for liquids, 7–42
  - of nozzle flow process, 7–48
  - of Rankine cycle, 7–53
  - for throttling process, 7–46
  - vapor compression cycle, 7–79
  - water and water vapor, 7–43
- **Hue** (color), 9–27
- **Human** ear, 9–48
  - occupancy (air conditioning), 7–94
  - visibility, spectral distribution of, 9–27
- **Humidity,** 9–61, 9–62
  - control of relative, 7–94
  - and hygrometry, 7–89 to 7–93
    - symbols and abbreviations for, 7–85, 7–86
- **Hurwitz and Routh,** test functions of, 8–60
- **Huyghens eyepiece,** 9–13
- **Hybrid physical equations,** 3–13
- **Hydrate,** 10–04
- **Hydrated lime,** 12–12
- **Hydraulic** radius, mean, 6–32, 6–51
  - testing machine, 5–82
- **Hydraulics,** 6–05, 6–13
  - symbols for, 1–04 to 1–11
- **Hydrochloric acid,** 10–06, 10–11, 10–28
  - (*see also* Hydrogen chloride)
  - properties, 10–11
- **Hydrodynamics,** 6–05
- **Hydrofluoric acid,** 10–28
  - (*see* also Hydrogen fluoride)
- **Hydrogen,** 12–77
  - bromide, properties of, 1–122
  - chloride, density of, 6–07
    - properties of, 1–122
  - compressibility of, 6–10
  - density of, 6–07
  - dielectric strength of, 12–74
  - electrode potentials, values of, 10–37
  - fluoride, properties of, 1–122
  - index of refraction of, 9–15
  - insulating properties of, 12–74
  - iodide, properties of, 1–122

Hydrogen, peroxide, properties of, 10–11
  properties of, 1–121, 7–16, 10–24
  selenide, properties of, 1–22
  specific heat of, 7–17
  in steel, 11–26
  sulfide, 10–29
    properties of, 1–122
  telluride, properties of, 1–122
  viscosity of, 6–08
  weight of, 10–11
Hydrolysis, 10–08
Hydrostatics, 4–02, 6–05, 6–13, 6–14
Hydroxide, 10–04
Hygrometry and humidity, 7–89 to 7–93
Hyperbola, 2–52, 2–64, 2–65
  geometrical construction, 2–52
  mensuration formulas, 2–39
Hyperbolic angles, 2–58
  cylinder, 2–74
  functions, 2–59
    identities, 2–59
    relation to circular functions, 2–60
    values and logarithms of, 1–102 to 1–112
  logarithms, 2–10
  paraboloid, 2–74
  spiral, 2–69
  trigonometry, 2–58 to 2–60
Hyperboloid, 2–73
  mensuration formulas, 2–43
Hypocycloid, 2–53, 2–68
  mensuration formulas, 2–40
Hypotrochoid, 2–68
Hysteresis, 8–31
  coefficient, non-retentive magnetic materials, 11–102
  dielectric, 8–43
  loops for retentive magnetic materials, 11–108
  loss, high-purity iron, 11–22

Ice, 12–84
  dry, 10–30
  point, 3–26
Ideal (resistance alloy), properties of, 11–99
Ideal fluids, dynamics of, 6–18 to 6–22
  application of results, 6–22 to 6–26
Identities, algebraic, 2–08
  hyperbolic functions, 2–59, 2–60
  trigonometric, 2–55, 2–56
Igneous rocks, 12–14
Illium, 11–110
Illuminants, spectral distribution of radiant energy in, 9–31
Illumination, 9–29
  elements of, 9–30 to 9–33
  units of, interrelations between, 9–29
Illuminometers, 9–30
Images, electrical, 8–41
  formed by spherical lenses, 9–12
  formed by spherical mirrors, 9–11
  real and virtual, 9–09
Imaginary angles, functions of, 2–60, 2–61
  numbers, 2–06
  roots (equations), 2–15
Impact, 4–37
  axial, on bars, 5–17
  on beams, 5–18
  bending, wood, 12–44 to 12–47
  Charpy, magnesium alloys, 11–78
    zinc-base die-casting alloys, 11–83
  Izod, bronze bearing alloys, 11–87
    copper-base sand-cast alloys, 11–41 to 11–43
Impact, Izard, nickel, 11–71
    structural alloy steels, 11–36
  resistance of steel, 11–31
  rupture from, 5–18
  testing machines, 5–83
  tests, specimens for, 5–86
  tube, 7–29
Impedance, acoustic, measurement of, 9–54
  electrical, 8–51, 8–52, 8–54, 8–55
    equations for a network, 8–51
  mechanical, 9–43
Imperial bushel, 3–21
  gallon, 3–22
  pound (avoirdupois), 3–22
  yard, 3–21
Impressed voltage, 8–12
Improper integrals, 2–89, 2–90
Impulse, 4–36
  turbine, 7–68
Incandescence, 9–30
Incandescent lamps, electric, characteristics of, 9–31
Incense cedar, properties of, 12–44
Inch, 3–21
  circular, 1–131
  miner's, 1–135
  to decimals of foot, 1–28
Imcompressible fluids, *see* Viscous incompressible fluids
Incremental magnetic permeability, 11–107
Indefinite integral, 2–86
Indemnity (contracts), 13–27
Indene resin, 12–54
Indeterminate forms, 2–76
Index, precision, 2–24
  of refraction, 9–03, 9–15
    of gases, 9–15
    of glass, 9–15
    of liquids, 9–15
  relative, of refraction, 9–04
Indicated horsepower, 7–77
  mean effective pressure, 7–67
  work per cycle, 7–67
Indices, Miller, 9–25
Indicial admittance, 8–58
Induced electromotive force, 8–20, 8–21
Inductance, 8–28
  dimensions, 3–08, 3–09
  leakage, 8–30
  mutual, 8–28, 8–50
  self, 8–28, 8–50
  units of, 3–18, 3–30, 3–31, 3–33, 3–34
    conversion of, 1–145
Induction data, non-retentive magnetic materials, 11–103
  dimensions, 3–08, 3–09
  electromagnetic, 8–27 to 8–33
  electrostatic, 3–20, 8–40 to 8–43
  furnace, 10–39
  high-, magnetic materials, 11–109
  law, Faraday's, 3–20
  low-, magnetic materials, 11–109
  non-retentive magnetic materials, 11–103
  regulator oils, 12–71
  residual, high-purity iron, 11–22
    permanent magnet materials, 11–108
  units, 3–30 to 3–32
Inductive capacitance, specific, 8–43
  capacity, specific, insulating materials, 12–60
    of rubber, 12–67
Industrial chemistry, 10–12 to 10–30
  compounds, composition, etc., of, 10–11
Inequalities, 2–10
  symbols for, 1–02

- **Inertia,** 4–02
  - of a body, principal axes of, 4–19
    - product of, 4–19
  - center of, 4–15
  - circle, 4–18
  - and gravitation functions, 4–38
  - moment of, *see* Moment of inertia
  - of a plane surface, principal axes of, 4–17
    - product of, 4–17
- **Infinite series,** 2–80
- **Infra-red** radiation, 9–22, 9–23, 9–34
  - rays, 8–07
- **Infringement of patent rights,** 13–10
- **Ingot** iron, Armco, 11–21
    - properties, 11–25
      - under repeated stress, 5–13
  - nickel, composition and uses, 11–71
- **Initial value of current,** 8–53
- **Inorganic substances,** crystalline form of, 8–62
- **Input indicial admittance,** 8–58
- **Instantaneous value (alternating current),** 8–45
- **Instruments,** acoustical, 9–53, 9–54
  - optical, 9–13, 9–14
  - sealed (contracts), 13–05
  - string, 9–44
- **Insulating** brick, uses of, 12–28 to 12–31
  - materials, acoustic absorption coefficients, 9–51, 9–52
    - electric, 12–58 to 12–74
      - classification of, 12–58
      - electrical properties of, 12–60
      - fibrous organic solid, 12–62 to 12–65
      - liquid, 12–70 to 12–74
      - natural solid, 12–59 to 12–61
      - plastic, 12–68 to 12–70
      - rubber and rubber substitutes, 12–65 to 12–67
      - solid, 12–59 to 12–61
      - vitreous solid, 12–61 to 12–62
    - thermal, 12–27, 12–32, 12–33
      - properties of, 12–34 to 12–38
  - refractory brick, 12–27
  - varnishes, 12–71 to 12–73
- **Insulation, thermal,** 12–32
- **Insulators, electric,** 8–11, 8–63, 12–58
- **Insurance, liability and fire** (contracts), 13–23
- **Integer,** 2–02, 2–06
- **Integral** calculus, 2–86 to 2–99
  - of differential equation, 2–99
  - Duhamel, 8–59
  - roots, 2–15
- **Integrals,** definite, 2–86, 2–88 to 2–92
  - elliptic, 2–87
  - fundamental, 2–87
  - improper, 2–89, 2–90
  - indefinite, 2–86
  - line, surface, and volume, 2–92 to 2–96
  - multiple, 2–89
  - particular, 2–102
  - table of, 1–113 to 1–120
  - uniform convergence of, 2–91
- **Integrating factor,** 2–101
- **Integration,** applications, 2–96 to 2–99
  - approximate, Simpson's rule for, 2–89
  - under integral sign, 2–91
  - of irrational functions, 2–86
  - by parts, 2–86
  - of rational fractions, 2–86
  - of vectors, 2–114, 2–115
- **Integro-differential equations, linear constant-coefficient,** solution of, 2–108 to 2–111
- **Intensity,** electric field, dimensions of, 3–08, 3–09
  - luminous, 9–28
  - magnetic, units of, 3–31, 3–33
- **Intensity,** of radiation, 9–02
  - of rainfall, maximum, 9–59
  - of sound, 9–40, 9–41, 9–48
- **Interest,** 2–22 to 2–26
- **Interference of radiation,** 9–06
- **Internal-combustion engine,** 7–71 to 7–77
  - energy, 7–02
  - resistance to heat flow, 12–32
- **International** candle, 9–28
  - centigrade scale, 3–27
  - electrical units and standards, 3–34 to 3–36
  - joule, 3–25
  - kilo-calorie, 3–26, 3–28
  - Roentgen, 9–34
  - steam-table calorie, 3–26
  - watt, 3–26
- **Interpolation in tables,** 2–06
- **Intersecting lines,** 2–63
- **Intersection of two planes,** line of, 2–72
- **Inverse** hyperbolic functions, 2–60
  - functions of complex numbers, 2–61
    - relations between, 2–60
  - photoelectric effect, 9–25
  - trigonometric functional relations, 2–56
    - functions, 2–55

  impulse, 4-36
  momentum, 4-36
  networks, 8-52
  velocity, units of, conversion factor, 1-135
Linen, 12-62
Lines, angle between two, 2-63, 2-71
  center of gravity of, 4-16, 4-20
  of dielectric flux, 8-38
  of electric force, 8-35
  of electric intensity, 8-35
  Fraunhofer, 9-19
  geometrical construction, 2-44 to 2-45
  induction, 11-103
  intersection, 2-63
  of magnetic field intensity, 8-23
  of magnetizing force, 8-23
  parallel, 2-32, 2-62
  perpendicular, 2-63
Lines, properties of, 4-20
  stream, of electric current, 8-37
Linkages, magnetic flux, 8-21
Linseed oil, 12-55, 12-70
  density of, 6-06
  properties of, 1-124
  viscosity of, 6-07
Lipowitz fusible alloy, 11-110
Liquefaction, lead-tin solder, 11-92
  white metal bearing alloys, 11-86
Liquids, compressed, 7-40
  compressibility of, 6-09, 6-10
  conduction in, 8-67
  definition of, 6-04
  density of, 6-05 to 6-07
  index of refraction (light), 9-15
  magneto-optic rotation of, 9-18
  measure, units of, 1-133
  properties of, 1-123, 1-124
  specific optical rotation, 9-18
  surface tension of, 6-09
  and vapors, 7-31 to 7-52
    H-S (Mollier) diagram for, 7-42
    physical conditions, 7-32
    properties of, 7-32 to 7-40
    P-V diagram for, 7-41
    state changes and processes for, 7-43 to 7-47
    T-S diagram for, 7-42
  viscosity of, 6-07
Liter, 3-23
Litharge, 10-22
Lithium, 10-14
  electrode potentials, values of, 10-37
  properties of, 1-125
Lithopone, properties of, 12-51
Live oak, 12-40
Loads on an airplane in flight, 6-47
  allowable safe, on cast-iron columns, 5-46, 5-47
  on brick piers, maximum, 12-18
  classification of, 5-16
  cross-bending, on columns, 5-45, 5-46
  dynamic, 5-16
  eccentric, on columns, 5-44, 5-45
    on short compression members, 5-44
  energy, 5-16 to 5-18
  increment of, in testing machines, 5-89
  live, stress due to, 5-17
  moving, 5-16
  multiples due to gusts, 6-48
  safe, on simple beams, 5-28
  static, 5-16
    reinforced concrete, allowable unit stresses, 5-62
  sudden, effect of, 5-17
  transverse, on columns, 5-45, 5-46
Loblolly, southern yellow pine, properties of, 12-47
Locust (wood), 12-39
  properties of, 12-36
Lodgepole pine, properties of, 12-47
Logarithmic spiral, 2-69
Logarithms, 2-10 to 2-12
  of exponentials, 1-102 to 1-112
  of hyperbolic functions, 1-102 to 1-112
  of numbers, common, 1-30 to 1-51
    natural (Napierian), 1-52, 1-53
  symbols for, 1-02
  of trigonometric functions, 1-57 to 1-101
London wire gage, 1-151
Longitudinal waves, 9-05
Long-leaf yellow pine, 12-40
  properties of, 12-47
  thermal conductivity of, 12-37

Loss, core, factor for non-retentive magnetic materials, 11-102, 11-104, 11-105
    of non-retentive magnetic materials as a function of gage, 11-106
  dielectric, 8-43, 8-44
  hysteresis, high purity iron, 11-22
  total core, 8-33
Loudness (sound), 9-48
Lubricants, 12-75, 12-76
Lubricated surfaces, laws of friction for, 4-44
Lubricating oils, compressibility of, 6-10
  properties of 12-76
  surface tension, 6-09
  viscosity, 6-07
Lumbang oil, 12-56
Lumber, classification and grading, 12-43
  common, 12-48
  factory, 12-43
  hardwood, grades of, 12-48
  select, 12-48
  shop, 12-43
  soft wood, yard, grades of, 12-48
  standard yard, properties of, 1-167, 1-168
  thermal conductivity, 12-37
  yard, 12-43
Lumen, 9-28
Luminescence, 9-30
Luminosity curves, 9-31
Luminous efficiency, 9-31
  flux, 9-28
  intensity, 9-28
Lummer and Brodhun photometer, 9-30
Lux, 9-29
Lyman series, 9-20

Machines, special tests of, 5-93
  testing, 5-81 to 5-83
    increment of load, 5-89
    for miscellaneous tests, 5-89 to 5-94
    placing specimens in, 5-88
    speed of, 5-89
Machining aluminum, 11-69
Mach's number, 6-16
Maclaurin's form of Taylor's formula, 2-79
Magnesite brick, 12-21
  properties of, 12-22 to 12-25
  uses of, 12-28 to 12-31
Magnesium, 10-15, 11-75, 11-76
  alloys, 11-76 to 11-79
  -base die-casting alloys, 11-84
  carbonate, properties of, 10-11
  electrode potentials, values of, 10-37
  lime, 12-11
  non-aqueous solutions, 10-39
  oxide, 10-15
  properties, 1-125, 1-127
    under repeated stress, 5-14
  sulfate, 10-16
    properties of, 10-11
Magnet materials, permanent, properties of, 11-108
Magnetic circuit, and electrokinetics, 8-18 to 8-35
    Kirchhoff's laws, 8-27
    and magnetizing force, 8-21 to 8-27

- **Minuend,** 2–02
- **Minutes (angle),** 2–32
  - in decimals of a degree, 1–54
  - in radians, 1–54
- **Mirror,** perfect, 9–03
  - spherical, 9–10, 9–11
- **Mistakes,** in contracts, 13–03
- **Mks comprehensive unit system,** 3–16, 3–19
  - system of units, 3–14
    - derived units in the, 3–35
  - thermal unit system, 3–15
- **Models,** ownership of, 13–19
  - theory of, 3–44, 3–45
- **Modulus,** bulk (mechanics of fluids), 6–02
  - of elasticity, 5–05
    - aluminum, 11–59
    - brick piers, 12–18
    - bronze bearing alloys, 11–87
    - copper, 11–43
    - copper-base alloys, wrought, 11–44 to 11–50
    - copper-nickel alloys, 11–72
    - iron, 11–20, 11–25
    - magnesium, 11–76
    - metals, 1–127
    - Monel metal, 11–73
    - nickel, 11–71
    - in sheer, 5–06
    - steel, 11–25
    - stone, 12–15
    - in torsion, wrought iron, 11–21
    - tungsten, 11–80
    - units expressed in, 5–05
    - wood, 12–44 to 12–47
    - zinc, 11–57
  - of resilience, 5–08
  - of rigidity, 5–06
    - aluminum, 11–59
    - metals, 1–127
  - rigidity (mechanics of fluids), 6–02
  - of rupture, 5–22
    - brick, 12–17, 12–18
    - refractories, 12–23
    - stone, 12–15
    - wood, 12–44 to 12–47
  - section, 5–22
    - of beam sections, 5–22
    - of steel sections, 1–153 to 1–163

- **Modulus, section, yard lumber,** 1–167, 1–168
  - shearing, metals, 1–127
  - in torsion, Monel metal, 11–73
    - nickel, 11–71
- **Moh's scale of hardness,** 5–90
- **Moisture** absorption, phenolic sheet materials, 12–68
  - content, in air conditioning, 7–95
    - of wood, 12–44 to 12–47
  - effect on strength of wood, 12–49
  - resistance, insulating varnishes, 12–72
- **Mol,** 7–16
  - -volume, 7–16
- **Mold** (wood), 12–42
- **Molecular weights of gases,** 1–121, 1–122, 10–24
  - of industrial compounds, 10–11
- **Molecules,** 10–03
  - Debye's model of, 9–07
- **Mollier diagram,** 7–09, 7–42
  - (*see also* H–S diagram)
- **Molybdenum,** 11–81, 11–82
  - properties of, 1–126, 1–127
  - steel, mechanical properties of, 11–36
  - structural steel, 11–35
- **Moment,** 2–98, 4–05
  - of airfoils, 6–24
  - bending, 5–20, 5–21
    - of beams of uniform cross-section, 5–26 to 5–28
    - in rectangular flat slabs, 5–56
    - reinforced concrete, 5–66
  - of a couple, 4–07
  - and couples, 4–05 to 4–07
  - diagram of beams, 5–21, 5–26 to 5–28
  - of force, about a line, 4–06
    - about a point, 4–05
    - units of, conversion of, 1–139
  - of inertia, 2–98, 4–17 to 4–19, 5–22
    - of beam sections, 5–22
    - of a body, determination of, 4–19
    - of plane surfaces, determination of, 4–17, 4–18
    - polar, 4–17
      - in shafts, 5–48
    - rectangular, 4–17
    - relation of rectangular and polar, 4–18
    - of steel pipe, 1–165
    - of steel sections, 1–153 to 1–163
    - of surfaces, volumes and bodies, 4–20 to 4–26
    - yard lumber, 1–167, 1–168
  - magnetic, unit of, 3–31
  - principle of, 4–06
  - resisting, 5–20, 5–21
    - in shafts, 5–48
  - static, 4–16
  - twisting, in shafts, 5–48
- **Moments,** theorem of three, 5–35
- **Momentum,** 4–36, 4–37
  - angular, 4–36
  - dimensions of, 3–05
  - and impulse, principle of, 4–36
  - linear, 4–36
  - unit of, 4–36
- **Monel metal,** 11–73, 11–74
  - properties, 11–73, 11–99
    - under repeated stress, 5–14
- **Monochromatic emissive power,** 9–02
- **Monomethylamine,** properties, 1–122
- **Montan wax,** 12–69
- **Mortality,** American experience table of, 2–31
- **Mortar,** 10–14, 12–12, 12–13
  - for laying refractory brick, 12–26
  - thermal conductivity of, 12–34
- **Motion of a body,** 4–31, 4–32
  - curvilinear, 4–27, 4–30, 4–31
    - formulas for, 4–38, 4–39
  - fluid, laws of, 6–15 to 6–18
  - graphs, 4–28, 4–29, 4–31, 4–32
  - Newton's laws of, 4–02
  - of a particle, 4–27
  - plane, 4–31 to 4–34, 4–39, 4–40, 4–43
  - of a projectile, 4–31
  - rectilinear, 4–27 to 4–29
    - formulas for, 4–38
  - simple harmonic, 4–29
  - three-dimensional, 4–31, 4–39, 4–40, 4–43
- **Mottled iron,** 11–17
- **Multiple integrals,** 2–89
  - least common, 2–03
- **Multiplicand,** 2–03
- **Multiplication,** 2–03, 2–05, 2–07
  - by logarithms, 2–10
  - by slide rule, 2–11
  - symbols for, 1–02
- **Multiplier,** 2–03
- **Munk's span factor (aerodynamics),** 6–26
- **Muntz metal,** properties of, 11–46
    - under repeated stress, 5–15
- **Muriatic acid,** 10–28
- **Musical** pitch specification, 9–50
  - scales, 9–49, 9–50
  - sounds, 9–49, 9–50
- **Mutual** impedance, 8–51
  - inductance, 8–28, 8–50
  - induction, coefficient of, 8–28

- **Naphtha,** surface tension of, 6–09
- **Naphthalene,** properties of, 1–124
- **Napierian logarithms,** 2–10
  - of numbers, 1–52, 1–53
- **Natural** cement, 12–02
    - mortar, 12–13
  - comprehensive unit system, 3–19 to 3–21
  - electrical dimension systems, 3–07 to 3–09
  - gas, 12–78
  - logarithms, 2–10
    - of numbers, 1–52, 1–53
  - oils, 12–70 to 12–73
  - periodicities of, 8–57
  - resins, 12–54, 12–55
  - resonance, 8–57
- **Nautical** measure, 1–130
  - mile, 3–21
- **Naval brass,** properties of, 11–43, 11–46
- **Navier-Stokes equations,** 6–15
- **Neat cement,** 12–02, 12–03
- **Neatsfoot oil,** properties of 1–124
- **Negative** electron, 8–02, 8–03
  - eyepiece, 9–13
  - terminal (electricity), 8–11
- **Negligence,** 13–10
- **Neon,** density of, 6–07
  - properties of, 1–122
  - viscosity of, 6–08
- **Nernst's law,** 10–36
- **Networks,** direct-current, 8–14 to 8–16
  - impedance equations for a, 8–51
  - linear, 8–52
- **Neutral** axis of beams, 5–19
  - surface of beams, 5–19
- **Neutralization (chemistry),** 10–06, 10–07
  - value, mineral oils, 12–71
- **Neutron,** 8–03, 8–04
  - radiation, 9–05
- **Newton's** laws of motion, 4–02
  - number, 3–40, 3–43

Nichrome, properties of, 11–99
Nickel, 10–20, 11–70 to 11–72
  aluminum steel, magnetic properties of, 11–108
  bronze, properties of, 11–41
  copper, alloys of, 11–72 to 11–75
  chromium alloys, 11–75
    properties of, 11–99
  -chromium-iron, properties of, 11–99
  -chromium steel, 5–08
  -clad steel, 11–72
  electrode potentials, values of, 10–37
  electroplating with, 11–09
  optical constants, 9–16
  properties of, 1–126, 1–127, 11–71, 11–72, 11–99
    under repeated stress, 5–14
  silver, properties of, 11–48, 11–99
  steel, 11–34
    mechanical properties of, 11–36
  zinc and copper, alloys of, 11–75
Nitric acid, properties of, 1–124, 10–11
  oxide, 10–40
    properties of, 1–122
Nitrobenzene, properties of, 1–124
Nitrocellulose, 12–57, 12–79, 12–80
  lacquers, composition of, 12–57
Nitrogen, 10–25
  density of, 6–07
  dielectric strength of, 12–74
  index of refraction of, 9–15
  insulating properties of, 12–74
  magneto-optic rotation, 9–18
  properties of, 1–122, 7–16, 10–24
  specific heat of, 7–17
  in steel, 11–26
  viscosity of, 6–08
  weight of, 10–11
Nitroglycerin, 12–79, 12–80
Nitrostarch, 12–80
Nitrosyl chloride, properties of, 1–122
Nitrous oxide, properties of, 1–122, 10–24
Noise, 9–53
Nomograms, 2–116 to 2–122
Nonane, properties of, 1–124
Non-aqueous solutions, 10–39
Nonconcurrent forces, 4–03
  composition of, 4–07 to 4–10
  resultant of, 4–10
Noncoplanar forces, 4–03
  composition of, 4–05, 4–09
  resolution of, 4–05
Non-drying oils, 12–71
Non-ferrous metals, endurance limit, values of, 5–12
  under repeated stress, 5–14
Non-flow processes, 7–04
  energy equations for, 7–06, 7–11
Non-magnetic cast iron, 11–18
  steels, 11–101
Non-metallic materials, Section 12
  solids, density of, 1–128
    linear expansion, coefficient of, 1–129
    specific heat of, 1–129
Non-oscillatory current, 8–12
Non-planar angles, 2–34, 2–35
Non-retentive magnetic materials, 11–101 to 11–107
Non-sinusoidal periodic currents and voltages, 8–49, 8–50
Non-systematic physical equations, 3–13
Non-viscous incompressible fluids, 6–18
Normal atmosphere, 3–25
  to curve, 2–67
  to a surface, 2–75
North pole unit (magnetic), 8–26
Northern black cottonwood, properties of, 12–45
  white cedar, allowable unit stresses, 5–29, 5–31
    properties of, 12–45
  white pine, allowable unit stresses, 5–29, 5–31
    properties of, 12–47
Norway pine, 12–40
  allowable unit stresses, 5–29, 5–31
  properties of, 12–47
  thermal conductivity, 12–37
Notation, number, 2–02
Notches, effect of, in members under simple stress, 5–03
  flow over, 6–52
Nova Scotia stone, durability of, 12–16
Nozzles, 6–35, 7–27, 7–28
  efficiency, 7–27
  and orifices, flow of gases through, 7–25, 7–30
    flow of vapors through, 7–47 to 7–52
***N*th degree equation,** 2–14 to 2–16
  special system, 2–19
Nuisance, 13–12
Numbers, classification of, 2–06
  complex, 2–06, 2–111
    flows obtained by, 6–21
    inverse functions of, 2–61
    solutions of electrical networks, 8–54
  logarithms of, common, 1–30 to 1–51
    natural (Napierian), 1–52, 1–53
  notation, 2–02
Numerical parameters, 3–38
  example, 3–39
Nuts and bolts, standard, 1–166

Oak, 12–40

- **Organic** crystals, crystalline form of, 8-62
  - substances in solution, fluorescence of, 9-21
- **Orifice,** flow of fluids through, 6-22, 6-34, 6-35, 6-36
  - and nozzles, flow of gases through, 7-25 to 7-30
    - flow of vapors through, 7-47 to 7-52
- **Orthogonal** projection, 2-33
- **Oscillating quantity (alternating current),** 8-45
- **Oscillation,** center of, 4-42
  - forced, 9-43
  - free, 9-42
  - method of small, 8-60
- **Oscillators,** supersonic, 9-47
- **Oscillatory current,** 8-12
- **Osmium,** 10-19
  - properties of, 1-126
- **Ostwald calorie,** 3-26, 3-28
- **Otto cycle,** 7-72, 7-74, 7-75
- **Ounce (avoirdupois),** 3-22
- **Oxidation,** 10-21
- **Oxide** coatings, 11-09
  - iron, 11-26
- **Oxygen,** compressibility of, 6-10
  - concentration, effect on zinc, 11-54
  - corrosion, 11-07
  - density, 6-07
  - -free high-conductivity copper, 11-40
  - index of refraction of, 9-15
  - magneto-optic rotation of, 9-18
  - properties, 1-122, 7-16, 10-24
  - specific heat, 7-17
  - viscosity, 6-08
  - weight, 10-11
- **Ozokerite,** 12-70
- **Ozone,** 10-40

- **π,** constants containing, 1-11
  - theorem, 3-41
- **Packet,** wave, definition of, 9-05
- **Packings and gaskets,** 12-83
- **Painting,** preparation of surface for, 12-51
- **Paints,** diffuse reflecting power of, 9-16
  - and enamels, 12-50 to 12-52
- **Palladium,** 10-19
  - electrode potentials, values of, 10-37
  - properties of, 1-126, 1-127
- **Palmetto,** 12-40
- **Paper** birch, allowable unit stresses, 5-29, 5-31
    - properties of, 12-44
  - diffuse reflecting power of, 9-16
  - electrical properties of, 12-60
  - insulating, 12-62, 12-63
    - dielectric strength of, 12-64
- **Parabola,** 2-51, 2-64, 2-65
  - geometrical construction of, 2-51, 2-52
  - mensuration formulas for, 2-39
- **Parabolic** cylinder, 2-74
  - horn, 9-47
  - segment, properties of, 4-22
- **Paraboloid,** 2-74
  - mensuration formulas for, 2-43
  - properties of, 4-26
- **Paraffin,** 12-69
  - electrical properties of, 12-60
- **Parallel** circuits, 8-14
  - lines, 2-32, 2-62
  - planes, 2-72
- **Parallelepiped,** mensuration formulas for, 2-41
  - properties of, 4-23
- **Parallelepipedon law,** 4-05
- **Parallelogram,** 2-32
  - law, 4-03
  - mensuration formulas for, 2-37
- **Paramagnetic substances,** 8-25
- **Parameters,** class, and similarity conditions, 3-37 to 3-40
  - electric circuit, 8-50
- **Paris green,** 10-27
- **Parkerizing,** 11-09
- **Parson's turbine,** 7-68
- **Partial** derivatives, 2-78, 2-79
  - differential equations, 2-99, 2-104 to 2-108
  - fractions, 2-08
  - pressure, of gases in a mixture, 7-86
    - of vapor in atmosphere, 7-93
- **Particles,** positive, 8-04
- **Particular integral,** 2-102
- **Parties to a contract,** 13-02
- **Partnerships,** competence of (contracts), 13-02
- **Paschen series,** 9-20
- **Patent rights,** infringement of, 13-10
  - and royalties, 13-19
- **Pauli exclusion principle,** 8-63
- **Payments,** specification for, 13-22, 13-23
- **Peak factor,** 8-46
- **Pearlite,** 11-27
- **Pearlitic cast iron,** 11-18
- **Peat,** 12-77
- **Pecan hickory,** allowable unit stresses, 5-29, 5-31
  - properties of, 12-46
- **Peltier effect,** 8-10
- **Pendulum,** 4-42
  - ballistic, 4-37
- **Pentagon,** geometrical construction, of, 2-49
- **Pentane,** properties of, 1-124, 7-82
- **Percentage,** 2-03
- **Percussion,** center of, 4-41
- **Performance of contract,** 13-05, 13-06
  - measures of, 7-55 to 7-58
- **Perigon,** 2-32
- **Perilla oil,** 12-55
- **Perimeters of similar figures,** 2-36
- **Period (alternating current),** 8-45
- **Periodic currents and voltages,** non-sinusoidal, 8-49 to 8-50
  - quantities (alternating current), 8-45
- **Periodicities,** natural, 8-57
- **Periodicity of current,** 8-53
- **Permalloy,** magnetic properties of, 11-102
  - normal induction data, 11-103
- **Permanent magnet materials,** 11-107 to 11-109
  - mold castings, aluminum, 11-62, 11-63
- **Permeability,** 8-24
  - absolute, 3-20, 3-30
    - dimensions, 3-08, 3-09
    - of free space, 3-30

Permeability, determination of physical properties from, 5–93
  high purity iron, 11–22
  incremental, 11–107
  of iron, 8–26
  non-retentive magnetic materials, 11–102
  of steel, 8–26
  units, 3–16, 3–18
Permeance, magnetic, 8–27
Perminvar, 11–109
Permits (contracts), 13–19
Permittivity, 3–20, 3–29
  units, 3–18
Permutations, 2–21
Permutits, 10–15
Perpendicular lines, 2–63
Peter's formula, 2–126
Petroleum, crude, 12–78
  properties of, 1–124
***p*H and acidity,** 10–08
***P-H* diagram** for freon, 7–82
Phase, 8–47
  angle, 4–29
  changes in solid solutions, 11–03
  resonance, 8–57
Phenol-formaldehyde resins, 12–54
  index of refraction, 9–15
  properties of, 1–123
Phenolic sheet materials, properties of, 12–68
Phonometer, Webster's, 9–54
Phosgene, properties of, 1–121
Phosphine, properties of, 1–122
Phosphor bronze, properties of, 11–46
Phosphorescence, 9–04, 9–21
Phosphoric acid, 10–26
  properties of, 10–11
Phosphorus, 10–26
  effect on cast iron, 11–17
  pentoxide, 10–26
Phot, 9–29
Photochemical actions (ultraviolet radiation), 9–34
Photoconductivity, 8–66, 9–23
Photoelasticity, 9–17
Photoelectric cells, 9–24
  effect, 8–07, 8–66, 9–08, 9–23
    inverse, 9–25
Photoelectricity, 9–23
Photographic action of x-rays, 9–24
Photography, 9–21
Photoionization, 9–24
Photometer, Bunsen, 9–30
  Lummer and Brodhun, 9–30
Photometry, 9–28 to 9–30
Photon, 8–03, 8–04, 9–08
  gas, 9–08
Photovoltaic effect, 8–66
Physical dimension system, 3–05
  equations, 3–03, 3–13
    dimensional homogeneity of, 3–36, 3–37
    style of writing, 3–37
  and mathematical tables, Section 1
  metallurgy, 11–03
  properties, determination from magnetic permeability, 5–93
    of materials, 1–121 to 1–129
  quantities, 3–36
    and their relations, 3–02, 3–03
    symbols for, 1–04 to 1–11
  similarity, 3–37
  units and standards, Section 3
Physics, 3–02
  of radiation, 9–15 to 9–26
Physiological acoustics, 9–48, 9–49
Physiology of radiation, 9–26 to 9–35
Picric acid, 12–80
Piers, brick, test of, 12–18
Piezoelectric effect, 8–10
Pig iron, 11–13 to 11–15
Pigments, 12–50, 12–51
  diffuse reflecting power of, 9–16
Pine, 12–40
  allowable unit stresses, 5–29, 5–31
  column formula constants, 5–41
  properties of, 12–47
  thermal conductivity of, 12–37, 12–38
  tar, 12–70
Pint, 3–22
Pipe couplings, steel, dimensions of, 1–165
  dimensions and properties of, 1–165
  flow, of gases through, 7–23 to 7–25
    of viscous incompressible fluids in, 6–28 to 6–33
  stationary flow of viscous fluid through a, 3–39
Pitch, musical specifications, 9–50
  pocket (wood), 12–42
  stearin, 12–70
Pitot-static tube, 6–22
  tube, 7–29, 9–65
Pivot friction, 4–45, 4–46
Planck's constant, 8–03
Plane analytic geometry, 2–61 to 2–70
  angles, 2–32
    circular functions of, 2–53 to 2–56
      table of, 1–57 to 1–101
    units of, conversion factor for, 1–134
  area, 2–97
  curves, higher, 2–66 to 2–70
    properties of, 4–20
  curvilinear figures, 2–33, 2–34
    mensuration formulas for, 2–38 to 2–40
  equation of, 2–71
  geometry, symbols for, 1–02
  motion, 4–31 to 4–34, 4–39, 4–40, 4–43
  point, line (solid analytic geometry), 2–70 to 2–72
  -polarized light, production of, 9–17
  rectilinear figures, 2–37, 2–38
  surface, properties of, 4–20 to 4–22
  tangent, 2–74
Planing coefficient, 6–49
  surfaces, resistances of, 6–50
  vessels, 6–50
Plans (contracts), 13–13
Plaster, 12–13, 12–14
  board, thermal conductivity of, 12–36
  neat, gypsum, 12–14
  of Paris, 10–14
    properties of, 10–11
  Portland cement, 12–13
  thermal conductivity of, 12–36
Plasticity, definition of, 5–06
Plasticizers, 12–57
Plates, copper, aluminum and brass, weight of, 1–150
  smooth flat, flow along, 6–37
  stresses in, 5–53 to 5–55
Platinum, 10–19
  properties of, 1–126, 1–127
Plumber's solder, 11–110
Plywood, 12–49
  tensile strength of, 12–49
Point, 2–67
  and line (plane analytic geometry), 2–61 to 2–63
  line and plane (solid analytic geometry), 2–70 to 2–72

Point, perpendicular distance, from line, 2–62
    from plane, 2–71
Poise, 6–03
Poisson's ratio, 5–06
  aluminum, 11–59
  metals, 1–127
  tungsten, 11–80
Polar coordinates, 2–61, 2–70, 2–73
  moment of inertia of, 4–17
    in shafts, 5–48
  radius of gyration in shafts, 5–48
  and rectangular moments of inertia, relation of, 4–18
Polarization of light, 9–17, 9–18
  of radiation, 9–06
Poles, magnetic, 8–26
Pollution (riparian rights), 13–11
Polygonal angles, table of, 2–50
Polygons, 2–32, 2–33
  of force, 4–04, 4–07, 4–08
  geometrical construction, 2–49, 2–50
  mensuration formulas for, 2–38
  properties, 4–21
  spherical, 2–36
    mensuration formulas for, 2–43
  string (or funicular), 4–07
Polyhedral angle, 2–34
Polyhedron, 2–35
  mensuration formulas for, 2–41
Polytropic atmosphere, 6–12
  law, 6–12
Polytropics, 7–21
Ponderosa pine, properties of, 12–47
Poplar, 12–40
  allowable unit stresses, 5–29, 5–31
  plywood, 12–49
  properties of, 12–47
Porcelain, 12–61
  electrical properties of, 12–60
Porosity, refractories, 12–23
Port Orford cedar, allowable unit stresses, 5–29, 5–31
  column formulas constants, 5–41
  properties, 12–45
Portland cement, 12–02
  lime mortar, 12–13
  mortar, 12–12
  plaster, 12–13
Positive electron, 8–02, 8–04
  eyepiece, 9–13
  particles, 8–04
  radiation, 9–04
  terminal (electricity), 8–11
Positron, 8–02, 9–04
Potassium, 10–13, 10–14
  carbonate, 10–14
    properties of, 10–11
  chlorate, properties of, 10–11
  chloride, 10–13
    properties of, 10–11
  chromate, properties of, 10–11
  cyanide, properties of, 10–11
  electrode potentials, values of, 10–37
  ferricyanide, 10–20
    properties of, 10–11
  ferrocyanide, 10–20
    properties of, 10–11
  hydroxide, 10–14
    properties of, 10–11
  manganate, 10–22
  nitrate, 10–14
    properties of, 10–11
  permanganate, 10–22
    properties of, 10–11
Potassium, properties of, 1–126, 1–127
  sulfate, 10–14
    properties of, 10–11
Potential, electric, coefficients, 8–40, 8–41
    difference, units of, 3–29, 3–32, 3–33
    difference of, 8–10, 8–11, 8–36
    drop, instantaneous, through a coil, 8–29
    units of, 3–18
      conversion of, 1–143
  electrode, of metals, values of, 10–37
  energy, 4–35
    mechanical, 7–02
  gradient, electric, unit of, 3–30
      units of conversion, of, 1–143
    magnetic, unit of, 3–32
      units of conversion of, 1–147
  ionizing, 8–67
  magnetic, 8–26
    units of, 3–31
      conversion of, 1–146
  velocity (fluid dynamics), 6–19
Potentials, currents, electrostatic fields, 8–35 to 8–38
Pound, 3–22, 4–34
  -foot, 3–25
  -force, 3–24
Poundal, 3–24
  -foot, 3–25
Pour test, mineral oils, 12–71
Power, apparent, 8–47
  conversion factors, 7–03
  corresponding to non-sinusoidal currents and voltages, 8–50
  diffuse reflecting, of non-metallic materials 9–16
  dimensions of, 3–05, 3–08, 3–09
  electric, 8–46, 8–47
    calculation of, 8–56
  and energy, electric, 8–16 to 8–19
  energy, force, 3–24 to 3–26
  energy and work, 4–34 to 4–36
  factor, 8–46, 8–47
    angle, 8–48
    phenolic sheet materials, 12–68
  of a force, 4–35
  mechanical, 7–03
  monochromatic, emissive, 9–02
  penetrating, of radiation, 9–08
  reactive, 8–47, 8–48
  resolving, 9–19
  series, 2–80
    region of convergence of, 2–81
  spectral distributions of emissive, 9–02
  of a torque, 4–35
  total emissive, 9–02
  units of, 3–14, 3–16, 3–25, 3–26, 4–35
    conversion of, 1–141
Powers of a number, 2–03, 2–07
  by logarithms, 2–11
  by slide rule, 2–12
  symbols for, 1–02
  tables of, 1–12 to 1–28
Poynting vector, 3–20
Practical comprehensive unit systems, 3–16, 3–19
  dimension systems, 3–12
  similarity, 3–37
  units, so-called absolute, 3–18, 3–33
    derived theoretical, 3–33
Prandtl boundary layer theory, 6–27
  formula, 6–31
  -Karman law, 6–31
Precipitation (chemistry), 10–09, 10–10
  relative humidity, annual means, 9–61

Precision of measurements, 2–123 to 2–128
Preheaters, air, 7–71
Pre-ignition, 7–72
Preservation of timber, 12–43
Pressboard, 12–62

  fundamentals, 9-02 to 9-04
  geometry of, 9-09 to 9-14
    bibliography of, 9-14
  heat, measurement of, 9-23
  infra-red, 9-22, 9-23
    physiological action, 9-34
    sources of, 9-34
    transmission of, 9-23
  intensity of, 9-02
  nature of, 9-02
  neutron, 9-05
  penetrating power of, 9-08
  physics of, 9-15 to 9-26
    bibliography of, 9-25, 9-26
  physiology of, 9-26 to 9-35
    bibliography of, 9-35
  positive, 9-04
  proton, 9-04
  theory of, 9-02 to 9-09
    bibliography of, 9-09
  therapy of, 9-33 to 9-35
  thermal, 9-04, 9-22, 9-23
    spectral distribution of, 9-22
  types of, 9-04, 9-05
  ultraviolet, 9-21
    physiological action, 9-34
    sources of, 9-34
  velocity of, 9-02
  wave, 9-04
  wave aspects of, 9-05 to 9-08
Radical (chemical), 10-06
Radio waves, 8-07
Radioactivity, 9-05, 10-06
Radiography, 9-25
Radiometer, 9-23
Radius of curvature, 2-67, 5-22
  of gyration, beam sections, 5-22
    of a body, 4-19
    columns, 5-37
    plane surface, 4-17
    polar in shafts, 5-48
    steel pipe, 1-165
    steel sections, 1-153 to 1-163
    surfaces, volumes and bodies, 4-20 to 4-26
    vector, 2-70
  mean hydraulic, 6-32, 6-51
Rain gage, 9-58
Rainfall, 9-58, 9-59
Raman effect, 9-20
Ramsden eyepiece, 9-13
Rankine cycle, 7-52 to 7-55
Rankine's column formula, 5-38, 5-39
  for eccentrically loaded columns, 5-45
  for transverse loaded columns, 5-45
Rape oil, viscosity of, 6-07
Rapeseed oil, properties of, 1-124
Rate of doing work, units of, conversion of, 1-141
  of interest, 2-22
Rateau turbine, 7-68
Ratio and proportion, 2-09
Rational fraction, 2-08, 2-09
    integration of, 2-86
  numbers, 2-06
  units, 3-18, 3-32
Rationalized unit systems, 3-16, 3-17
Rawhide, 12-83
Rayleigh disk, 9-53
  Lord, method of (dimensional analysis), 3-41
      example, 3-42
  scattering, 9-40
Rays, actinic, 9-21
  alpha (α), 9-05, 10-06
  beta (β), 9-04, 10-06
  cosmic, 8-07, 9-04
  gamma (γ), 9-04, 10-06
  residual, 9-23
Reactance, 8-55
Reaction, 4-02
  chemical, 10-04, 10-10
  at supports of beams, 5-19
Reactive power, 8-47, 8-48
Real image, 9-09
  numbers, 2-06
Réaumur temperature scale, 3-27
Receiver of sound, horn as, 9-47
Reciprocals, 1-12 to 1-28, 2-03
Records (contracts), 13-13
Rectangle, 2-32
  geometrical construction of, 2-49
  mensuration formulas for, 2-37
  properties of, 4-21
Rectangular and angular acceleration, relation between, 4-32
  and angular velocities, relations between, 4-32
  beams of uniform strength, 5-32
    reinforced concrete, 5-63 to 5-68
  coordinates, 2-61, 2-113
  flat plates, stresses in, 5-54, 5-55
  moment of inertia, 4-17
  and polar moments of inertia, relation of, 4-18
Rectilinear figures, plane, mensuration formulas, 2-37, 2-38
  motion, 4-27 to 4-29
    formulas for, 4-38
Red alder, properties of, 12-44
  ash (wood), 12-39
  brass, properties of, 11-42, 11-44
  cedar, 12-39
    allowable unit stresses, 5-29, 5-31
    column formula constants, 5-41
    properties of, 12-44
  cypress, thermal conductivity of, 12-38
  gum (wood), allowable unit stresses, 5-29, 5-31
    plywood, 12-49
    properties of, 12-45
  lead, 10-22
  maple, allowable unit stresses, 5-29, 5-31
    properties of, 12-46
  oak, 12-40

- **Red oak,** allowable unit stresses, 5–29, 5–31
    - column formula constants, 5–41
    - properties of, 12–47
    - thermal conductivity of, 12–38
  - pine, 12–40
  - spruce, 12–40
    - allowable unit stresses, 5–29, 5–31
    - column formula constants, 5–41
- **Reduction,** of area in tensile tests, of bronze bearing alloys, 11–87
    - copper-base alloys, 11–41 to 11–43
    - copper-nickel alloys, 11–72
    - determination of, 5–88
    - iron, 11–20
    - metals, 1–127
    - molybdenum, 11–38
    - Monel metal, 11–73, 11–74
    - nickel, 11–71
    - stainless steel, 11–38
    - steel, 11–25
    - structural alloy steels, 11–36
  - chemistry, 10–21
  - in height, copper-base alloys, 11–41 to 11–43
- **Reduction, stadia,** 1–55, 1–56
- **Redundant frames,** 4–14
- **Redwood,** 12–40
  - Admiralty viscosimeter, formula for, 6–08
  - allowable unit stresses, 5–29, 5–31
  - column formula constants, 5–41
  - plywood, 12–49
  - properties of, 12–47
  - thermal conductivity of, 12–37
  - viscosimeter, formula for, 6–08
- **Reflecting** power, diffuse, of non-metallic materials, 9–16
  - surfaces and media, 9–39
  - telescope, 9–14
- **Reflection** of light, 9–09, 9–32, 9–33
  - radiation, 9–03
  - sound, 9–38, 9–39
  - ultraviolet, 9–21
  - x-rays, 8–08
- **Reflectivity,** 9–03
  - aluminum, 11–59
  - magnesium, 11–76
- **Refracting telescope,** astronomical, 9–14
- **Refraction,** index of, 9–03, 9–15
    - of gases, glass, liquids, 9–15
    - of pigments, 12–51
  - of light, 9–09, 9–15, 9–17
  - radiation, 9–03
  - sound, 9–38, 9–39
  - ultraviolet, 9–21
  - x-rays, 8–08, 9–24
- **Refractive index,** *see* Refraction, index of
- **Refractivity (radiation),** 9–03
- **Refractories,** 12–20 to 12–31
  - properties of, 12–22 to 12–25
- **Refractoriness,** 12–24
- **Refractory brick,** applications of, 12–28 to 12–31
  - common types of, 12–20, 12–21
  - mortars for laying, 12–26
- **Refrigerants,** properties of, 7–82
- **Refrigeration,** 7–77 to 7–85
  - absorption system, 7–84, 7–85
  - air compression system, 7–82 to 7–84
  - Carnot cycle, 7–77
  - performance and capacity, 7–77 to 7–79
  - vapor compression system, 7–79 to 7–82
- **Regenerative feed-heating cycle,** 7–61
- **Regions,** connectivity of (calculus), 2–93
- **Regulations (contracts),** 13–19
- **Reheating cycle,** 7–61
- **Reinforced concrete,** 5–59 to 5–80
  - allowable unit stresses under static loads, 5–62
  - beams and slabs, 5–62 to 5–72
    - bending moment and external shear, 5–66
    - bond of, 5–66
    - shearing stress in, 5–65
    - web reinforcement, 5–65
  - columns, 5–72 to 5–75
    - effective area of, 5–73
    - footings, 5–75 to 5–78
    - formulas, 5–73
  - cored columns, 5–73
  - footings, 5–75, 5–78
  - girderless or flat slab construction, 5–78 to 5–80
  - principles of design, 5–60 to 5–62
  - rectangular beams, example, 5–67, 5–68
    - and solid slabs, flexure formulas for, 5–63, 5–64
  - reinforcements for, 5–59
  - ribbed floor construction, 5–71, 5–72
  - slabs, 5–68, 5–69
  - specifications, 5–59, 5–60
  - spiraled columns, 5–73 to 5–75
  - square column footings, 5–77
  - T-beams, 5–69 to 5–71
    - flexure formulas for. 5–64, 5–65
  - tied columns, 5–73, 5–74
  - uses, general, 5–59
- **Reinforcement (concrete),** 5–59
  - anchorage of, 5–66
  - bars, areas, weights and perimeters of, 5–60
    - properties of, 5–61
  - insulation of, 5–60
  - placing of, 5–60
  - stirrups, 5–65
  - web, 5–65
- **Relative** humidity, 7–89, 7–93, 7–94, 9–61
  - index of refraction, 9–04
  - visibility, 9–26
- **Reluctance (magnetic),** 8–22, 8–26, 8–27
  - dimensions, 3–08, 3–09
  - units of, 3–18, 3–31, 3–33
- **Rent,** annual, 2–26
- **Repeated stress,** 5–11 to 5–16
  - testing machine, 5–83
- **Repeating section,** riveted joints, 5–58
- **Residual** charge, 8–43
  - induction, high-purity iron, 11–22
    - permanent magnet materials, 11–108
  - magnetism, 8–31
  - rays, 9–23
- **Resilience,** 5–08
  - modulus of, 5–08
- **Resin products,** synthetic, 12–54, 12–68, 12–69
- **Resins,** function of, in varnish, 12–52
  - lacquers, 12–57
  - varnishes, 12–54, 12–55
- **Resistance,** acoustic specific, 9–38, 9–40
  - air, of automobiles, 9–69
    - of trains, 9–69
  - electric conductance and Ohm's law, 8–12 to 8–14
    - dimensions of, 3–08, 3–09
    - effective, 8–17
    - materials, electrical, properties of, 11–99
    - metals, effect of temperature on the, 8–66
    - method for determining endurance limit, 5–92
    - in parallel, 8–14
    - in series, 8–14
    - specific, 8–13, 8–38
      - (*see also* Resistivity)

Resistance, electric conductance and Ohm's law, specific, carbon brushes, 11–100
   gutta percha, 12–67
   rubber, 12–66
  temperature coefficient of, 8–13
   (*see also* Resistivity, temperature coefficient of)
  units of, 3–16, 3–18, 3–30, 3–32, 3–33, 3–34
   conversion of, 1–144
 fluid, of spheres and ellipsoids, 6–40
  of surface vessels, 6–48 to 6–51
 impact, of steel, 11–31
 thermal, internal, 12–32
 in vibrating systems, 9–42
Resisting moment, in beams, 5–20, 5–21
  in shafts, 5–48
 shear, 5–20
Resistivity, electric, 8–13, 8–38
  aluminum, 11–59
  aluminum wire, 11–97, 11–98
  copper, 11–43
  copper-base alloys, wrought, 11–45 to 11–51
  copper-nickel alloys, 11–72
  copper wire, 11–93 to 11–95
  insulating materials, 12–60
  magnesium, 11–76
  magnesium alloys, 11–78
  metals, 1–125, 1–126
  molybdenum, 11–81
  Monel metal, 11–73
  nickel, 11–71
  non-retentive magnetic materials, 11–102
  resistance materials, 11–99
  stainless steel, 11–38
  temperature coefficient of, of aluminum, 11–97
   copper, 11–40, 11–93, 11–96
   copper-nickel alloys, 11–72
   gutta percha, 12–67
   magnesium, 11–76
   metals, 1–125, 1–126
   molybdenum, 11–81
   Monel metal, 11–73
   nickel, 11–71
   resistance materials, 11–99
   tungsten, 11–80
   zinc, 11–53
  tungsten, 11–80
  units of, 3–18
   conversion of, 1–144
  zinc, 11–53
 thermal, building and insulating materials, 12–34 to 12–38
  refractories, 12–25
  wood, 12–37, 12–38
Resistor furnace, 10–39
 materials, metallic, 11–98, 11–99
Resolution of concurrent forces, 4–03 to 4–05
 of non-concurrent forces, 4–10
 truss analysis by method of joint, 4–15
Resolving power of a spectroscope, 9–19
Resonance of electrical circuits, 8–56
 frequency, sound, 9–43
 zinc, 11–53
Restitution, coefficient of, 4–37
Restrained beams, 5–19, 5–25
Resultant of concurrent forces, 4–05
 forces, 4–03
 non-concurrent forces, 4–10
Retentive magnetic materials, 11–101, 11–107 to 11–109
Reverberation of sound, 9–39, 9–50
Reversed Carnot cycle, 7–77
Reversible adiabatic, 7–10, 7–20, 7–45
 cycle, 7–06, 7–11
 processes, 7–04, 7–10, 7–11
Reversibility, 10–07
Reynolds' experiments, 6–29
 number, 3–40, 6–15, 6–29
Rhodium, 10–19
 properties of, 1–126, 1–127
Rhomboid, 2–32
 mensuration formulas for, 2–37
Rhombus, 2–32
 mensuration formulas for, 2–37
Riccati's equation, 2–101
Riehle testing machine, 5–81
Rigidity modulus (mechanics of fluids), 6–02
 modulus of, 5–06
  aluminum, 11–59
  metals, 1–127
Riparian rights, 13–11, 13–12
Rise-in-temperature method for endurance limit, 5–91
Ritter's rational column constant, 5–39
Riveted joints, 5–58
Rms value of alternating current, 8–46
 value of non-sinusoidal currents, 8–50
Robinson anemometer, 9–64, 9–65
Rock elm, allowable unit stresses, 5–29, 5–31
  properties of, 12–45
 salt, grating spacings, 9–25
 wool, thermal conductivity of, 12–35
Rocks, 12–14, 12–15
Rockwell hardness, aluminum alloys, sand-cast, 11–61
 copper-base alloys, wrought, 11–45 to 11–51
 magnesium alloys, 11–78
 nickel, 11–71
 testing machine, 5–89
Rods, properties of, 4–23
 reinforcement, *see* Reinforcement
Roentgen, international, 9–34
Rolled zinc, 11–56 to 11–58
Rollers, stresses in, 5–55, 5–57
Rolling friction, 4–44, 4–45
 steel, 11–29
Roman notation, 2–02
Roofing, zinc sheet, 11–57, 11–58
  thermal conductivity of, 12–36
Roots, 2–03, 2–07
 cube, to extract, 2–04
 by logarithms, 2–11
 of *n*th degree equations, 2–14 to 2–16
 by slide rule, 2–12
 square, to extract, 2–04
 symbols for, 1–02
 table of, 1–12 to 1–28
Ropes (unit of length), 1–130
Rose's fusible alloy, composition and melting point of, 11–110
Rosin, electrical properties of, 12–60
Rot (wood), 12–42
Rotating beam method, 5–12
Rotation, 4–31, 4–39 to 4–42
 magnetic, 9–18
 magneto-optic, of non-metallic materials, 9–18
 optical, 9–17
Roughness number, various materials, 6–51
Round steel bars, size and weight of, 1–164
Routh and Hurwitz, test functions of, 8–60
Royalties (contracts), 13–19
Rubber, electrical properties of, 12–60
 and rubber substitutes, 12–65 to 12–67
Rubbing varnish, 12–56
Rubidium, 10–14

- **Rule, slide**, 2–11, 2–12
- **Rupture from impact**, 5–18
  - modulus of, 5–22
    - brick, 12–17, 12–18
    - refractories, 12–23
    - stone, 12–15
    - wood, 12–44 to 12–47
  - point of, 5–04, 5–05
  - work required for, 5–08
- **Rust-resisting metals**, 11–10
- **Ruthenium**, 10–19
- **Rydberg constant**, 9–20

- **Sabine's formula**, 9–50
- **SAE numbering system** of steel alloys, 11–34
- **Safety, factor of**, 5–10, 5–11
- **Salts**, acid, 10–13
  - acids and bases, 10–06 to 10–08
  - properties of various, 10–11
  - solubility of, in water, 10–09
- **Samples**, contractor's, 13–19
- **Sand-cast** aluminum alloys, 11–60 to 11–63
  - copper-base alloys, 11–41 to 11–43
- **Sand-lime brick**, 12–17
- **Sandstone**, 12–15, 12–16
- **Saponification** value of lubricants, 12–76
- **Saturated liquid and vapor**, 7–32
  - line, 7–41
  - steam, pressure table, 7–33 to 7–35
- **Saturation** of a color, 9–27
  - magnetic, iron, 11–22
    - non-retentive magnetic materials, 11–102
  - region of vapors, 7–41
  - and solubility, 10–08
  - temperature of emission, 8–06
  - voltage of emission, 8–05
- **Sawdust**, thermal conductivity of, 12–35
- **Sawing timber**, 12–40
- **Saybolt** Universal viscosimeter, formula for, 6–08
  - viscosity, 6–03
    - of lubricants, 12–76
- **Scalar product**, 2–113
- **Scale** effect (fluid dynamics), 6–17
  - factors (models), 3–44
- **Scales**, musical, 9–49, 9–50
- **Scattering** of radiation, 9–03
  - sound, 9–40
  - x-rays, 8–08
- **Scavenger blower**, 7–73
- **Schiller's value**, 6–29
- **Scleroscope hardness**, aluminum alloys, 11–67
  - carbon brushes, 11–100
  - nickel, 11–71
  - testing machine, 5–90
- **Screw-power**, compound-lever testing machine, 5–81
  - threads, standard, 1–166
- **Sealed instruments (contracts)**, 13–05
- **Seasoning timber**, 12–40, 12–41
- **Secant**, 2–54
  - of a circle, 2–33
  - formula, column, 5–38
    - eccentric loads, 5–45
    - transverse loads, 5–46
  - hyperbolic, 2–59
- **Second** law energy balance, 7–60
    - of thermodynamics, 7–07
  - unit of angle measurement, 2–32
  - unit of time, 3–23
- **Section, dangerous**, of beams 5–21
  - modulus, 5–22
    - beam sections, 5–22
- **Section, modulus, steel sections**, 1–153 to 1–163
    - yard lumber, 1–167, 1–168
  - repeating, riveted joints, 5–58
- **Sections of beams, properties of**, 5–22
  - conic, 2–64 to 2–66
  - method of, analysis by, 4–14
  - structural aluminum, 1–153
    - steel, 1–153 to 1–163
  - wing, 6–41
- **Sector** of a circle, 2–33
  - circular, mensuration formulas for, 2–39
    - properties of, 4–22
  - spherical, 2–36
    - mensuration formulas for, 2–42
    - properties of, 4–25
- **Securities**, issue of, 13–13
- **Sedimentary rocks**, 12–14, 12–15
- **Seebeck effect**, 8–10
- **Segments**, circular, 1–28, 1–29
    - mensuration formulas for, 2–39
    - properties of, 4–22
  - of a curve, 2–33
  - parabolic, properties of, 4–22
  - spherical, 2–36
    - mensuration formulas for, 2–43
    - properties of, 4–25
- **Select lumber**, 12–48
- **Selenium**, 10–29
- **Self-inductance**, 8–28, 8–50
- **Semicircle**, mensuration formulas for, 2–39
  - properties of, 4–22
- **Semi-Diesel cycle**, 7–73
- **Semi-drying oils**, 12–56
- **Semi-red brass**, properties of, 11–42
- **Sense of a force**, 4–02
- **Series** circuits, 8–14
  - expansion of functions, 2–79 to 2–84
  - -parallel circuits, 8–15
  - special, 2–19, 2–20
- **Serpentine**, average strength, 12–15
- **Set method**, determination of yield strength, 5–87
- **Shafts**, 5–48 to 5–52
- **Shake** (wood), 12–42
- **Shale building brick**, strength of, 12–18
- **Shape factor** (wind pressure), 9–66 to 9–69
- **Shavings**, thermal conductivity of, 12–35
- **Shear**, 5–02
  - allowable unit stress, reinforced concrete, 5–62
    - riveted joints, 5–58
    - structural steel, 5–24
    - timber, 5–31
  - due to axial stress, 5–09
  - combined with tension or compression, 5–10
  - deflection due to, 5–23
  - diagram, 5–20
  - external, reinforced concrete, 5–66
  - horizontal, 5–21
    - example in beam design, 5–30
    - in timber beams, 5–25
  - modulus of elasticity in, 5–06
  - due to normal stress at right angles, 5–09
  - resisting, 5–20
  - tensile or compression stress due to, 5–09
  - vertical, 5–20
    - of beams of uniform cross-section, 5–26 to 5–28
  - web, in beams, 5–23
- **Shearing** modulus, metals, 1–127
  - strength, aluminum sand-cast alloys, 11–61
    - aluminum wrought alloys, 11–67
    - copper-base wrought alloys, 11–45 to 11–51
    - magnesium alloys, 11–78
    - stone, 12–15

- **Shearing** strength, wood, 12–44 to 12–47
    - zinc, 11–57
    - zinc-base die-casting alloys, 11–83
  - stress, design for aluminum alloys, 11–68
    - maximum, in members subjected to torsion, 5–50, 5–51
    - reinforced concrete, 5–65
    - in solids under pressure, 5–57
    - in terms of horsepower (shafts), 5–49
- **Sheet,** copper, aluminum and brass, weight of, 1–150
  - materials, laminated phenolic, properties of, 12–68
  - metal gages, 1–148 to 1–150
- **Shellac,** 12–70
  - electrical properties of, 12–60
  - spirit varnish, 12–56
  - water varnish, 12–57
- **Sherardizing,** 11–55
- **Shingles,** thermal conductivity of, 12–36
- **Shipping measure,** 1–133
- **Ships,** surface, 6–48
- **Shop lumber,** 12–43
- **Shore scleroscope,** 5–90
- **Short-leaf yellow pine,** 12–40
  - properties of, 12–47
  - thermal conductivity of, 12–38
- **Shot,** nickel, composition and uses of, 11–71
- **Shrinkage,** bronze bearing alloys, 11–87
  - cast iron, 11–18
  - fits, cylinders, 5–53
  - timber, 12–41
- **Signal bronze,** properties of, 11–46
- **Signals of U. S. Weather Bureau,** 9–55
- **Silica,** 10–30
  - brick, 12–21
    - properties of, 12–22 to 12–25
    - uses of, 12–28 to 12–31
- **Silicates,** 10–30
- **Silicic acid,** 10–30
- **Silico-manganese steel,** properties of, 11–36
- **Silicon,** 10–30
  - brass, properties of, 11–41, 11–42
  - brick, 12–27
  - carbide, 10–30
  - dioxide, 10–30
  - effect, on cast iron, 11–17
    - on steel, 11–26
  - -manganese steel, 11–37
    - mechanical properties of, 11–36
  - steel, 11–35
    - magnetic induction of, 11–103
    - magnetic properties of, 11–102
    - mechanical properties of, 11–36
  - tetrafluoride, properties of, 1–122
- **Silicospiegel,** analysis of, 11–13
- **Silk,** 12–62
  - dielectric strength, 12–64
- **Silver,** 10–18
  - bromide, 10–18
  - chloride, 10–18
  - electrode potentials, value of, 10–37
  - electroplating with, 11–09
  - German, properties under repeated stress, 5–14
  - iodide, 10–18
  - maple, allowable unit stresses, 5–29, 5–31
    - properties of, 12–46
  - nitrate, 10–18
    - properties of, 10–11
  - optical constants of, 9–16
  - properties of, 1–126, 1–127
  - solders, 11–91, 11–92
  - sulfide, 10–18
- **Similarity** conditions and **class parameters,** 3–37 to 3–40
  - dynamical, 6–15, 6–17
  - laws, 6–15
  - physical, 3–37
- **Simple** beam, 5–19
    - safe loads on, 5–28
    - uniform cross-section, diagrams, 5–26 to 5–28
    - uniform strength, diagrams, 5–32
  - discount, 2–26
  - interest, 2–22
  - microscope, 9–13
- **Simpson's rule,** 2–40
  - for approximate integration, 2–89
- **Sine,** 2–53
  - hyperbolic, 2–59
- **Sines,** law of, 2–56, 2–58
- **Singular point,** 2–67
- **Sinking fund,** 2–29, 2–30
- **Sinusoidal** currents and voltages, 8–47 to 8–49
  - emf's, 8–53
- **Sinusoids,** vector representation of, 8–48, 8–49
- **Sitka spruce,** 12–40
  - allowable unit stresses, 5–29, 5–31
  - column formulas constants, 5–41
  - properties of, 12–47
- **Skin effect,** 8–29
- **Sky,** luminous efficiency and brightness of, 9–31
- **Slab,** flat, construction, reinforced concrete, 5–78 to 5–80
  - zinc, 11–54 to 11–56
- **Slabs** and beams, reinforced concrete, 5–62 to 5–72
  - rectangular flat, bending moments in, 5–56
- **Slagging, resistance to,** refractories, 12–24
- **Slaked lime,** 10–14
- **Slaking of quicklime,** 12–11
- **Slander,** 13–10
- **Slate,** 12–59
  - electrical properties of, 12–60
  - strength of, 12–15
- **Slenderness ratio,** columns, 5–37
  - for steel columns, 5–42
- **Slide rule,** 2–11, 2–12
- **Sliding friction,** coefficient of, 4–45
- **Slippery elm,** allowable unit stresses, 5–29, 5–31
  - properties of, 12–45
- **Slug (unit of mass),** 3–22, 3–23, 4–34
- **Slump test,** 12–07
- **Slush casting of zinc,** 11–56
- **Snell's law of refraction,** 9–03
- **Soapstone,** 12–61
- **Soda,** caustic, electrolytic, 10–37
- **Sodium,** 10–12, 10–13
  - bicarbonate, 10–13
    - properties of, 10–11
  - bisulfate, 10–12
  - bisulfite, 10–29
  - borate, properties of, 10–11
  - bromate, specific optical rotation of, 9–18
  - carbonate, 10–13
    - properties of, 10–11
    - magneto-optic rotation of, 9–18
  - chlorate, 10–28
  - chloride, 10–12
    - properties of, 10–11
  - chromate, 10–20
  - cyanide, properties of, 10–11
  - dichromate, 10–20
  - electrode potentials, values of, 10–37
  - hydroxide, 10–06, 10–13
    - properties of, 10–11

Sodium, hypochlorite, 10–28
  nitrate, 10–13
    properties of, 10–11
  properties of, 1–126, 1–127
  silicate, 10–30
    properties of, 10–11
  sulfate, 10–12
    properties of, 10–11
  sulfide, 10–29
  sulfite, 10–29
    properties of, 10–11
  thiosulfate, 10–29
    properties of, 10–11
  zincate, 10–16
Soil corrosion, 11–10
Solar day, 3–23
  year, 3–23
Soldering, 11–89 to 11–92
  aluminum, 11–69
Solders, 11–91, 11–92, 11–110
Solenoid, magnetizing force due to a, 8–24
Solid analytic geometry, 2–70 to 2–75
  angle, 2–34, 2–116
    units of conversion of, 1–134
  injection (Diesel engine), 7–76
  state, 8–62
Solids, 4–16, 6–02
  conduction of electricity in, 8–62 to 8–67
  curved surface, 2–35, 2–36
    mensuration formulas for, 2–42 to 2–44
  magneto-optic rotation, 9–18
  non-metallic, coefficient of linear expansion of, 1–129
    density of, 1–128
    specific heat of, 1–129
  plane surface, mensuration formulas, 2–41
  of revolution, volume of, 2–98
  similar, volumes of, 2–36
  specific optical rotation of, 9–18
  stresses in, under pressure, 5–55 to 5–57
  transparent, 9–15
  velocity of sound in, 9–37
Solubility, rules for, 10–08 to 10–10
Solutions, acid character of, 10–06
  electrochemistry of, 10–36 to 10–39
  magneto-optic rotation of, 9–18
  and rules for solubility, 10–08 to 10–10
  solid, crystals of, decomposition of, 11–27
    phase changes in, 11–03
  specific optical rotation of, 9–18
Solventless varnishes, 12–70
Solvents, function of, in varnish, 12–53
  insulating properties of, 12–73
  for lacquers, 12–57
Sonims, 11–27
Sorbite, 11–27
Sound absorption coefficients, 9–51, 9–52
    and reverberation, 9–50, 9–51
  diffraction, 9–40
  horns, 9–47
  intensity of, 9–40, 9–41
  musical, 9–49, 9–50
  nature of, 9–35, 9–36
  proofing, 9–53
  propagation of, influence of medium on, 9–41, 9–42
  reflection and refraction of, 9–38, 9–39
  transmission through tubes, 9–45, 9–46
  velocity of, 9–36 to 9–38
Sources of radiation, 9–34
South pole (magnetic), 8–26
Southern cedar, allowable unit stresses, 5–29, 5–31
    properties of, 12–45
Southern cypress, allowable unit stresses, 5–29, 5–31
    properties of, 12–45
  pine, allowable unit stresses, 5–29, 5–31
    column formula constants, 5–41
    properties of, 12–47
Soya bean oil, 12–56
  density of, 6–06
  properties of, 1–124
Space charge, 8–06, 8–69
  diagram of forces, 4–03, 4–08
  free, dielectric constant of, 3–32
  magnetic permeability of, 3–30
  -time diagram of motion, 4–28
Spacings, grating, of various crystals, 9–25
Spalling, resistance to, refractories, 12–25
Span factor, Munk's (aerodynamics), 6–26
Special bronze, properties of, 11–46
Specific acoustic resistance, 9–38, 9–40
  conductance, 8–13
  density (fluids), 6–03
  gravity, aluminum alloys, 11–67, 11–68
    bronze bearing alloys, 11–87
    compounds, industrial, 10–11
    copper-base alloys, wrought, 11–44 to 11–5
    fiber, 12–65
    gases, 10–24
    iron, 11–20, 11–22, 11–25
    laminated tubing, 12–69
    lubricants, 12–76
    magnesium alloys, 11–78
    mineral oils, 12–71
    non-retentive magnetic materials, 11–102
    refractories, 12–25
    stainless steel, 11–38
    steel, 11–22, 11–25
    structural material, 11–78
    white metal bearing alloys, 11–86
    wood, 12–44 to 12–47
  heat, 7–13, 7–16
    aluminum, 11–59
    copper, 11–40
    equivalent for gas mixture, 7–87
    gases, 1–121, 1–122, 7–16 to 7–18, 10–24
      chart of, 7–18
    iron, wrought, 11–20
    liquids, 1–123, 1–124
    magnesium, 11–76
    metals, 1–125, 1–126
    Monel metal, 11–73
    nickel, 11–71
    non-metallic solids, 1–129
    ratio of, gases, 1–121, 1–122, 10–24
    refractory materials, 12–25
    stainless steel, 11–38
    units of, 3–28
      conversion of, 1–147
    zinc, 11–53
    zinc-base die-casting alloys, 11–83
  inductive capacitance, 8–43
    rubber, 12–67
  optical rotation of non-metallic materials 9–18
  refractivity, 9–03
  resistance, 8–13, 8–38
    gutta percha, 12–67
    rubber, 12–66
Specifications (contracts), 13–13
Specimens, placing in testing machine, 5–88
  standard test, 5–84 to 5–86
Spectra, line, excitation of, 9–20
    origin of, 9–19
Spectral distribution of absorptivity, 9–03 to
    emissive power, 9–02

Spectral distribution of absorptivity, radiant energy in illuminants, 9–31
  relative human visibility, 9–27
  thermal radiation, 9–22
 visibility, 9–26
Spectrophotometry, 9–24
Spectroscope, performance of, 9–19
Spectroscopy, infra-red, 9–23
 light, 9–18 to 9–20
 ultraviolet, 9–21
 x-ray, 9–25
Spectrum, corpuscular, of radiation, 9–09
 of radiation, electromagnetic, 9–06 to 9–08
 visible, 9–18
Speech, flow of energy in, 9–49
 origin of, 9–48
Speed, 4–27
 dimensions of, 3–05
 of winds in the United States, 9–59, 9–60
Spelter, 11–54
Sperm oil, properties of, 1–124
 viscosity of, 6–07
Sphere, 2–36, 2–74
 drag coefficient of, 6–40
 flow around, 6–39, 6–40
 mensuration formulas, 2–42
 properties of, 4–25
 Ulbricht, 9–30
Spherical aberration, 9–12
 angle, 2–35
 candlepower, mean, 9–29
 coordinates, 2–70, 2–73, 2–115
 lenses, 9–11 to 9–13
 mirrors, 9–10, 9–11
 polygon, 2–36
  mensuration formulas for, 2–43
 rollers, stresses in, 5–55, 5–57
 sector, 2–36
  mensuration formulas for, 2–42
 properties of, 4–25
 segment, 2–36
  mensuration formulas for, 2–43
  properties of, 4–25
 triangle, mensuration formulas for, 2–43
 trigonometry, 2–58
 waves, 9–41
 zone, mensuration formulas for, 2–43
Spiegeleisen, 11–13, 11–18
Spinning brass, properties of, 11–44
 electron, 8–18
Spiral of Archimedes, 2–69
 mensuration formulas for, 2–40
Spiraled columns, reinforced concrete, 5–73 to 5–75
Spirals, 2–69
Spirit varnishes, 12–56, 12–57, 12–71
Spring brass, properties of, 11–44
Spruce, 12–40
 allowable unit stresses, 5–29, 5–31
 column formula constants, 5–41
 properties of, 12–47
Square, 2–32
 column footings, reinforced concrete, 5–77
 flat plates, stresses in, 5–54
 geometrical construction of, 2–49
 mensuration formulas of, 2–37
 properties of, 4–21
 roots, tables of, 1–12 to 1–28
  to extract, 2–04
 steel bars, size and weight, 1–164
 tied columns, reinforced concrete, 5–74
Squares, table of, 1–12 to 1–28
"Squatter's right," 13–12
Stability of body, completely immersed, 6–14
 electrical circuit, 8–59 to 8–61
Stability of body, equilibrium, 4–11
Stadia reductions, 1–55, 1–56
Stain (wood), 12–42
Stainless iron, mechanical properties of, 11–36
 steels, 11–37 to 11–39
  properties under repeated stress, 5–13
Stalling angle, 6–43
Standard deviation, 2–123, 2–127
 structural sizes, 1–153 to 1–168
 test specimens, 5–84 to 5–86
 and units, physical, Section 3

Turbulent flow of fluids, 6-29 to 6-31, 7-24
Turnbull's blue, 10-20
Turpentine, properties of, 1-124
  specific optical rotation of, 9-18
  varnish, 12-57
Twist, angle of, 5-49
    in members subjected to torsion, 5-50, 5-51
Twisting moment, 5-48
Two-cycle engine, 7-73
Two-stroke cycle, 7-72, 7-73
Type efficiency, 7-56

Ulbricht sphere, 9-30
Ultimate strength, 5-04
  copper-base sand-cast alloys, 11-40 to 11-42
  determination of, 5-88
  ferrous metals, 5-13
  iron, 11-25
  laminated tubing, 12-69
  non-ferrous metals, 5-14, 5-15
  non-retentive magnetic materials, 11-102
  in shear, wrought iron, 11-21
  stainless steel, 11-38
  steel, 11-25
  on stress-deformation diagram, 5-05
  structural alloy steel, 11-36
  in torsion, 5-51
  white metal bearing alloys, 11-86
  wrought iron, 11-20
Ultraviolet radiation, 9-21, 9-34
  rays, 8-07
Undersoil corrosion, protection against, 11-10, 11-11
Underwater corrosion, protection against, 11-10
Undue influence (contracts), 13-04
Ungula, mensuration formulas for, 2-42
Unit north pole (magnetic), 8-26
  stress, 5-02
  systems, 3-12 to 3-21, 8-02
Unitary homogeneous equations, 3-37
United States gallon, 3-21
  pound (avoirdupois), 3-22
  speed of winds in, 9-59, 9-60
  standard gage, 1-149, 11-56
  steel wire gage, 1-151, 1-152
  temperature in, 9-57
  Weather Bureau, signals of, 9-55
  yard, 3-21
Units, conversion factors, 1-130 to 1-147
  of quantities, *see* particular quantity or unit in question
  relations between, 3-02
  and standards, 3-21 to 3-36
  of weights and measures, 1-130 to 1-147
Unstable systems, electrical circuits, 8-59, 8-60
Uranium, properties of, 1-126
Urea-formaldehyde resins, 12-55
Urea resin, 12-68

Valence, chemical, 10-05
Valves, 7-66
Van der Waals' equation, 10-25
Vanadium oxide, properties of, 10-11
  properties of, 1-126
  steel, 11-35
    modulus of resilience of, 5-08
    properties of, 11-36
    relative toughness of, 5-08
Vapor in atmosphere, partial pressure of, 7-93
  compression system, 7-79 to 7-82
  cycles, modern, 7-60 to 7-62
  flow of, through, nozzles and orifices, 7-47 to 7-52

Vapor in atmosphere, and gas mixtures, 7–87 to 7–89
  pressure, 9–61
  properties, graphical representation of, 7–41 to 7–43
Vaporization, latent heat of, aluminum, 11–59
    gases, 1–121, 1–122, 10–24
    liquids, 1–123, 1–124
    magnesium, 11–76
    metals, 1–125, 1–126
    zinc, 11–53
Vapors and liquids, 7–31 to 7–52
  properties of, 7–32 to 7–40
  state changes and processes for, 7–43 to 7–47
Variables, complex, 2–112
  functions of four, alignment charts for, 2–120 to 2–122
  functions of three, alignment charts for, 2–117 to 2–120
  functions of two, partial derivative of, 2–78
  limit of, 2–75
  Taylor's formula for two, 2–80
Varnishes, asphaltic, 12–71
  crystallizing, 12–56
  insulating, 12–71 to 12–73
  oil, 12–71
  oleoresinous, 12–52 to 12–56
  rubbing, 12–56
  solventless, 12–70
  spirit, 12–56, 12–57 12–71
  wrinkle, 12–56
Varnish-treated cloth, 12–63
Vector, 2–112
  admittance, 8–55
  analysis, 2–112 to 2–116
    symbols for, 1–02
  computations by slide rule, 2–12
  diagram, 4–03
  impedance, 8–54
  product, 2–113
  radius, 2–70
  representation of sinusoids, 8–48, 8–49
Vectorial angle, 2–70
Vectors, differentiation and integration of, 2–114, 2–115
  sum and product of, 2–112 to 2–114
Vehicles, paint, 12–50
Velocity, angular, 4–32
    alternating current, 8–45
    and rectangular, relations between, 4–32
    units of, conversion factor, 1–136
  coefficient of (nozzle), 7–27
  components, 4–30
  critical (fluid dynamics), 6–29, 6–32
  curvilinear motion, 4–30
  dimensions, 3–05
  distribution, in laminar flow, 6–29
    in turbulent flow, 6–30
  increase due to an airplane propeller, 6–23
  induced (aerodynamics), 6–25
  of light, 9–15
  of a particle, 4–27
  of any point in plane motion, 4–33
  potential (fluid dynamics), 6–19
  of propagation (radiation), 3–20, 9–06
  rectilinear motion, 4–27
  of sound, 9–36 to 9–38
  -space diagram, 4–29
  -time diagram, 4–28
  units of, 4–27
    conversion of, 1–135
  wind, 9–59
    measurement of, 9–64
Vena contracta, 6–31
Venturi tubes, 6–23, 6–36
Verification of testing machines, 5–82
Versine, 2–54
Vertex, 2–32
Vertical deflection, 5–24
  shear, 5–20
    of beams of uniform cross-section, 5–26 to 5–28
Vessels, planing, 6–50
  surface, resistance of, 6–48 to 6–51
Vibrating systems as sources of sound, 9–42, 9–43
  special, 9–44, 9–45
Vibration of air columns, 9–44
  of strings, 9–44
Vickers pyramid hardness-testing machine, 5–89
Vinyl resins, 12–55, 12–68
Violation of right of support, 13–10
Virginia pine, thermal conductivity of, 12–38
Virtual image, 9–09
Viscosity, 6–03, 6–04
  dimensional analysis of pressure drop due to, 6–28
  gases, 1–121, 1–122, 6–08
  kinematic, 6–08
  liquids, 1–123, 1–124, 6–07
  mineral oils, 12–71
  oils under pressure, 6–07
  Saybolt, 6–03
    lubricants, 12–76
  solids, 6–04
  water, 6–07
Viscous incompressible fluids, aerodynamics of, 6–41 to 6–48
  dynamics of, 6–27, 6–28
  flow of, 6–27
    around bodies, 6–37 to 6–40
    near boundaries, 6–48
    through nozzles, 6–35, 6–36
    through orifices, 6–34, 6–35
    in rough tubes, 6–32, 6–33
    in smooth pipes and tubes, 6–28 to 6–33
    through venturi tubes, 6–36
Visibility, 9–26
  spectral distribution of, 9–27
Visible spectrum, 9–18
Vision, 9–26 to 9–28
Volt, 3–33, 8–10
  international, 3–34
Volta effect, 8–10
Voltage and current relationships, 8–50 to 8–53
  dimensions of, 3–08, 3–09
  gradient, 8–35, 8–36
  non-sinusoidal periodic, 8–49, 8–50
  saturation (emission), 8–05
  sinusoidal, 8–47 to 8–49
  terminal and impressed, 8–12, 8–13
  units of, 3–18, 3–29, 3–32
Volt-amperes, 8–47
Volume by integration, 2–97, 2–98
  center of gravity of, 4–16
  of components in gas mixtures, 7–87
  metric multiples, 1–132
  specific, saturated steam, 7–33 to 7–35
  units of, conversion factor, 1–132
Volumes, properties of, 4–23 to 4–26
  of similar solids, 2–36
Von Mises' formula, 6–51
Vortex line, aerodynamics, 6–24

Wages, lien of, 13–08
Walloon process, 11–20
Walls, reflection from, 9–32
Walnut, black, 12–40

Walnut, properties of, 12–47
  oil, 12–56
  white, 12–39
Wane (defect in wood), 12–42
Wastes, manufacturing (riparian rights), 13–11
Water, chemistry of, 10–04
  compressibility of, 6–09
  corrosion in the presence of, 11–05
  critical velocity in smooth tubes, 6–29
  density of, 6–05
  equivalent, 3–28
  gas, 12–78
  hardness of, 10–14, 10–15
  heavy, 10–05
  index of refraction, 9–15
  javelle, 10–28
  magneto-optic rotation, 9–18
  properties of, 1–124
  solubilities of salts in, 10–09
  surface tension of, 6–08
  vapor, index of refraction of, 9–15
    saturated, pressures in contact with ice, 7–93
  viscosity of, 6–07
Waterproofing concrete, 12–10
Waters, surface (riparian rights), 13–11
  well (riparian rights), 13–11
Watt, 3–26, 3–33, 7–03, 8–17
  international, 3–26, 3–34
Watt-seconds, 8–17
Wave aspects of radiation, 9–05 to 9–08
  compressional, 9–35
  definition of, 9–05
  electromagnetic, 8–07, 9–05
  packet, definition of, 9–05
Wavelength of radiation, 9–02
Wavelengths for calibration of the spectroscope, 9–19
Waves, sound, 9–36
    spherical, 9–41
    wave length of, 9–38
Waxes, 12–69
Weather bureau, U. S., observations, 9–58
    predictions, local, 9–56
    signals of, 9–55
Web, buckling of, 5–25
  reinforcement, reinforced concrete, 5–65
  shear, 5–23
Weber, 3–33
  -Fechner psychophysical law, 9–48
Weber's number, influence of, 6–51
Webster's phonometer, 9–54
Weddle's rule, 2–40
Wedge, mensuration formulas for, 2–41, 2–42
Weierstrass' test, 2–81, 2–82
Weighing procedure, accurate, 3–24
Weight, aluminum, alloys, 11–67
    sheet and plate, 1–150
    wire, 11–98
  apothecaries', 1–138
  atomic, chemical elements, 10–02, 10–03
    metals, 1–125, 1–126
  avoirdupois, 1–137
  brass, sheet and plate, 1–150
  bronze bearing alloys, 11–87
  copper sheet and plate, 1–150
  copper wire, 11–93
  density, definition of, 6–02
  vs. force, 3–24
  hollow clay tile, 12–19
  iron, 11–25
    sheet and plate, 1–149
  magnesium alloys, 11–78
  and mass, 4–02
  vs. mass, 3–22
Weight, molecular, gases, 1–121, 1–122, 10–24
    industrial compounds, 10–11
  non-retentive magnetic materials, 11–102
  stainless steel, 11–38
  steel, 11–25
    bars, 1–164
    pipe, 1–165
    sections, 1–153 to 1–163
    sheet and plate, 1–149
  of a substance in a chemical reaction, 10–10
  troy, 1–137
  units of, conversion of, 1–137
  yard lumber, 1–167, 1–168
Weighted observations, 2–126
Weights and measures, units of, 1–130 to 1–147
Weirs, flow over, 6–52
Welded joints, 5–59
Welding aluminum, 11–69
  materials, 11–89 to 11–91
Well waters (riparian rights), 13–11
Western (West Coast) hemlock, allowable unit stresses, 5–29, 5–31
    column formula constants, 5–41
    properties of, 12–46
    thermal conductivity of, 12–38
  larch, allowable unit stresses, 5–29, 5–31
    column formula constants, 5–41
    properties of, 12–46
  pine, allowable unit stresses, 5–29, 5–31
    properties of, 12–47
  red cedar, allowable unit stresses, 5–20, 5–31
    column formula constants, 5–41
    properties of, 12–45
Wet vapor, 7–32
  properties of, 7–40
White ash (wood), 12–39
    allowable unit stresses, 5–29, 5–31
    properties of, 12–44
  cedar, 12–39
    allowable unit stresses, 5–29, 5–31
    properties, of, 12–45
  elm, 12–39
  fir, allowable unit stresses, 5–29, 5–31
    properties of, 12–45
  iron, 11–17
  lead, 10–22
  maple, 12–40
  metal (Babbitt) bearing alloys, 11–85, 11–86
  oak, 12–40
    allowable unit stresses, 5–29, 5–31
    column formula constants, 5–41
    properties of, 12–47
  pine, 12–40
    allowable unit stresses, 5–29, 5–31
    properties of, 12–47
    thermal conductivity of, 12–38
  spruce, 12–40
    allowable unit stresses, 5–29, 5–31
    column formula constants, 5–41
  walnut, 12–39
Whiting, 10–15
Wide flange steel sections, properties of, 1–153 to 1–156
Wiedermann-Franz ratio, 8–65
Wien's displacement law, 9–22
Winchester bushel, 3–21
Wind and barometer indications, 9–56
  pressure data, method of giving, 9–66
    on structures, 9–64 to 9–69
  speed of, in United States, 9–59, 9–60
  tunnel boundary effects, 6–52
    sketch of, 6–42
  velocity measurement, 9–64
  -velocity pressures, 9–65

- **Windstorm damage,** 9–64
- **Wing sections,** 6–41
- **Wire,** copper, allowable current carrying capacities, 11–95
    - and aluminum, comparison of, 11–97
    - specifications, 11–94, 11–95
  - enamels, 12–73
  - gages, 1–150 to 1–152
  - in magnetic field, force on, 8–34
  - straight, magnetizing forces due to, 8–23
  - table, aluminum, 11–96, 11–98
    - copper, 11–93, 11–96
- **Witness,** engineer as expert, 13–09
- **Women,** competence of (contracts), 13–02
- **Wood,** *see also* Lumber and Timber
  - column formula constants, 5–41
  - as electric insulating material, 12–63
  - electrical properties of, 12–60
  - as fuel, 12–77
  - properties of, 12–44 to 12–47
  - tests of strength of, 5–93
  - thermal conductivity of, 12–37, 12–38
- **Wooden** beam, design, example, 5–30, 5–36
  - columns, 5–40, 5–41
- **Wood's fusible alloy,** composition and melting point, 11–110
- **Wool,** glass, thermal conductivity of, 12–35
  - mineral, thermal conductivity of, 12–35
  - rock, thermal conductivity of, 12–35
- **Work,** 5–08, 7–02
  - application of integration to, 2–99
  - conditions regarding, as appearing in contracts, 13–19 to 13–22
  - diagram, 4–34
  - done by a varying magnetic flux, 8–22
  - effect on iron and steel, 11–29
  - external, 5–08
  - of a force, 4–34
  - function (photoelectricity), 8–07
  - indicated, per cycle, 7–67
  - and kinetic energy, principle of, 4–35
  - power, energy, 4–34 to 4–36
  - rate of doing, units of, conversion of, 1–141
  - of a torque, 4–35
  - units of, 3–24, 3–25, 4–34
    - conversion of, 1–140
- **Working,** cold, effect on aluminum, 11–65
  - mechanical, of steel, 11–29, 11–30
- **Workmen's compensation,** 13–08
- **Wrinkle varnish,** 12–56
- **Written agreement (contracts),** 13–03
- **Wrought** aluminum alloys, 11–64 to 11–70
    - composition and nomenclature, 11–64, 11, 65
    - design stresses for, 11–68
    - effect of heat treatment on, 11–66
    - fabrication of, 11–69
    - properties of, 11–67, 11–68
    - structural uses of, 11–70
    - temper designations of, 11–64
  - copper-base alloys, 11–52
    - properties and uses of, 11–44 to 11–51
  - iron, 11–19 to 11–21
    - column formula constants, 5–39
    - factor of safety of, 5–11
    - magnetization characteristic, 8–25
    - permeability, 8–26
    - properties under repeated stress, 5–13
  - metals, specimens for tension tests of, 5–84

- **Xenon,** properties of, 1–122
- **X-radiation,** physiological action, 9–34
- **X-rays,** 8–07, 8–08, 9–04, 9–24, 9–25
  - dosage of, 9–34
- **X-rays,** inspection, 5–92, 5–93
  - sources of, 9–34
- **Xylene O,** properties of, 1–124
- **Yard,** 3–21
  - lumber, 12–43
    - softwood, grades of, 12–48
    - standard, properties of, 1–167, 1–168
- **Year,** solar, 3–23
- **Yellow** birch, allowable unit stresses, 5–29, 5–31
  - plywood, 12–49
  - brass, properties of, 11–43
  - pine, 12–40
    - allowable unit stresses, 5–29, 5–31
    - properties of, 12–47
    - thermal conductivity of, 12–37, 12–38
  - poplar, 12–40
    - allowable unit stresses, 5–29, 5–31
    - plywood, 12–49
- **Yield point,** 5–04
  - bronze bearing alloys, 11–87
  - concrete reinforcement bars, 5–61
  - copper-base, die-casting alloys, 11–84
    - sand-cast alloys, 11–40 to 11–42
    - wrought alloys, 11–44 to 11–50
  - determination of, 5–87, 5–88
  - ferrous metals, 5–13
  - Monel metal, 11–73, 11–74
  - nickel, 11–71
  - non-retentive materials, 11–102
  - on stress-deformation diagram, 5–05
  - structural alloy steels, 11–36
  - white metal bearing alloys, 11–86
  - wrought iron, 11–20
- **Yield strength,** 5–04
  - aluminum, 11–59
    - cast alloys at elevated temperatures, 11–64
    - sand-cast alloys, 11–61
    - wrought alloys, 11–67
  - determination of, 5–87
  - iron, 11–25
  - magnesium, 11–76
    - alloys, 11–78
  - steel, 11–25
  - structural material, 11–78
- **Young's modulus,** 5–05

- **Zeeman effect,** 9–20
- **Zees, steel,** properties of, 1–163
- **Zeta function,** 7–12
- **Zilloy roofing sheets,** 11–57, 11–58
- **Zinc,** 10–16, 11–52 to 11–58
  - -base alloys, 11–52 to 11–58
  - -base die-casting alloys, 11–55, 11–82, 11–83
  - carbonate, 10–16
  - chloride, properties of, 10–11
  - copper, and nickel, alloys of, 11–75
  - dust, 10–16
  - electrode potentials, values of, 10–37
  - gage, 11–56
  - hydroxide, 10–16
  - oxide, 10–16
    - properties of, 10–11, 12–51
  - properties of, 1–126, 1–127
  - rolled, 11–56 to 11–58
  - roofing sheets, 11–57, 11–58
  - roughness number, 6–51
  - slab, 11–54 to 11–56
  - slush casting of, 11–56
  - sulfate, 10–16
    - properties of, 10–11
  - sulfide, 10–16
    - properties of, 12–51
- **Zirconium,** properties of, 1–126
- **Zone, spherical,** mensuration formulas, for, 2–43

WILEY ENGINEERING HANDBOOK SERIES

HANDBOOK OF ENGINEERING FUNDAMENTALS

Section Edited by Ovid W. Eshbach. 1081 Pages

1 MATHEMATICAL AND PHYSICAL TABLES: Symbols and Abbreviations; Mathematical Tables; Physical Properties of Materials; Tables of Conversion Factors—Units of Weights and Measures; Gages; Standard Structural Sizes; by Ovid W. Eshbach in collaboration with J. L. Barnes, J. G. Brainerd, R. T. Kent, and H. C. Knutson.

2 MATHEMATICS: Arithmetic; Algebra; Mathematics of Finance; Geometry, Trigonometry; Plane Analytic Geometry; Solid Analytic Geometry; Differential Calculus; Integral Calculus; Differential Equations, Solution of Linear Constant-coefficient Integro-differential Equations by the Laplacian Transformation (Operational Calculus); Functions of Complex Variables; Vector Analysis; Alignment Charts (Nomograms), Precision of Measurements, by J. L. Barnes in collaboration with J. G. Brainerd, C. Eisenhart, M. J. Fish, and J. M. Rice.

3. PHYSICAL UNITS AND STANDARDS. Dimension Systems; Unit Systems; Units and Standards; Dimensional Analysis; by Ernst Weber.

4. THEORETICAL MECHANICS: Statics; Kinematics, Kinetics; by Janvier M. Rice.

5 MECHANICS OF MATERIALS: Simple Stresses; Beams; Columns; Shafts; Cylinders, Plates, Rollers, and Riveted Joints; Testing of Materials; by Jasper O. Draffin. Reinforced Concrete; by Theodore Crane.

6 MECHANICS OF FLUIDS Properties of Fluids, Divisions of Fluid Mechanics; Fluid Statics, Fluid Dynamics; by P. E. Hemke.

7 ENGINEERING THERMODYNAMICS: Principles of Thermodynamics; Gases; Liquids and Vapors, The Steam Power Plant; The Internal-combustion Engine; Refrigeration, Gas and Vapor Mixtures, Humidity, and Air Conditioning; by Milton C. Stuart and Paul J. Kiefer.

8 ELECTRICITY AND MAGNETISM: Electron Theory, Direct-current Circuits; Electrokinetics and the Magnetic Circuit; Electrostatics and the Dielectric Circuit; Alternating-current Circuits; Transients; Conduction of Electricity in Solids and Fluids; by Charles Weyl and Irven Travis.

9. RADIATION AND LIGHT: Theory of Radiation; Geometry of Radiation; Physics of Radiation, Physiology of Radiation; by Ernst Weber. ACOUSTICS; by R. B. Lindsay. METEOROLOGY; by Edgar W. Woolard, R. J. Martin, and H. L. Dryden.

10. CHEMISTRY: General Chemistry; Industrial Chemistry; Qualitative Analysis; Electrochemistry; by Joseph Mattiello and Sidney B. Tuwiner.

11. METALLIC MATERIALS: Corrosion of Metals; by Frank N. Speller. Iron and Steel; by Bradley Stoughton. Copper and Copper-base Alloys; by members of the staff of the American Brass Co. and W. M. Corse. Zinc and Zinc-base Alloys; by W. M. Peirce. Aluminum and Aluminum Alloys; by Junius D. Edwards and Zay Jeffries. Nickel and Non-ferrous Nickel Alloys; by Robert Worthington. Magnesium and Magnesium Alloys; by John A. Gann. Tungsten, Molybdenum; by Zay Jeffries. Die-casting Alloys; by J. C. Fox. Bearing Metals; by Christopher H. Bierbaum. Welding, Brazing, and Soldering Materials; by Bradley Stoughton and D. F. Miner. Electrical Conductor Materials; by H. C. Knutson and D. F. Miner. Magnetic Materials, by J. B. Seastone. Miscellaneous Materials.

12. NON-METALLIC MATERIALS: Cement, Concrete, Lime, Mortar, and Plaster; by Theodore Crane. Stone, Brick, and Terra-cotta; by Jasper O. Draffin. Refractories; by J. Spotts McDowell and E. B. Guenther. Thermal Insulating Materials. Timber; by H. C. Knutson and H. F. Moore. Paints, Enamels, Varnishes, and Lacquers; by Joseph Matiello. Electric Insulating Materials; Lubricants; Adhesive Materials; by D. F. Miner. Fuels and Explosives. Miscellaneous Materials.

13. CONTRACTS. By R. L. Sackett.

MECHANICAL ENGINEERS' HANDBOOK

POWER

Edited by Robert Thurston Kent

1226 Pages

SECTION

1. AIR: Properties of Air. Compressed Air, by Robert Peele. **Fans and Blowers**, by Robert T. Kent.
2. WATER: Properties of Water. Hydraulics, by William P. Creager. Hydraulic Turbines, by R. E. V. Sharp. Pumps and Pumping Engines, by Robert T. Kent. Centrifugal Pumps, by V. deP. Gerbereux.
3. HEAT: Measurement of Heat. Heat Transmission, by W. J. King. Evaporators and Evaporation, by W. L. Badger. Dryers and Drying, by Francis E. Finch. Kiln Drying of Lumber, by L. V. Teesdale. Heat Insulation, by P. Nicholls. Thermodynamics, by A. G. Christie.
4. COMBUSTION AND FUELS: Combustion and Solid Fuels, by Robert T. Kent. Liquid Fuels, by Harry L. Tapp. Gaseous Fuels. Illuminating Gas, by Alfred E. Forstall.
5. STEAM: Properties of Steam; The Mollier Diagram, by A. G. Christie. Flow of Steam in Pipes, by Robert K. Behr. Steam Piping. Stresses in Pipe Lines, by A. S. McCormick. Commercial Pipe and Fittings. Steam Valves.
6. THE STEAM BOILER: Boiler Construction; Superheaters, Economizers and Air Heaters; Utilization of Waste Heat; Moisture in Steam. Boiler Feeding. Feedwater for Steam Boilers. By D. S. Jacobus, Robert K. Behr and Robert T. Kent. Boiler Furnaces; Stokers; Gas and Oil Burners, by W. S. Carter. Chimneys and Draft. Smoke.
7. THE STEAM ENGINE: Capacity of Engines; By W. Trinks. Compound and Triple-expansion Engines; Steam Engine Economy; Operation of Engines; Valve Gears; Operating Data; Steam Engine Parts; Selection of Type of Engine; Cost of Engines.
8. THE STEAM TURBINE: By A. G. Christie. Types of Turbines. Steam Turbine Cycles. Nozzles. Blading. Steam Supply. Rotors. Turbine Details. Reduction Gearing. Lubrication. Turbine Governors. Casings. Erection and Operation. Correction Factors. Turbine Performance. Turbine Calculations. Reheating Turbines. Economic Selection of Operating Conditions. Mercury Turbines.
9. CONDENSING AND COOLING EQUIPMENT: By Robert T. Kent. Direct Contact Condensers. Properties of Saturated Steam below Atmospheric Pressure. Surface Condensers. Air Pumps. Cooling Towers. Cooling Ponds.
10. REFRIGERATION AND ICE MAKING: By Louis A. Harding. Refrigeration. Cold Storage. Heat Transmission. The Ammonia Absorption Machine. Vapor Condensers. Brine Circulating System. Ice Manufacture.
11. HEATING, VENTILATING AND AIR CONDITIONING: By Louis A. Harding. Estimating Heating Requirements of Buildings. Heating Systems. Rating of Heating Boilers. Design of Air Ducts. Ventilation. Air Conditioning.
12. INTERNAL COMBUSTION ENGINES: Diesel Engines, by E. J. Kates. Gas Engines, by H. A. Gehres. Gasoline Engines.
13. GAS PRODUCERS: By John Blizard. General Design and Operation of Gas Producers. Properties of Producer Gas. Design of Furnaces for Producer Gas.
14. TRANSPORTATION: Railroad Engineering, by G. E. Rhoads. Automotive Vehicles, by Ralph A. Richardson. Aeronautics, by Edward P. Warner and S. Paul Johnston.
15. ELECTRIC POWER: By E. S. Dibble. Purchased Power. Generated Power. Conversion Equipment. Switchboard Equipment. Batteries. Power Factor. Power Distribution.
16. POWER TEST CODES: Instruments and Apparatus. Test Codes.
17. MATHEMATICAL TABLES.

MECHANICAL ENGINEERS' HANDBOOK

DESIGN. SHOP PRACTICE

Edited by Robert Thurston Kent

1378 Pages

SECTION

1. GENERAL PROPERTIES OF MATERIALS.
2. IRON AND STEEL: Iron and Steel, by Bradley Stoughton. Ingot Iron, by R. L. Kenyon. Welding of Iron and Steel, by J. C. Hodge and R. E. Hiller.
3. CORROSION AND CORROSION-RESISTANT METALS: Corrosion of Metals, by Frank N. Speller. Corrosion-resistant Metals, by Robert T. Kent.
4. NON-FERROUS METALS AND ALLOYS: General Properties of Metals and Alloys, by Paul D. Merica and Norman B. Pilling. Copper, by W. H. Bassett (deceased). Zinc and Its Alloys, by W. M. Peirce. Brass and Bronze Sand-cast, Copper-base Alloys, by W. M. Corse. Wrought Brasses, Bronzes and Nickel-silver Alloys, by W. H. Bassett (deceased), H. G. Jennison, and W. R. Hibbard. Aluminum and Its Alloys, by Zay Jeffries. Nickel and Its Non-ferrous Alloys, by Robert Worthington. Magnesium and Its Alloys, by John A. Gann. Tungsten and Molybdenum, by Zay Jeffries. Die-casting Alloys, by J. C. Fox. Bearing Metals, by Christopher H. Bierbaum. Solders.
5. NON-METALLIC MATERIALS: Refractories, by J. Spotts McDowell. Wood, Cork, Rubber, Carbon and Miscellaneous Materials.
6. FABRICATED MATERIALS: By Robert T. Kent. Plates, Sheets, Bars, Rods and Shapes. Steel, Copper and other Wires. Ropes, Chains, and Wire Rope. Rivets, Nails and Washers.
7. STRENGTH OF MATERIALS: By Edward R. Kent and Jasper O. Draffin. Simple Stresses. Beams. Columns. Shafts. Cylinders, Plates and Rollers. Testing of Materials.
8. MECHANISM AND MECHANICS: By Robert T. Kent. Elements of Machines. Mechanics. Friction.
9. FASTENINGS: By Robert T. Kent. Screws and Screw Fastenings. Rivets and Riveted Fastenings. Fastenings for Timber Joints.
10. MECHANICAL SPRINGS: By Mortimer F. Sayre.
11. ROTATING MEMBERS: By Robert T. Kent. Axles and Shafts. Cranks and Crank-pins. Fly-wheels.
12. KEYS, COTTERS, PINS, TAPERS AND FITS: By Robert T. Kent.
13. BEARINGS AND LUBRICANTS: Oil Film Bearings, by H. A. S. Howarth. Ball Bearings, by J. S. Tawresey. Roller Bearings, by Robert T. Kent Lubricants, by J. C. Geniesse.
14. GEARING: By Earle Buckingham. Friction Gearing. Spur Gears. Helical Gears. Bevel Gearing. Screw Gearing. Spiral Gear Drives. Worm Gear Drives.
15. CONTROL MECHANISMS: Governing, Regulation and Control, by W. Trinks. Brakes, by Robert T. Kent.
16. VIBRATION AND NOISE: By Arthur L. Kimball.
17. STRUCTURES AND BUILDINGS: Stresses in Framed Structures. Building Construction, by Theodore Crane. Properties of Structural Materials, by Robert T. Kent.
18. INDUSTRIAL HEATING PROCESSES: Industrial Furnaces, by W. Trinks. Industrial Electric Heating, by R. M. Cherry.
19. FORGING PRACTICE: By Eugene C. Clarke.
20. FOUNDRY PRACTICE: Iron Foundry Practice, by D. M. Avey. Malleable Castings, by Enrique Touceda. Non-ferrous Foundry Practice, by N. K. B. Patch.
21. THE MACHINE SHOP: Lathe Work. Single-point Metal-cutting Tools, by Robert C. Deale. Planer Work, by Forrest E. Cardullo. Pressure Working of Metals, by H. B. Morse. Drills and Drilling; Abrasive Processes; Broaching; Metal Sawing; Machine Tool Motor Drives; Measurements, by Robert T. Kent.
22. WOODWORKING: By Thomas D. Perry. Materials. Primary Conversion Machinery. Processing. Small Tools. Machine Tools for Wood.
23. MATERIALS HANDLING: By Frederic V. Hetzel. Hoisting. Handling Materials in Bulk. Cranes and Derricks. Hoists. General Conveying and Elevating. Belt Conveyors. Screw Conveyors. Pneumatic and Hydraulic Conveying. Package Handling. Vehicles. Manufacturers of Material Handling Equipment.
24. MECHANICAL POWER TRANSMISSION: By Robert T. Kent. Shafting. Pulleys. Belt Drives. Chain Drives. Rope Driving. Couplings and Clutches. Speed Changing Mechanisms. Dynamometers.
25. ELECTRIC MOTORS AND THEIR CONTROL: By M. N. Halberg. Electric Motors. Electric Motor Control.
26. MISCELLANEOUS SHOP EQUIPMENT: Dust Collection, by M. S. Kice, Jr. Illumination, by Matthew Luckiesh.
27. SAFETY ENGINEERING: By Sidney J. Williams. Accident Prevention. Mechanical Power Transmission. Machinery. Electrical Hazards. Eye Protection and Safe Clothing. First Aid. Supervision and Education. Organizations.
28. MATHEMATICAL TABLES.

HANDBOOK FOR ELECTRICAL ENGINEERS

ELECTRIC POWER

Edited by Harold Pender, William A. Del Mar, and Knox McIlwain

1300 Pages

SECTION

1. MATHEMATICS, UNITS, AND SYMBOLS: Mathematics; by Carl C. Chambers. Mathematical Tables. Units and Conversion Factors; by J. G. Brainerd and Carl C. Chambers. Symbols and Abbreviations. Constants; by Carl C. Chambers.
2. PROPERTIES OF MATERIALS: Weights of Materials; Conductor Materials; Insulating Materials; Magnetic Materials; Thermal Properties of Materials; by D. F. Miner.
3. ELECTRIC CIRCUITS AND ELECTRIC LINES: Alternating Currents; Linear Circuits; Non-linear Circuits; Polyphase Systems and Symmetrical Components; Electrical Machines; Transmission Lines; Stability of Power Systems; by Irven Travis.
4. RESISTORS, REACTORS, MAGNETS: Resistors, Rheostats; Capacitors—Condensers; Inductors; Magnets, Magnetic Devices; by A. Dexter Hinckley.
5. MEASUREMENTS AND MEASURING APPARATUS: by H. B. Brooks.
6. PRINCIPLES OF ELECTROCHEMISTRY: by H. M. Goodwin, revised by Martin Kilpatrick and Mary L. Kilpatrick.
7. BATTERIES: Primary Batteries; by C. F. Burgess. Lead-acid Storage Batteries; by J. Lester Woodbridge. Alkaline-type Storage Batteries; by E. W. Allen and F. Brehme.
8. DIRECT-CURRENT MACHINES: Direct-current Generators; Direct-current Motors; by Walter I. Slichter.
9. ALTERNATING-CURRENT MACHINES: Alternating-current Generators; Synchronous Motors; Polyphase Induction Motors; Single-phase Induction Motors; Alternating-current Commutator Motors; by Walter I. Slichter.
10. TRANSFORMERS; by Walter I. Slichter.
11. CONVERTERS AND RECTIFIERS: Energy Converters; Frequency Converters; Phase Converters and Balancers; Rectifiers; by Walter I. Slichter.
12. SWITCHING, CONTROL, AND PROTECTION: Circuit Elements; Circuit Breakers; Controllers and Regulators; Protection; Station Equipment; Station Structures and Layout; by Stephen Q. Hayes.
13. POWER STATIONS AND SUBSTATIONS: Steam Power Stations; by F. S. Bennett. Hydroelectric Power Stations; by R. A. Hopkins and A. G. Cherry. Internal-combustion Power Stations; by W. A. Sloan. Substations; by W. I. Slichter. Power Station Circuits; by R. A. Hopkins.
14. POWER TRANSMISSION AND DISTRIBUTION: Systems; Capacitance and Inductance Tables; Underground Conduits; Distribution; Bare Wires and Cables; Insulated Wires and Cables; Electrolysis of Underground Structures; by W. A. Del Mar. Electrical Design of Transmission and Distribution Systems; by W. A. Del Mar, J. H. Palmer, F. W. Peek, and R. A. Philip. Pole and Tower Lines; by Howard Enos. Wiring of Buildings; by G. W. Zink. Grounding of Electric Circuits and Accessories; by R. F. Abele.
15. LIGHTING AND HEATING: Lighting; by F. C. Caldwell. Household Heating Appliances and Cooking; by Frank Thornton, Jr. Water Heating; by C. J. Fay and J. F. Reifenberg. Heating and Air Conditioning of Buildings; by Otto W. Walter.
16. INDUSTRIAL APPLICATIONS OF MOTORS; by Francis A. Westbrook.
17. TRANSPORTATION: Electric Traction; by H. A. Currie and Robert S. Rhodes. Electrical Equipment of Internal-combustion Automobiles; by H. Chase. Electric Automobiles; by W. P. Kennedy. Electric Propulsion of Ships; by W. N. Zippler.
18. ELECTROCHEMICAL AND ELECTROTHERMAL INDUSTRIES: Electrochemical Processes; Electric Furnaces and Their Products; by M. de K. Thompson. Electric Resistance Heating; by Frank Thornton. Jr. Electrical Precipitation of Suspended Particles; by N. W. Sultzer. Electric Welding; by H. M. Hobart.

ELECTRICITY ON THE FARM; by Lee C. Prickett.

HANDBOOK FOR ELECTRICAL ENGINEERS

COMMUNICATION. ELECTRONICS

Edited by Harold Pender and Knox McIlwain. 1022 Pages

Section

1. MATHEMATICS, UNITS, AND SYMBOLS: Mathematics; by Carl C. Chambers. Mathematical Tables. Units and Conversion Factors; by J. G. Brainerd and Carl C. Chambers. Symbols and Abbreviations. Constants; by Carl C. Chambers.
2. PROPERTIES OF MATERIALS: Conducting Materials; Insulating Materials; Luminescent Materials; Magnetic Materials; Special Properties of Dielectrics; by William F. Diehl with W. R. Dohan, H. W. Leverenz, D. G. C. Luck, and C. R. Nelson.
3. ELECTRIC CIRCUITS, LINES, AND FIELDS: Linear Electric Circuits; General Network Theory; Recurrent Networks; Non-linear Electric Circuits; Electromagnetic Radiation; Electromechanical Systems; by Knox McIlwain.
4. RESISTORS, INDUCTORS, CAPACITORS: Resistors and Rheostats; Inductors with Air Cores; Ferrous-cored Inductors; Capacitors, Condensers; by A. Dexter Hinckley.
5. ELECTRON TUBES: Thermionic Vacuum Tubes; by B. J. Thompson with J. M. Stinchfield, Bernard Salzberg, and E. W. Herold. Gaseous Conduction Tubes; by O. W. Livingston. Cathode-ray Oscillograph Tubes; by G. F. Metcalf. X-ray Tubes; by S. Reid Warren, Jr. Photoresponsive Devices; by H. E. Ives.
6. ELECTROMECHANICAL-ACOUSTIC DEVICES: Effects of the Acoustic Medium; Loud Speakers and Telephone Receivers; Microphones; by Hugh S. Knowles. Mechanical Recording and Reproducing of Sound; Optical Recording and Reproducing; Magnetic Recording and Reproducing; by H. A. Frederick and A. C. Keller.
7. CIRCUIT ELEMENTS: Single Mesh and Coupled Circuits; by Vernon D. Landon and Knox McIlwain. Transformers with Iron Cores; by J. I. Cornell and A. J. Rohner. Electrical Wave Filters; by T. E. Shea and C. E. Lane. Radio Antennas; by G. C. Southworth. Vacuum-tube Amplifiers; by Loy E. Barton. Modulators; Power Supply; Radio Transmitters; by J. E. Young. Detectors; Radio Receivers; by Vernon D. Landon. Oscillators; by Carl C. Chambers.
8. HIGH-FREQUENCY TRANSMISSION: Wire Transmission Lines; by Knox McIlwain. Transmission in Space; by John C. Schelleng. Mechanical Features of Transmission Lines; by C. H. MacDonald. Coordination of Communication and Power Systems; by C. H. MacDonald and H. A. Dambly.
9. ACOUSTICS: The Sense of Hearing; Speech and Music; Effects of Distortion on Speech and Music; by John C. Steinberg. Acoustic Properties of Rooms; Sound Insulation; Acoustic Design of Auditoriums; by Vern O. Knudsen.
10. ELECTRICAL MEASUREMENTS: Frequency Measurements; by W. A. Marrison. Measurement of Primary Electrical Quantities; by W. J. Shackelton and J. G. Ferguson. Wire Transmission Measurements; by F. H. Best. Measurements of Transmission through Space; by R. K. Potter. Wave Analysis; by E. Peterson and T. G. Castner.
11. TELEGRAPHY: Elements of Telegraph Systems; D-c Telegraph Systems; A-c Telegraph Systems; Printing Telegraph Systems; Local Equipment; Submarine Cable Telegraphy; by Allison A. Clokey. Radio Telegraph Systems; by J. L. Finch.
12. SOUND-REPRODUCTION SYSTEMS: Acousto-electric Equipment; Radio Telephone Broadcasting; by Howard A. Chinn. Electro-acoustic Equipment; by W. H. Bohlke and Knox McIlwain. Public Address Systems; Sound Pictures; by Knox McIlwain. Police Radio Systems; by Loren F. Jones.
13. TELEPHONY: Substation Equipment and Circuits; Central Office Systems; by Knox McIlwain. Telephone Lines; by C. H. MacDonald. Radio Telephone Systems; by A. A. Oswald.
14. FACSIMILE TRANSMISSION AND RECEPTION: Scanning Systems; Recording Systems; Transmission and Synchronization; Complete Facsimile Systems; by Maurice Artzt.
15. TELEVISION: Transmitting Point Analyzer; Transmission Channel; Receiving Point Reproducer; Scanning Systems (Electrical); Complete Television Systems; Circuit Elements Peculiar to Television Systems; by H. Branson and R. L. Campbell.
16. ELECTRONIC CONTROL AND NAVIGATION EQUIPMENT: Fundamental Electronic Control Circuits; Light-sensitive Control Equipment; Thyratron Control Equipment; by W. R. King. Radio Aids to Air and Marine Navigation; by W. E. Jackson and J. C. Hromada.
17. MEDICAL APPLICATIONS OF ELECTRICITY: Electrotherapy; Diathermy and High-frequency Surgery; Ultra-violet-ray Therapy; Physiological Electromotive Forces; Electro-acoustic Devices; Roentgen Therapy; Roentgenography and Roentgenoscopy; High-voltage Shock and X-ray Burn; by Charles Weyl.

MINING ENGINEERS' HANDBOOK

Edited by the late Robert Peele. 2442 Pages. In Two Volumes

Volume I

SECTION

1. MINERALOGY by the late Alfred J. Moses and Paul F. Kerr.
2. GEOLOGY AND MINERAL DEPOSITS by the late James F. Kemp and Paul F. Kerr.
3. EARTH EXCAVATION by Halbert P. Gillette, Richard T. Dana, and Clinton L. Bogert.
4. EXPLOSIVES by H. G. Haskell, Fletcher B. Holmes, Arthur LaMotte, and F. J. LeMaistre.
5. ROCK EXCAVATION by Halbert P. Gillette, Richard T. Dana, Arthur P. Ackerman, and Samuel R. Russell.
6. TUNNELING by Charles F. Jackson.
7. SHAFT-SINKING IN ROCK by Homer L. Carr and John A. Church.
8. SHAFT-SINKING IN UNSTABLE AND WATERBEARING GROUND by Francis Donaldson, Edwin S. Jarrett, and Ralph H. Chambers.
9. BORING by Arthur F. Taggart and Robert S. Lewis.
10. PROSPECTING, DEVELOPMENT AND EXPLOITATION OF MINERAL DEPOSITS by James F. McClelland, W. W. Lynch, and Edward K. Judd.
10-A. GEOPHYSICAL PROSPECTING by Frederick W. Lee.
11. UNDERGROUND TRANSPORT by Edwin C. Holden.
12. HOISTING PLANT, SHAFT POCKETS AND ORE BINS by William M. Weigel and Philip B. Bucky.
13. DRAINAGE OF MINES by the late Robert Van Arsdale Norris and Robert E. Hobart.
14. MINE VENTILATION by the late F. Ernest Brackett and George E. McElroy.

Volume II

SECTION

15. COMPRESSED AIR PRACTICE by Richard T. Dana and A. W. Loomis.
16. ELECTRIC POWER FOR MINE SERVICE by George R. Wood and Charles M. Means.
17. SURVEYING by Charles B. Breed.
18. UNDERGROUND SURVEYING by Edward K. Judd.
19. MINE GEOLOGIC MAPS AND MODELS by Reno H. Sales.
20. MINE ORGANIZATION AND ACCOUNTS by J. R. Finlay and Arthur Notman.
21. COST OF MINING by J. R. Finlay and Arthur Notman.
22. WAGES AND WELFARE by Edward K. Judd.
23. MINE AIR, GASES, DUSTS, HYGIENE, EXPLOSIONS, AND ACCIDENTS by George S. Rice.
24. MINING LAWS by the late Horace V. Winchell and Archibald Douglas.
25. MINE EXAMINATIONS, VALUATIONS AND REPORTS by William Young Westervelt.
26. AERIAL TRAMWAYS AND CABLEWAYS by Edward B. Durham.
27. UNDERGROUND MECHANICAL LOADING, CONVEYING AND HANDLING by Walter M. Dake.
28. BREAKING, CRUSHING AND SORTING OF ORES by Arthur F. Taggart.
29. ORE SAMPLING by the late T. R. Woodbridge.
30. ASSAYING by the late E. J. Hall and Edward F. Kern.
31. TESTING OF ORES by Arthur F. Taggart.
32. SELLING, PURCHASING AND TREATMENT OF ORES by Arthur L. Walker.
33. GOLD AMALGAMATION AND CYANIDATION by Edward L. Dufourcq and John V. N. Dorr.
34. PREPARATION AND STORAGE OF ANTHRACITE COAL by Paul Sterling.
35. PREPARATION AND COKING OF BITUMINOUS COAL by the late H. McKean Conner, Noel Cunningham, S. M. Parmley, V. D. Hanson, D. H. Davis, and Howard N. Eavenson.
36. MATHEMATICS AND MECHANICS by C. H. Burnside.
37. CHEMICAL AND PHYSICAL NOTES AND TABLES by Edward K. Judd and the late Robert Peele.
38. ELEMENTS OF HYDRAULICS by J. K. Finch.
39. ENGINEERING THERMODYNAMICS by Edward D. Thurston.
40. POWER AND POWER MACHINERY by Theodore Baumeister, Jr.
1. MECHANICAL ENGINEERING MISCELLANY by H. L. Parr.
ELECTRICAL ENGINEERING by Walter I. Slichter.
ELEMENTS OF STRUCTURAL DESIGN by J. K. Finch.
ETROLEUM PRODUCTION METHODS by S. F. Shaw.
GINEERS' TABLES compiled by C. H. Burnside, James F. McClelland, and the lat-
t Peele.
